Abstract

Using data from a large Canadian longitudinal dataset, we examine whether earnings of wives and teenagers increase in response to layoffs experienced by husbands. We find virtually no evidence of an "added worker effect" for the earnings of teenagers. However, we find that among families with no children of working age, wives' earnings offset about one-fifth of the earnings losses experienced by husbands five years after the layoff.

We also contrast the long-term earnings losses experienced by husbands and unattached males. Even though the former group might be less mobile geographically than the latter, we find that both groups experience roughly the same earnings losses in the long run. Furthermore, the income losses (before tax and after tax) of both groups are also very similar. However, because unattached males have much lower pre-layoff income, they experience much greater *relative* income shocks than (families of) laid-off husbands.

Executive summary

Do individuals respond to the occurrence of a layoff in the family by increasing their employment income? If so, what is the magnitude of their response? Since what happens at the family level is a key determinant of individuals' well-being, identifying the degree to which family members stabilize family income in the event of a layoff is critical for a thorough understanding of the welfare consequences of earnings shocks. Yet, even though a large body of empirical evidence has shown that worker displacement leads to long-term earnings losses at the individual level relatively few studies have examined these questions.

The goal of this paper is twofold. First, we wish to provide recent evidence on whether earnings of wives and teenagers increase in response to husbands' layoffs. To do so, we use a large longitudinal Canadian data set that covers the 1987-2001 period. Our data set is based on tax records and thus, contains fairly accurate information about the annual earnings of husbands, wives and teenagers. It also contains accurate information on Employment Insurance (EI) benefits and income tax paid by family members, thereby allowing us to assess whether earnings of wives and teenagers stabilize family income to a greater extent than EI benefits and the tax system do, in the event of husbands' layoffs.

Second, we wish to contrast the long-term earnings losses experienced by laid-off husbands to those of unattached individuals, thereby providing estimates of the consequences of layoffs for an increasingly important type of household who cannot rely on the presence of a second earner. When doing so, we compare the magnitude of the income losses (before tax and after tax) experienced by families of laid-off husbands, on the one hand, and unattached males, on the other. As a result, we can quantify the magnitude of the relative income shocks experienced in the long term by both groups.

Our main findings can be summarized as follows. First, we find virtually no evidence that earnings of youth increase in response to fathers' layoffs. We also find no evidence of an "added worker effect" for Canadian wives in the aggregate. However, we do find evidence that, among families with no children of working age, earnings of wives increased during the 1990s following husbands' layoffs. Our estimates for this group of families imply that, five years after husbands' layoff, increases in wives' earnings compensated for roughly 22% of the earnings losses experienced by husbands.

Second, we show that laid-off husbands and unattached men experience roughly the same earnings losses in the long run. We also find that families of laid-off husbands incur similar income losses before tax and after tax, compared to unattached males. However, because unattached males have much lower pre-layoff after-tax income, they end up experiencing much greater *relative* income shocks than families of laid-off husbands. This in turn suggests that layoffs among adult male earners increase income instability much more for unattached males than they do for families of laid-off husbands.

I. Introduction

Do individuals respond to the occurrence of a layoff in the family by increasing their employment income? If so, what is the magnitude of their response? Since what happens at the family level is a key determinant of individuals' well-being, identifying the degree to which family members stabilize family income in the event of a layoff is critical for a thorough understanding of the welfare consequences of earnings shocks. Yet, even though a large body of empirical evidence has shown that worker displacement leads to long-term earnings losses at the individual level (Ruhm 1991; Jacobson *et al*. 1993; Stevens 1997; Morissette, Zhang and Frenette 2007), relatively few studies have examined these questions.

One notable exception is Stephens (2002), who quantifies the labour supply response of wives to husbands' displacement. Based on U.S. data (from the Panel Study of Income Dynamics) that covers the 1968-1992 period, his findings suggest that, five years after displacement, increases in wives' work hours compensate for roughly 30% of husbands' earnings losses.

While these numbers shed new light on the degree to which increases in wives' labour supply mitigated the earnings losses of displaced husbands during the 1970s and the 1980s in the United States, whether they can be generalized to other industrialized countries or time periods is unknown. In particular, there are good reasons to believe that they might overestimate the degree to which wives' earnings respond to husbands' layoffs nowadays.

One reason is that women's labour supply behaviour changed significantly over the last two decades. Recent evidence suggests that women's labour supply has become much less responsive both to their own wages and to the wages of their husbands in the 1990s, as compared to the 1980s (Blau and Kahn, 2005). Since a growing proportion of women entered the labour market and started working full-time over the last two decades, fewer of them now have the ability to increase their work hours at the extensive margin (by entering the labour market) or at the intensive margin (by increasing their hours, conditional on participation) in response to declines in husbands' wages. Hence, fewer of them might also have the ability to increase their labour supply in response to husband's displacement. The substantial growth in the risk of divorce over the last three decades along with changes in women's attitudes towards family and work might also have induced some women to adopt a labour supply behaviour that is fairly independent of their husband's outcomes. All of these factors suggest that wives' labour supply response to husbands' job loss might have been smaller in the 1990s than it was during the 1970s and 1980s. Unless the growth in female wages over the last few decades fully offset this potentially smaller labour supply response, the implication is that wives' annual earnings are likely to have compensated for the earnings losses of displaced husbands to a smaller extent in the 1990s than they did in the 1970s and 1980s.

Conversely, it is conceivable that families now adjust to husbands' layoffs not only through changes in wives' labour supply, but also through increases in work hours of children of working age. Given that a growing proportion of youth postponed departure from home in recent years (Card and Lemieux, 1997), families may, *a priori*, respond to husbands' layoffs partly through an increase in youth earnings. However, since many teenagers and young adults attend school full-time and thus, cannot devote much time to paid work, whether this happens or not is unclear and remains to be investigated.

While changes in women's labour supply and youth living arrangements have potentially altered families' response to layoffs, the substantial growth in the proportion of unmarried individuals over the last two decades has increased the relative importance of households who cannot benefit from *any* "added worker effect". In 2005, 34% of all family units in Canada consisted of unattached individuals, up from 27% in 1980.[1] These changes in family structure raise one important question: how do earnings losses of unattached workers compare to those of their married counterparts?

Earnings losses of unattached workers might differ from those of married workers for a variety of reasons. Since the former are likely to be more mobile geographically than the latter, they might take advantage of favourable job offers in other local labour markets more frequently, after losing their job. As a result, they might incur smaller earnings losses than the latter following displacement. Furthermore, as long as they have lower wealth holdings than their married counterparts, unattached individuals might search more intensely for new jobs following a layoff. This may reduce the duration of the unemployment spell they incur after job loss, thereby mitigating their earnings losses in the short run. However, this may also lead them to accept lower wage offers and thus, potentially incur greater long-term earnings losses than those suffered by displaced married workers.

Even if long-term earnings losses of married workers and unattached workers were identical and no "added worker effect" whatsoever were observed among families, the mere presence of a second earner in many families suggests that the magnitude of the *relative income* shocks due to layoffs might be much smaller among families than among unattached individuals. This in turn raises the possibility that job loss might increase income instability much more among the latter group than among the former. While recent work has investigated whether job loss can account for part of the increase in earnings instability in the United States (Stevens, 2001), the question of whether earnings shocks due to layoffs generate relative income shocks—and thus, increases in income instability—of varying magnitude across household types has received little attention.

The goal of this paper is twofold. In light of the changes in women's labour supply and youth living arrangements outlined above, we first wish to provide recent evidence on whether earnings of wives and children of working age increase in response to husbands' layoffs. To do so, we use a large longitudinal Canadian data set that covers the 1987-2001 period. Our data set is based on tax records and thus, contains fairly accurate information about the annual earnings of husbands, wives and teenagers. It also contains accurate information on Employment Insurance (EI) benefits and income tax paid by family members, thereby allowing us to assess the income losses (before tax and after tax) experienced by families as a result of layoffs.

Second, we wish to contrast the long-term *earnings* losses experienced by laid-off husbands to those of unattached individuals, thereby providing estimates of the consequences of layoffs for an increasingly important type of household who cannot rely on the presence of a second earner. When doing so, we compare the magnitude of the *income* losses (before tax and after tax) experienced by families of laid-off husbands, on the one hand, and unattached males, on the other. As a result, we can quantify the magnitude of the relative income shocks experienced in the long term by both groups.

---

[1] These numbers are drawn from Cansim Table 202-0401.

Our main findings can be summarized as follows. First, we find virtually no evidence that earnings of youth increase in response to fathers' layoffs. We also find no evidence of an "added worker effect" for Canadian wives in the aggregate. However, we do find evidence that, among families with no children of working age, earnings of wives increased during the 1990s following husbands' layoffs. Our estimates for this group of families imply that, five years after husbands' layoff, increases in wives' earnings compensated for roughly 22% of the earnings losses experienced by husbands.

Second, we show that laid-off husbands and unattached men experience roughly the same earnings losses in the long run. We also find that families of laid-off husbands incur similar income losses before tax and after tax, compared to unattached males. However, because unattached males have much lower pre-layoff after-tax income, they end up experiencing much greater *relative* income shocks than families of laid-off husbands. This in turn suggests that that layoffs among adult male earners increase income instability much more for unattached males than they do for families of laid-off husbands.

II.   Prior research

Since the early 1990s, numerous studies have examined the magnitude of the earnings losses due to displacement (see the reviews by Fallick, 1996 and Kletzer, 1998).   Using Pennsylvania administrative data, Jacobson et al. (1993) show that the earnings losses of high-tenure prime-age workers persist well beyond the time of displacement. Earnings fall even before the displacement takes place and drop sharply at the time of the displacement. Even several years after the displacement took place, displaced workers report quarterly earnings that are about 25% lower than their pre-displacement earnings. Worse still, it seems very likely that the earnings of displaced workers do not return to their expected levels at any time. Ruhm (1991) and Stevens (1997) also analyze the earnings losses of displaced workers, using data from the Panel Study of Income Dynamics (PSID). While Ruhm (1991) finds that, four years after displacement, weekly earnings of displaced workers are 10-13% lower than those of their non-displaced counterparts, Stevens (1997) shows that the annual earnings of displaced workers remain about 9% below their expected levels 6 or more years after displacement.[2] Eliason and Storrie (2006) also find long-term earnings losses as a result of job displacement. In all of the aforementioned studies, no attempt is made to distinguish the long-term earnings losses of displaced husbands from those of displaced unmarried males.

Since individuals who become unemployed through mass layoffs suffer substantial and persistent earnings losses, one important question is whether various family members, especially the wives of displaced husbands, adjust their labor supply to mitigate the impact of their husbands' earnings losses. While earlier studies using cross-sectional data have failed to detect an empirically important "added-worker" effect (e.g. Heckman and MaCurdy, 1980; Cullen and Gruber, 2000), Stephens (2002) uses longitudinal data from the PSID and finds that five years

---

[2] While Jacobson et al. (1993) require displaced workers to have at least 6 years of tenure with their employer, Ruhm (1991) and Stevens (1997) do not impose this restriction.

after husbands' displacement, wives' work hours increase significantly, compensating for 30% of husbands' earnings losses.[3]

Because government transfers such as Employment Insurance benefits are generally provided for a limited period of time (e.g. 50 weeks) while others like social assistance are generally provided when EI benefits are exhausted, the finding that wives' earnings only partially offset husbands' earnings losses suggests that husbands' displacement induces, in the longer run, a drop in family income.[4] However, because the tax system mitigates the income fluctuations experienced by families (Kniesner and Ziliak, 2002), the extent to which families' disposable income drops following husbands' unemployment remains to be determined. Moreover, it is conceivable that other family members adjust partially their labor supply in response to husbands' unemployment (Jenkins, 2000: 552), providing an additional channel through which the adverse consequences of husbands' unemployment on family income could potentially be reduced.

III. Data and concepts

We use the Longitudinal Administrative Databank (LAD) constructed by Statistics Canada along with records from the Employment Insurance Administrative Database (EIAD) constructed by Human Resources and Social Development Canada (HRSDC). The LAD is a 20 percent random sample of Canadian tax filers. It contains numerous income and demographic variables such as employment income, self-employment income, Employment Insurance benefits, registered pension plan contributions, age, marital status, gender and family composition.[5]

The LAD has numerous strengths. First, because it draws information from personal income tax returns, it provides fairly accurate measures of the annual earnings of husbands, wives and other family members for the 1982-2004 period. Second, it contains information about government transfers and after-tax income and thus, allows us to assess the stabilization role played by EI benefits and the tax system. Third, because it covers a relatively long time period, it allows us to analyze the earnings of husbands, wives and teenagers several years before and after husbands' layoffs, thereby satisfying an important requirement of any reliable estimation method of the impact of programs or events (Jacobson *et al.* 1993).

Like most administrative data sets, the LAD has limited information about family demographics. While it includes data on individuals' age, sex, marital status and province of residence, it has no information about a person's work hours, educational attainment or occupation. To minimize

---

[3] Stephens (2002) also shows that the magnitude of the increase in wives' work hours depends on the magnitude of husband's earnings losses: the larger are husbands' earnings losses, the larger is the increase in wives' work effort.

[4] This is what Stephens (2001) finds, using data from the PSID.

[5] Filers are attached to their spouses (legal and common law) by the spouse's Social Insurance Number (SIN) listed on the tax form or by matching on name, address, age, sex, and marital status. Once selected, individuals are in the sample whenever they appear on the annual T1 Family File (T1FF). The LAD is representative on a cross-sectional basis, i.e. each year's sample is a representative sample of the population of all persons in T1FF who have a Social Insurance Number (SIN). To maintain a representative sample, a part of each year's sample consists of a selection of those individuals who appear on the T1FF for the first time since 1982.

concerns regarding unobserved heterogeneity in workers' age-earnings profiles (across, say, education levels), we use fixed effects models that allow for the presence of worker-specific intercepts.

To identify layoffs, we link the LAD to the Employment Insurance (EI) record files containing selected variables from the Employment Insurance Administrative Database (EIAD) developed by HRSDC. The EI files contain data for all EI *applicants* (rather than only for EI *recipients*) from 1987 to 2001 and provide the breakdown of specific EI benefit types as well as reasons for separation taken from the Record of Employment (ROE).

Our comparison of LAD-EIAD with data from the Longitudinal Worker File (LWF) of Statistics Canada shows that LAD-EIAD captures between 91% and 100% of the layoffs registered by LWF (Appendix Table 1), thereby confirming that LAD-EIAD provides a fairly good coverage of layoffs that occurred during the 1990s. Unlike LAD-EIAD, the LWF also contains information that allows us to distinguish permanent layoffs from temporary layoffs. [6] The LWF shows that during the 1990s, roughly 55% of the layoffs observed were permanent while the remaining portion consisted of temporary layoffs. Hence, the earnings losses and income losses documented in this study using LAD-EIAD will result from a mixture of permanent layoffs and temporary layoffs. As will be shown below, however, we will also conduct separate analyses for a subset of permanent layoffs: those that are associated with a loss in pension coverage.

Our first sample consists of families where husbands are aged 25 to 40 in 1987. This age restriction is implemented to ensure that husbands are aged at most 54 in 2001, the last year used in our multivariate analyses. To have at least three usable observations, we require that couples be present in the sample for at least three years (1987, 1988 and 1989). We do not have layoff information prior to 1987, so our estimation results are based on the 1987-2001 period. Nevertheless, we exclude those husbands who received EI benefits between 1982 and 1986 as the best possible way to avoid the "contamination" from previous layoffs.

To focus on families which primarily rely on earnings from paid work, we exclude couples with combined self-employment income over $500 (in 1992 dollars, or over $595 in 2002 dollars) in absolute terms, in any year between 1982 and 2001. Similarly, we exclude families with combined total income over $200,000 (in 1992 dollars, or over $238,000 in 2002 dollars) and those who lived outside ten Canadian provinces. Couples had to be married from 1987 until and including the year in which the husband was laid-off (or until 1989 if the husband was laid off before 1989).

Our layoff variable is based on the first layoff experienced by a husband during the 1987-2001 period. After the first layoff occurs, couples are kept in the sample for as long as they are present in LAD as a married couple but for a maximum of five years. If the first layoff occurs after 1987, we also require couples to have positive earnings prior and including the layoff year. For instance, if a husband was laid off in 1992, he has to have positive earnings and be married during the 1987-1992 period. Couples are then followed for another five years (until 1997) or until their breakup if it happens before 1997, regardless of whether the husband experienced other layoffs or had positive earnings after 1992.

---

[6] Permanent layoffs occur when workers separate from their employer in year t and do not return to that employer in year t or year t+1. Otherwise, layoffs are classified as temporary.

Those families in which husbands were laid-off in any year between 1987 and 2001 constitute our "treatment" group. Our "control" group consists of families in which husbands had positive earnings in 1987-2001, remained married during this period and did not experience a layoff in any year between 1987 and 2001.

The sample of unattached individuals (single men and single women) has been selected in a similar fashion. The restrictions on total income, self-employment income and EI receipts in 1982-2001 were identical to those for the married men.

Our final sample of married couples consists of approximately 60,500 families and 806,800 family-year observations. The sample of single men consists of 4,700 men and 52,100 person-year observations. The sample of single women consists of 6,100 women and 76,200 person-year observations.

Finally, we build on the idea that the loss of pension coverage coinciding with a layoff is likely to indicate that the layoff is permanent. Our "pension loss" indicator variable (M_i) takes the value of 0 if both criteria hold: (1) husband's contribution to a registered pension plan (RPP) was positive in the year before the layoff and (2) it equals zero in the year after the layoff; otherwise the laid-off worker is not a "pension loser" ($M_i=1$). Such definition allows us to use "pension losers" as a bench-mark category in our multivariate analyses.[7]

Throughout the paper, we use the term husbands (wives) to refer to men (women) who are either married or live in common-law relationships. All estimates of earnings and income losses are expressed in 2002 dollars, using the Consumer Price Index as a deflator.

IV. Methods

To assess the impact of husbands' layoffs on family income, we take advantage of the methodology used by Jacobson et al. (1993) and Stevens (1997). The approach is to estimate a reduced-form income response to layoffs. The robust asymptotic variance matrix estimator is used to account for arbitrary form serial-correlation and heteroskedasticity (Wooldridge, 2002, p. 275).

In particular, we specify husbands' earnings trajectories using fixed effects models:

$$(1) \qquad y^h_{it} = \alpha_i + \gamma_t + X_{it}B_1 + \sum_{k=a}^{b} D_{it}{}^k \delta_k + \varepsilon_{it},$$

where y^h_{it} denote the annual earnings of husband i in year t, X_{it} includes a quadratic term in husbands' age, the number of children aged 15 and over and regional dummies; γ_t is a vector of year effects, $D_{it}{}^k$ is a vector of dummy variables which equal 1 if husband i is laid-off k years prior to year t (and $D_{it}{}^k=0$ otherwise), α_i is a vector of person-specific fixed effects and ε_{it} is an error term.

---

[7] See Appendix Table 2 for the sample sizes of various groups of families and unattached individuals.

Likewise, we specify the earnings trajectories of wives as follows:

$$(2) \qquad y^w_{it} = \phi_i + \vartheta_t + Z_{it} B_2 + \sum_{k=a}^{b} D_{it}{}^k \eta_k + v_{it},$$

where y^w_{it} denote the annual earnings of wife i in year t, Z_{it} is a vector of wives' observable characteristics (same as X_{it} except that the quadratic term in age is based on wife's age), ϑ_t is a vector of year effects, $D_{it}{}^k$ is a vector of dummy variables that equal 1 if husband i is laid-off k years prior to year t (and $D_{it}{}^k = 0$ otherwise), φ_i is a vector of person-specific fixed effects, and v_{it} is an error term. Consistent with Stephens (2002), equation (2) allows wives' earnings to respond to husbands' unemployment both before and after husbands become unemployed.

Finally, the earnings of other family members, y^o_{it}, are specified in a similar fashion:

$$(3) \qquad y^o_{it} = \mu_i + \kappa_t + X_{it} B_3 + \sum_{k=a}^{b} D_{it}{}^k \lambda_k + u_{it},$$

where X_{it} is the same as in (1). While equation (2) allows for the presence of an "added-worker effect" through changes in wives' earnings, equation (3) also allows other family members to alter their labor supply in response to husbands' unemployment.

Assuming that investment income follows an exogenous process, equations (1)-(3) can be used to derive a reduced form for both family income before-tax and family income after-tax[8]:

$$(4) \qquad y^f_{it} = \Omega_i + \Psi_t + X_{it} B_4 + \sum_{k=a}^{b} D_{it}{}^k \Theta_k + \tau_{it}$$

where y^f_{it} denote family income before (or after) tax, and where Θ_k measures the impact of husbands' layoffs on family income. By definition, Θ_k captures, apart from the contribution of government transfers and personal taxes, the influence on family income of husbands (δ_k), wives (η_k) and other family members (λ_k) before and after husbands' layoff. The 'husband's age' variable in X_{it} is used as a proxy for the 'family's age'.

Since the earnings of displaced workers start to fall substantially at least three years before displacement (Jacobson et al. 1993: 687), we specify a= -3. In order to allow husbands' layoffs to affect family income over several years, we specify b = 5. Thus, we allow husbands' layoffs to affect family income up to three years before and up to five years after their occurrence.

In the models above, we do not allow for the fact that some families have no children of working age (i.e. aged 15 and over) who can adjust their labour supply in response to their father's layoff. To examine the differences in responses by families with and without children aged 15 and over, we consider two additional samples: one in which children aged 15 and over are present in the family *at some point during the period in which the family was observed*, and another one in which no children aged 15 and over are ever present. In the models corresponding to the former sample, the set of explanatory variables is the same as in (1)-(4); in models corresponding to the latter sample, X_{it} does not include a variable for children aged 15 and over and equation (3) is not estimated.

---

[8] Family income before tax includes earnings from T4 slips, other employment income, pension and superannuation income, family benefits, EI benefits, dividends, interest and investment income, net limited partnership income, rental income, alimony or support income, other income, provincial refundable tax credit, child tax credit and child tax benefit, and GST/FST credits.

The earnings of single men and women are modeled in a fashion similar to married men with an obvious exclusion of children from X_{it} in equation (1):

$$(5) \qquad y^s{}_{it} = \alpha_i^s + \gamma_t^s + X_{it}^s B_1^s + \sum_{k=a}^{b} D_{it}^{sk} \delta_k^s + \varepsilon_{it}^s,$$

and similar adjustment in equation (4).

In addition to the models above, we also estimate models in which the set of explanatory variables includes interactions terms with a "pension loss" variable used as a proxy for permanent layoffs. Equation (1), for instance, takes the following form

$$(6) \qquad y^h{}_{it} = \alpha_i + \gamma_t + X_{it} B_1 + \sum_{k=a}^{b} D_{it}^{k} \delta_k + \sum_{k=a}^{b} \left(M_i D_{it}^k \right) \omega_k + \varepsilon_{it},$$

with other equations adjusted similarly. Note that $M_i=1$ if husbands do not lose pension coverage, so δ_k indicates income losses for those who lose their pension after the layoff (proxied by changes in contributions to RPPs) while the direction and magnitude of ω_k indicate the reduction (or increase) in income loss for those who did not lose their pension.

V. Descriptive evidence

V.1 Income trajectories of families

Table 1 and Figure 1 illustrate the differences in the income dynamics between families in which husbands experienced layoffs and those in which husbands did not. The upper panel represents income dynamics of an average family in which the husband was laid-off in 1992 after having experienced positive earnings and no layoffs between 1987 and 1991. The lower panel shows income dynamics for other families, i.e. those in which husbands experienced no layoffs and had positive earnings throughout the 1987-2001 period.[9]

Several points are worth noting. First, even in pre-layoff years, earnings of laid-off husbands are substantially lower than those of other husbands, thereby suggesting that the former might be less skilled than the latter.

Second, consistent with previous studies (Jacobson et al., 1993; Stevens, 1997), the earnings of laid-off husbands fall (by about 4%) in the year preceding the layoff and drop by an additional 15% (from $47,200 to $39,900) in the year they were laid-off.[10] The decline in husband's earnings continues in the year after the layoff; the earnings fall to $35,200 in 1993 so the total drop between year *t-1* and year *t+1* is approximately $12,000 or 25% of earnings received in 1991.

Third, although husbands' earnings do recover somewhat in the years after the layoff, even five years after the layoff they are still below their pre-layoff level. Since such comparison does not

---

[9] The data presented in Tables 1-2 and Figures 1-2 is based on an unbalanced panel whose construction is defined in Section III.

[10] All numbers are rounded to the nearest hundred for confidentiality reasons.

take account of the earnings growth laid-off husbands would have experienced in the absence of layoffs, it suggests that the earnings losses they experience extend at least over a five-year period. This in turn is consistent with the results of Morissette, Zhang and Frenette (2007).

Fourth, the evolution of wives' earnings shows, at least for the specific cohort examined in Table 1 and Figure 1, little support for an "added worker" effect. The earnings of the wives of laid-off husbands do not seem to deviate from their long-term pre-layoff trend (Figure 1). As will be shown below, this conclusion does not hold in our multivariate analyses for families who have no children of working age.

Fifth, as expected, Employment Insurance (EI) benefits of families of laid-off husbands rise sharply in 1992 and 1993 and return close to their pre-layoff levels in subsequent years, thereby highlighting the temporary stabilization role of the EI program.

Sixth, while earnings of laid-off husbands fell a solid $12,000 between 1991 and 1993, income coming from wives' earnings, earnings of other family members and EI benefits increased by fully $6,000 during that period. As a result, family income before tax fell only half as much as husbands' earnings.[11]

Seventh, while family income before tax fell by $5,500 between 1991 and 1993, family income after tax dropped by only $3,400 during that period. In fact, while EI benefits stabilize family income only in the short-term, the tax system stabilizes family income in all years preceding and following the layoff.

Finally, even though the earnings of laid-off husbands fell by $400 between 1991 and 1997, their family after-tax income rose by $5,500 during that period, from $71,500 to $77,000. Taken together, the results above suggest, both in the short run and the longer run, that the loss of after-tax income families suffer as a result of husbands' layoff differs markedly from the earnings losses of the husbands, even in the absence of an added worker effect from wives. We investigate this issue in greater depth in the next section.

V.2 Income trajectories of unattached individuals

The earnings losses suffered by single men appear to have more long term consequences (Table 2 and Figure 2A). The average earnings of single men laid-off in 1992 drop from $41,000 in 1990 to $38,600 in 1991 to $33,000 in 1992 and, finally, to $29,200 in 1993. This is a drop of about 25% from year *t-1* to year *t+1,* which is similar to the drop in the earnings of laid-off husbands. However, earnings of single men show a much slower recovery after the layoff. While the earnings of married men eventually reach pre-layoff levels, the earnings profile of single men is essentially flat in the post-layoff period. Note however, that the data shown in Table 2 and Figure 2 is based on an unbalanced panel defined in Section III and thus, does not represent the earnings trajectories of the *same group* of unattached individuals followed over the *whole* 1987-2001 period. Nevertheless, they provide useful trends for a particular cohort (i.e. unattached males laid-off in 1992) that is subsequently used along others for our multivariate analyses.

---

[11] Family income before tax fell by $5,500, thereby indicating that other sources of market income and non-market income also rose by $500.

Finally, in contrast to unattached men, unattached women who were laid-off showed faster earnings recovery. Although in 1991, the average earnings of women who lost their jobs in 1992 were $8,700 lower than those of men, by 2001, their earnings were well above their male counterparts. Similarly, in 1998, women's average before (and after) tax income already exceeded the 1991 level, while men's average income never reached its pre-layoff levels.

VI. Regression results

VI.1 Families

Table 3 presents the regression results for equations (1)-(4) estimated on our sample of families. As mentioned above, this sample includes both families with no children aged 15 and over (at some point during the observation period) as well as those with such children.

The results shown in the first column of Table 3 are in line with those of several studies that have quantified the earnings losses of displaced workers: earnings losses of husbands who go through a layoff are substantial and persist even five years after the layoff. In the year during which they are laid-off, husbands suffer earnings losses of about $13,100. The corresponding number five years after the layoff is about $12,300 (Figure 3).

The second column of Table 3 provides no evidence—at least in the aggregate—that wives increase their annual earnings in response to the layoff of their husbands. In fact, the estimates presented suggest that the years following husbands' layoffs are associated with a *decline* in wives' earnings. One potential explanation for this pattern is that increases in unemployment due to layoffs might affect negatively both husbands' earnings and wives' earnings (e.g. by decreasing the annual hours of work of both partners) in particularly depressed local labour markets. Alternatively, an added worker effect might be observed only for some family types, as will be shown below.

The third column of Table 3 indicates that earnings of children aged 15 and over change very little following the layoff of their father. Thus, omitting children of working age in an analysis of families' response to layoffs appears to be inconsequential.

In the year during which husbands are laid-off as well in the following year, income losses before tax of families experiencing layoffs are at least $5,000 lower than the earnings losses suffered by husbands. As shown in Table 1, the discrepancy is mainly due to the sharp increases in EI benefits that occur during those years.

Taken together, both EI benefits and the tax system tend to mitigate substantially the income losses experienced by families of laid-off husbands. For instance, the income losses after tax experienced by these families in the year during which the layoff occur amount to roughly $3,500, much less than the earnings losses of about $13,100 experienced by laid-off husbands. The corresponding numbers for the following year are $7,500 and $16,700, respectively. Likewise, while the earnings losses suffered by husbands amount to $12,300 five years after the layoff, the income losses after tax for their families are, at $6,400, about twice as low.

Similar qualitative patterns are observed in Table 4 and Figure 4 when the focus is on families with children aged 15 and over.

In contrast, Table 5 provides evidence of an added worker effect for the sub-sample of families with no children aged 15 and over. One year after their husband is laid-off, the annual earnings of wives increase by about $900. They keep rising in subsequent years and in the fifth year following the layoff, have risen by roughly $2,700, thereby offsetting 22% of the earnings losses of $12,200 experienced by their husbands (Figure 5).

Overall, the results of Tables 3-5 highlight the key stabilization role played by the tax system and EI benefits in response to layoffs. Both mechanisms lead Canadian families to experience income losses after tax that are substantially smaller than the earnings losses experienced by laid-off husbands. The numbers rule out the possibility that children aged 15 and over might play an important role in mitigating the earnings losses suffered by their fathers. Finally, the estimates provided are consistent with the presence of an added worker effect, at least for some groups of families.

VI.2 Layoffs leading to a loss of RPP coverage

So far, our analyses have pooled data on both temporary and permanent layoffs. Since the literature on worker displacement generally focuses on job loss, i.e. permanent layoffs, and since permanent layoffs are expected to generate greater earnings losses than temporary ones, it is worth investigating what the income losses are for families who experience permanent layoffs.

While the LAD-EIAD data do not allow us to distinguish temporary layoffs and permanent layoffs, they allow us to identify layoffs that are associated with a loss of RPP coverage. Since pension plan terminations by employers are a relatively rare event (Ippolito and Thompson, 2000), one can reasonably assume that most workers who lose pension coverage after being laid-off permanently lost their job with their former employer. However, because wages and pension coverage are positively correlated (Even and McPherson, 1990), the earnings losses experienced by husbands who lost pension coverage will likely exceed those experienced on average by husbands who go through permanent layoffs.

Table 6 confirms our expectations. Five years after being laid-off, husbands who lost RPP coverage suffered earnings losses that varied between $16,000 and $17,300 and thus were $4,400 to $5,600 higher (in absolute value) than those experienced by their counterparts who were laid-off but did not lose pension coverage.[12] As a result, the income losses after tax experienced by the former group of families were generally higher than those experienced by the latter.

Among families of laid-off husbands with no children aged 15 and over, wives' annual earnings rose $3,800 five years after the loss of husbands' RPP coverage and by about $2,500 five years after the occurrence of other layoffs. In both cases, the growth in the annual earnings of wives tended to offset between 22% and 24% of the long-term earnings losses experienced by

---

[12] The reference group regarding loss of RPP coverage consists of families where husbands lost pension coverage as a result of a layoff. To obtain the income losses of families where husbands were laid-off but did *not* lose pension coverage, one needs to add the coefficient estimate for the reference group and the interaction term (labelled as t+5 * No loss of RPP, in Table 6).

husbands. Once again, this suggests the presence of an added worker effect for this group of families, i.e. families with no children aged 15 and over.

VI.3 Unattached individuals

Earnings losses of unattached individuals might differ from those of husbands for a variety of reasons. Since the former are likely to be more mobile geographically than the latter, they might take advantage of favourable job offers in other local labour markets more frequently, after losing their job. As a result, they might incur smaller earnings losses than the latter following displacement. Furthermore, as long as they have lower wealth holdings than their married counterparts, unattached individuals might search more intensely for new jobs following a layoff. This may reduce the duration of the unemployment spell they incur after job loss, thereby mitigating their earnings losses in the short run. However, this may also lead them to accept lower wage offers and thus, potentially incur greater long-term earnings losses than those suffered by displaced married workers.

Table 7 shows the earnings losses and income losses experienced by unattached men and women following layoffs. As was the case for families, the income losses unattached men and women experience before tax are, in the year during which layoffs occur and in the following year, much smaller than the earnings losses these individuals suffer (Figures 6 and 7). This is in good part due to the receipt of EI benefits during that period. Fiver years after the layoffs, income losses after tax also differ substantially from earnings losses.

Are the earnings losses of unattached males lower than those of husbands in absolute terms? Not necessarily. A comparison of Table 3 and Table 7 shows that while unattached men experience, one year after the layoff, earnings losses that are smaller than those of husbands ($15,500 versus $16,700), the reverse is true five years after the layoff ($13,700 versus $12,300). In contrast, earnings losses of unattached women are, in absolute terms, always lower than those experienced by husbands.

More important, the after-tax income losses experienced by unattached men five years after a layoff ($7,700) are not lower than those experienced by families of laid-off husbands ($6,400). Combined with the fact that laid-off unattached males have lower after tax income than these families prior to layoffs, this suggests that the relative income shocks experienced by the former exceed those suffered by the latter group.

Table 8 replicates Table 6 for unattached men and women. It confirms that unattached individuals who lose pension coverage following a layoff experience substantially greater earnings and income losses than other laid-off unattached individuals.

VII. Relative income shocks following layoffs

The numbers presented in Tables 1-8 document the earnings and income losses that families and unattached individuals experience, in absolute terms, as a result of layoffs. One interesting issue is whether the magnitude of the income shocks, defined in relative terms, differs across family units. For instance, Tables 1 and 2 indicate that four years before being laid-off, unattached men who were laid-off in 1992 earned much less ($38,800) than husbands ($49,400). Since earnings

losses of the two groups do not differ that much in absolute terms (Tables 3 and 7), this suggests that the relative earnings shocks experienced by unattached males are greater than those experienced by husbands.

Table 9 shows that this is indeed the case. When dividing the earnings losses shown in Tables 3 and 7 by a weighted average of the earnings received by various cohorts over a 3-year period preceding the layoffs (i.e. in year t-2, t-3 and t-4), relative earnings losses of unattached men are always higher than those of husbands.[13] For example, earnings losses experienced five years after the layoff represent 39% of pre-layoff earnings of unattached men and 27% of those of husbands.

Differences in relative income shocks experienced by the two groups are, in relative terms (i.e. expressed in terms of ratios between the two groups), even more pronounced. Between t+1 and t+5 (i.e. during the period covering the first year following the layoff and the fifth year), relative after-tax income losses of families of laid-off husbands averaged 10%. In contrast, those of unattached males were, at 23%, more than twice as high. The reason is that pre-layoff after-tax income averaged $68,200 for families of laid-off husbands, more than twice the amount of $32,700 observed for unattached men. This finding suggests that layoffs among adult male earners increase income instability much more for unattached males than they do for families of laid-off husbands.

VIII. Conclusion

How do families and unattached individuals respond to layoffs? The answer to that question depends on the type of family considered. Families with no children of working age seem to adjust partially to husbands' layoffs through an increase in wives' employment income, which suggests that wives in these families increase their labour supply in response to their husband's layoff. Five years after husbands' layoffs, the increase in wives' earnings offsets about one-fifth of husbands' earnings losses. Thus, the data suggest the presence of an added worker effect, at least in some Canadian families. The magnitude of the response observed for these wives is somewhat smaller than that found by Stephens (2002). This is not surprising since: a) our definition of layoffs includes both temporary layoffs and permanent layoffs and, b) wives' response to temporary layoffs is expected to be smaller than their response to permanent layoffs.[14]

Children aged 15 and over do not play an important role in mitigating the earnings losses experienced by their father after his layoff. To a large degree, this finding is expected since many teenagers and young adults are still attending school full-time and thus, likely have little time to devote paid work.

---

[13] The denominator used is an average (weighted by the size of the various cohorts of husbands and unattached men who were laid-off between 1987 and 2001) of the mean earnings received in year t-2, t-3 and t-4, where year t refers to the year during which layoffs occurred. This denominator equals $46,200 for husbands and $34,700 for unattached men.

[14] In contrast, Stephens (2002) considers wives' labour supply response to husbands' displacement, where displacement is defined to occur when: a) plants closed or employers moved, b) worker was laid-off or fired. As a result, the sample of displaced workers used by Stephens (2002) is likely to measure predominantly permanent layoffs.

Even though they likely have greater geographic mobility than husbands, unattached males generally do not fare better than husbands after a layoff. In fact, unattached men experience greater relative earnings losses than husbands in all five years that follow a layoff. Furthermore, they also experience much greater relative (after-tax) income shocks than the latter as a result of layoffs.

Finally, our results highlight the key stabilization role played by EI benefits and the tax system in mitigating the income losses suffered by unattached individuals and families of laid-off husbands. Both stabilizers reduce after-tax income losses in the short run while the tax system also reduces these losses in all subsequent years. As a result, after-tax income losses of families and unattached individuals end up being substantially smaller than the earnings losses experienced on an individual basis by laid-off workers.

Table 9 : Relative earnings and income shocks experienced by husbands and unattached men

I. Relative earnings shocks

	Earnings losses		Relative earnings losses		
	husbands	unattached men	husbands		unattached men
	(1)	(2)	(3)		(4)
	(2002 $)		%		
Year of layoff	-13,117	-12,183	28.4		35.1
1 year after	-16,690	-15,516	36.1		44.7
2 years after	-14,009	-13,613	30.3		39.2
3 years after	-13,053	-13,911	28.3		40.1
4 years after	-12,708	-13,941	27.5		40.2
5 years after	-12,283	-13,681	26.6		39.4

I. Relative income shocks

	After-tax income losses		Relative after-tax income losses		
	husbands	unattached men	husbands		unattached men
	(5)	(6)	(7)		(8)
	(2002 $)		%		
Year of layoff	-3,510	-4,313	5.1		13.2
1 year after	-7,454	-7,563	10.9		23.1
2 years after	-7,113	-7,313	10.4		22.4
3 years after	-6,712	-7,665	9.8		23.4
4 years after	-6,562	-7,800	9.6		23.9
5 years after	-6,399	-7,712	9.4		23.6

Note: The numbers in colums 1-2 and 5-6 are taken from Tables 3 and 7. Relative earnings losses and income losses are obtained using as a denominator a weighted average of the earnings and income received over a 3-year period preceding the layoff (i.e. in year t-2, t-3 and t-4) by the various cohorts who were laid-off between 1987 and 2001.
