Abstract

This paper substantially extends the limited available evidence on existence and extent of downward nominal wage rigidity in the European Union and the Euro Area. For this purpose we develop an econometric multi-country model based on Kahn's (1997) histogram-location approach and apply it to employee micro data from the European Community Household Panel (ECHP) for twelve of the EU's current member states. Our estimates for the degree of downward nominal wage rigidity on the national as well as the EU-wide level point to marked downward nominal wage rigidity within the European Union.

Keywords:

Downward Nominal Wage Rigidity; Wage Stickiness; European Community Household Panel; ECHP; Histogram-Location Approach; European Union; Euro Area.

JEL-classification: J30; E24.

Zusammenfassung

Dieser Beitrag liefert eine erhebliche Erweiterung der bislang nur spärlich vorhandenen Evidenz zum Ausmaß der Abwärtsnominallohnstarrheit in der Europäischen Union und im Eurogebiet. Zu diesem Zweck wird auf Basis des Histogram-Location-Approach von Kahn (1997) ein ökonometrisches Mehrländermodell entwickelt und auf die Daten des Europäischen Haushaltspanels für zwölf EU-Mitgliedsländer angewandt. Die Schätzergebnisse deuten sowohl auf nationaler als auch auf europäischer Ebene auf ausgeprägte Abwärtsnominallohnstarrheit hin.

Abwärtsnominallohnstarrheit; Lohnrigidität; Europäisches Haushaltspanel; ECHP; Histogram-Location Approach; Europäische Union; Eurogebiet

1 Introduction

Whether and to which extent nominal wages are downwardly rigid are widely considered unresolved questions. Their scientific importance derives from their key role for the understanding of the workings of the labor market and from their implications for the shape of the long-run Phillips curve. Their policy relevance is due to the fact that downward nominal wage rigidity (DNWR) may lead to inadvertently high costs of low inflation targets in terms of higher long-term unemployment. Correspondingly, empirical evidence with respect to nominal rigidity is indispensable for an evaluation of recent low inflation targets of monetary policy makers.

At present, only for some European countries such evidence with respect to downward nominal wage rigidity does exist, see the surveys of Kramarz (2001), Stiglbauer (2002), and Rodríguez-Palenzuela, Garcia and Camba-Mendez (2003). In several cases the evidence is purely descriptive, it seems contradictory, and it is hard to compare across countries, because of differences in methods and data. This state of recent research has led the European Central Bank to conclude that ‘the importance in practice of downward nominal rigidities is highly uncertain and the empirical evidence is not conclusive, particularly for the euro area’ (European Central Bank 2003, p. 14).

This paper addresses this critique by substantially extending the available evidence on existence and extent of downward nominal wage rigidity in the European Union and the Euro Area. The analysis is based on the European Community Household Panel (ECHP) which is a large-scale annual longitudinal survey for the ‘old’ 15 member states of the European Union comprising the years 1994 to 2001. The great advantage of the ECHP is the uniform questionnaire asked in the EU-countries which makes the direct comparison of data across countries and over time possible. The comparison of results is also facilitated by use of a uniform method of analysis for the EU and Euro Area as a whole as well as for the individual member countries. For this purpose we develop an econometric multi-country model based on a widespread quantitative method of analysis in this context, the histogram-location approach introduced by Kahn (1997), in order to guarantee a high degree of comparability with earlier results. Further advantages of this line of analysis are that it is easier to interpret and based on fewer functional assumptions than the best alternative, the earnings-function approach proposed by Altonji and Devereux (2000). The most important drawback of the histogram-location approach, its lack of treatment of measurement problems, is not problematic in the context of a uniform cross-country data source, since measured degrees of downward nominal wage rigidity can consistently be interpreted as lower bounds of true nominal wage rigidity across countries.

The remainder of the paper starts with a section on the histogram-location approach and our proposed extensions. Sections 3 and 4 describe in some detail the ECHP data used and present descriptive evidence. Section 5 contains a description of the empirical implementation and the results with respect to existence and extent of downward nominal wage rigidity. Finally, we summarize our findings and offer conclusions and a brief outlook.

2 Histogram-location approach in a multi-country context

The histogram-location approach of Kahn (1997) models annual location-centered distributions of wage changes by histograms and tests in an econometric model of the histograms whether changes in shape of the histograms can be explained as the systematic interplay of downward nominal wage rigidity and changes in location of the original, uncentered distributions.¹ A number of detailed expositions and illustrations of the histogram-location approach are now available in the literature, e.g. Beissinger and Knoppik (2001), Stiglbauer (2002), Knoppik and Dittmar (2002), Lebow, Saks and Wilson (2003). Therefore, the basic formal model is only outlined very briefly, before we turn to our extensions of the histogram-location approach for a multi-country framework.

Basic model

The basic econometric model of the histogram-location approach explains observed factual bin sizes P_{rt} of the histogram of location-centered per cent annual wage changes (i.e. the relative frequency of wage changes in bin r in period t). Bin numbering starts from the origin of the location-centered histogram (corresponding to the location of the uncentered distribution, e.g. the median) and proceeds to the left, starting with one. Therefore bin r contains relative wage changes that are between r and $r-1$ times the bin width b smaller than the rate of wage change at the location of the uncentered distribution. The explanatory variables are dummy variables that capture bin status in different bins and years, i.e. whether the bins contain negative, zero, or positive nominal wage changes. The unknown parameters that are to be estimated are the rigidity parameter ρ , the counterfactual bin sizes α_r that would prevail under wage flexibility, and the pile-up parameter γ . The model consists of the following system of equations:

$$(1) \quad P_{rt} = \alpha_r \underbrace{(1 - \rho DN_{rt})}_{\text{thinning}} + \underbrace{\left(\gamma + \rho \sum_{j=r_{\min}}^{r_{\max}} \alpha_j DN_{jt} \right)}_{\text{pile-up}} DZ_{rt} + \mu_{rt} \text{ for } r = r_{\min} \dots r_{\max}.$$

Bins' status as a negative bin, zero bin or positive bin is encoded in two dummy variables, DN_{rt} and DZ_{rt} . A value of one in DN_{rt} indicates the exclusive presence of negative nominal

¹ The term 'wage' is used for any type of earnings from labor. The earnings variables used are discussed in Section 3 and Appendix A.

wage changes in the bin, whereas a value of one in DZ_{rt} indicates the presence of zero nominal wage changes in that bin. Bins with only positive changes are coded by setting to zero both DN_{rt} and DZ_{rt} . The rigidity parameter ρ can directly be interpreted as the degree of downward nominal wage rigidity, since it is equal to the proportion of nominal notional wage cuts that are prevented by the existence of downward nominal wage rigidity. The counterfactual bin sizes α_r are constant parameters because of the assumption of a time-invariant counterfactual distribution (up to shifts in location).

System (1) is a partial model of the total histogram including $R = r_{\max} - r_{\min} + 1$ equations, one for each bin modeled; this assumption will later be relaxed. All bins that change status at least once during the sample period contribute to the identification of downward nominal wage rigidity and should be included in the model. r_{\min} should therefore be the bin with the smallest number, that changes from positive to zero status at least once in the sample period, or a bin with an even lower number, and analogously for r_{\max} . Each equation of system (1) covers the three cases of negative, zero, or positive bins. Positive bins ($DN_{rt} = 0$ and $DZ_{rt} = 0$) are explained by the counterfactual bin sizes α_r . In the case of negative bins ($DN_{rt} = 1$ and $DZ_{rt} = 0$), a proportion ρ of the counterfactual bin size is subtracted from α_r . In contrast, for zero bins ($DN_{rt} = 0$ and $DZ_{rt} = 1$) there is a pile-up in addition to the counterfactual bin size from the wage freezes in the negative bins of the same period; parameter γ captures the contribution of those negative bins that are too far left to be explicitly modeled, or caused by reasons other than downward nominal wage rigidity.

Five remarks complete the introduction of the basic model. First, the model presented is a simplified version of the “proportional” model or “model 3” in Kahn (1997) without explicit treatment of small changes. The proportional model of downward nominal wage rigidity with uniform degree of rigidity for nominal wage reductions of all sizes is used, because it results in a single measure of rigidity that is easy to interpret and easy to compare to other results in the literature. There is also explicit support for the proportional form of rigidity in Knoppik (2003), an analysis of functional form of downward nominal wage rigidity. Explicit treatment of small nominal wage changes of either sign is not helpful in the present analysis in the light of available data quality. Second, note that even this basic specification implies nonlinear cross-equation parameter constraints and requires corresponding estimation procedures. Third, the measure of location must not itself be affected by downward nominal wage rigidity, since this measure captures the shifts of the counterfactual distribution which through the principle of joint variation of location and shape is crucial for identification in the histogram-location approach. Fourth, Knoppik and Beissinger (2003) showed that measurement error with classical properties tends to hide some of the rigidity present in the data. The estimated degree of downward nominal wage rigidity in the histogram-location approach is therefore a lower bound of the true extent of rigidity. Finally, a number of variants of the basic proportional model have been proposed in Kahn (1997), Beissinger and Knoppik (2001), Christofides and

Leung (2003), and Castellanos, García-Verdú and Kaplan (2004), but none of these is suitable for cross-country, cross-sectional, or cross-regional analysis.

Cross-country options

In our view there are three different ways in which the histogram-location approach can be used in a cross-country context. The first option is to build isolated *national models*, i.e. to construct national histogram bin sizes and to estimate national models independently of each other, using the basic econometric model (1) for example. The main drawback of this option for our purposes is that for several countries the distribution of per cent wage changes does exhibit only very little variation in location over the sample period which tends to make estimation less reliable or even impossible.

The second option is to construct one aggregate annual histogram for all countries together and to estimate an *aggregate model*. However, different developments over time of the location of the underlying national distributions of per cent wage changes give rise to a time-varying mixture of distributions which violates the assumption of time-invariance of the counterfactual distribution.

The third option is to pool the information on national histogram bin sizes and to estimate *pooled models*. In pooled models, the limited variation in location of the distributions of per cent nominal wage changes is substituted to some degree by cross-country variation in location. Two versions of pooled models, either with uniform or country-specific degrees of downward nominal wage rigidity are considered in the remainder of this section.

Pooled model

The pooled model with uniform parameters essentially consists of a version of equation (1) that is additionally indexed with a country index c

$$(2) \quad P_{rct} = \alpha_r \underbrace{(1 - \rho DN_{rct})}_{\text{thinning}} + \underbrace{\left(\gamma + \rho \sum_{j=r_{\min}}^{r_{\max}} \alpha_j DN_{jct} \right)}_{\text{pile-up}} DZ_{rct} + \mu_{rct} \quad \text{for } r = r_{\min} \dots r_{\max} .$$

Stacked data on bin sizes and status dummies from the different countries is used in this case. The pooled model with national rigidity and pile-up parameters is given by system of equations (3).

$$(3) \quad P_{rct} = \alpha_r \underbrace{\left(1 - \left(\sum_i \rho_i DCi_{rct} \right) DN_{rct} \right)}_{\text{thinning}} + \underbrace{\left(\sum_i \gamma_i DCi_{rct} + \left(\sum_i \rho_i DCi_{rct} \right) \sum_{j=r_{\min}}^{r_{\max}} \alpha_j DN_{jct} \right)}_{\text{pile-up}} DZ_{rct} + \mu_{rct}$$

for $r = r_{\min} \dots r_{\max} .$

Country dummies DCi_{rect} for each country i are used to replace the uniform rigidity and pile-up parameter in equation (2). Specifically, $\sum_i \rho_i DCi_{rect}$ is used to replace ρ , and $\sum_i \gamma_i DCi_{rect}$ replaces γ , where summation runs over all countries covered. In pooled models, the time-invariance of the counterfactual bin sizes continues to be assumed. The assumption of invariance of the counterfactual distribution is in fact extended to hold over countries as well which is reflected in the country-independent counterfactual bin sizes α_r . Any potential country differences of the counterfactual therefore have to be eliminated. Centering the national histograms takes account of the national differences in location. Additional differences in dispersion can be taken into account by standardizing the distributions.

Standardization effectively relaxes the assumption of time-invariant counterfactual distribution (up to variation in location) and replaces it by the weaker assumption of time-invariant counterfactual distribution (up to variation in location and some parameter of dispersion). The standardized per cent wage changes Δw^s are given by

$$\Delta w^s = \frac{\Delta w - l}{v},$$

with parameter of location l and parameter of dispersion/variability v . The choice of a suitable measure of variability depends on the question to be addressed. In the context of their otherwise unrelated analysis of downward nominal wage rigidity in aggregate industry wage data, Holden and Wulfsberg (2004) are interested in unbiased type I errors in a test of the null hypothesis of wage flexibility. For their analysis it therefore does not matter whether the measure of variability v is affected by downward nominal wage rigidity or not, and they choose the interquartile range (IQR) as their preferred measure of variability, i.e. $v^{IQR} = q_{75} - q_{25}$, where q_{75} and q_{25} denote the third and first quartile (75 and 25 percentile). Since we are interested in estimates of the extent of downward nominal wage rigidity, the measure of variability must not be affected by downward nominal wage rigidity. We therefore propose the use of interpercentile ranges (IPR) between the measure of location (which again must not be affected by downward nominal wage rigidity) and some higher percentile. For example, if the 60th percentile is used for location, $l = q_{60}$, the upper percentile could be q_{80} leading to

$$v^{IPR80|60} = q_{80} - q_{60},$$

and a corresponding standardization of

$$\Delta w^s = \frac{\Delta w - q_{60}}{v^{IPR80|60}} = \frac{\Delta w - q_{60}}{q_{80} - q_{60}}.$$

Closed model

A problem of the basic model is that it is a partial model and may thereby lead to inconsistent results. The solution is to 'close' the model by modeling the full left tail of the histogram. In the basic model (1) the part of the distribution to the left of r_{\max} is only taken into account implicitly, by adding the ad hoc "additional pile-up" parameter γ . The construction of location-centered histograms implies that the counterfactual outer left tail has probability mass of $F(q) - \sum_{j=1}^{r_{\max}} \alpha_j$, i.e. is equal to the difference between the percentile used as measure of location and the sum of all counterfactual bin sizes up to r_{\max} . Therefore, because of the proportional functional form of downward nominal wage rigidity assumed in the model, the pile-up from the far left must equal ρ times this difference. This restriction, however, is not taken into account in the partial model and may therefore be violated in estimates obtained from the basic model.

In order to close the model, the restriction can be used to replace the pile-up parameter γ in system (1),

$$\gamma = \rho \left(F(q) - \sum_{j=1}^{r_{\max}} \alpha_j \right).$$

The closed model therefore consists of the following system of equations:

$$(4) \quad P_{rt} = \alpha_r \underbrace{\left(1 - \rho DN_{rt} \right)}_{\text{thinning}} + \underbrace{\left(\rho \left(F(q) - \sum_{j=1}^{r_{\max}} \alpha_j \right) + \rho \sum_{j=1}^{r_{\max}} \alpha_j DN_{jt} \right)}_{\text{pile-up}} DZ_{rt} + \mu_{rt} \text{ for } r = 1 \dots r_{\max}.$$

Note that no explicit equation for the probability mass to the left of r_{\max} is needed since it is implied by the other bin sizes. Such an equation is not admissible either, because of the dependence of the error terms over the closed model.² Note also that r_{\min} has to be set to one. The pooled model is readily extended to the closed version.

3 Data

The analysis is based on the European Community Household Panel (ECHP) which is a large-scale annual longitudinal survey providing household and personal information on income and socio-economic characteristics for the 'old' 15 member states of the European Union (EU).³ The ECHP has been centrally designed and coordinated by the Statistical Office of the European Union (Eurostat). The great advantage of the ECHP is the uniform questionnaire asked in the EU-countries which makes the direct comparison of data across countries and over time possible.

² This situation is well known in the context of the estimation of expenditure shares, see e.g. Greene (2003).

³ EPUNet (2004) provides a short introduction to the ECHP and a reference to more detailed information; see also Eurostat (2003b). A large number of documents on the ECHP is provided by Eurostat (2004). Peracchi (2002) provides a detailed description of the first three waves of the ECHP data.

The ECHP started in 1994 and ended in 2001, thereby comprising eight waves, the last of which has only been made available for scientific use in January 2004. In the first wave in 1994 a sample of about 60,000 nationally representative households with approximately 130,000 individuals aged 16 years and over were interviewed in the then 12 participating Member States. Austria, Finland and Sweden joined the ECHP-project in 1995, 1996 and 1997, respectively. However, the Swedish data cannot be used in the analysis since it only contains cross-sectional information. Luxembourg and the Netherlands also have to be excluded because necessary information for the analysis is missing.⁴

In line with previous analyses in this field we are interested in the per cent earnings change distributions of ‘job stayers’, i.e. employees who have a ‘stable employment relationship’ with an employer for a certain period of time. Job stayers are defined as full-time working employees who do not change the job between two consecutive interviews. In the analysis, the robustness of estimation results will be checked by considering the consequences of alternative definitions for job stayers. We distinguish between three types of job stayers as explained in the upper part of Table 1. For type-I stayers no further restrictions are made, whereas type-II and type-III stayers have to fulfill further requirements with respect to interview distance, absence from work, and the main activity in each month between interviews. Choices with respect to these variables may affect the number of observed wage cuts and zero wage changes. Note that the numbering of stayer types from I to III reflects an increase in the restrictiveness of stayer definition. The reference subsample is based on type-II stayers, who, with regard to sample restrictions, lie in between type-I and type-III stayers.

Table 1

Choices also have to be made with respect to socio-economic characteristics of job stayers (sex, age and sector) and about other conditions (type of employment contract and mode of the interview). In the middle part of Table 1 three categories A to C are distinguished, with category A representing the least restrictive and category C the most restrictive sample selection. More restrictive data selection leads to a more homogenous subsample thereby reducing the problem of composition bias in the histogram-location approach. However, this advantage must be weighted against the disadvantage of losing too many observations.

The ECHP dataset provides information on monthly and annual nominal earnings from work, i.e. ‘current monthly (net and gross) wage and salary earnings’ and ‘total regular net wage and salary earnings’ (referring to the year prior to the wave year). Since the job stayer concept applied in the paper refers to the spell between interviews and not to the calendar

⁴ Data for Luxembourg do not contain information on the month of the interview. Moreover, information on the year of start of the current job is missing in most cases. Data for the Netherlands do not contain information on the monthly activity calendar.

year, we use the information on current monthly earnings.⁵ The question whether gross or net earnings are better suited for the analysis can be regarded as an open one, because arguments for and against each measure can be put forward. For example, the take-home pay may be better known to individuals, but net earnings changes may be affected by changes in the tax system. As a consequence, we will use both net and gross earnings in the analysis and check whether a change in the earnings concept affects the estimation results. As a further dimension of the earnings measure we also take into account whether reported working hours changed from one interview to the next, or not. We therefore distinguish between three earnings measures as explained in the lower part of Table 1. Earnings measures 1 and 2 refer to net earnings. However, earnings measure 2 is more restrictive than measure 1 because it is additionally required that the number of reported working hours remains constant. This restriction is also implemented for earnings measure 3, but in this case gross earnings are considered. Details on the variables used for data selection can be found in Appendix A.

For the analysis, the three stayer types could, in principle, be combined with each of the selection categories A to C and the earnings measures 1 to 3, leading to 27 different subsamples. In our view, however, more insight with respect to the robustness of estimation results can be gained by analyzing the consequences of partial variation of selection criteria. We therefore adopt the following strategy. Our focus is on a reference subsample selection, which represents a ‘middle way’ with respect to the restrictiveness of sample selection. This reference subsample consists of type-II stayers meeting the requirements of category B and of earnings measure 2. Table 2 summarizes the figures of the reference subsample which consists of 70,239 observations for 12 EU countries. In addition, we will check the robustness of estimation results for the reference subsample by systematically varying either the stayer definition, or the selection categories, or the earnings measure in comparison to the reference subsample selection.

Table 2

4 Descriptive evidence

In this section descriptive evidence for the existence of downward nominal wage rigidity is presented. Figure 1 plots the distributions of per cent changes of monthly net earnings between two consecutive interview dates for each country based on the reference subsample (defined in Section 3). This figure provides some preliminary evidence that the distribution of earnings changes is affected by downward nominal rigidity in almost all countries. The left tail of the distribution usually appears to exhibit some ‘deformation’, a spike in the distribu-

⁵ We also constructed ‘calendar year stayers’ from the ECHP for whom the annual earnings information is relevant. However, information on working hours or absence from work refers to the actual situation at the time of the interview. Since we want to control for variation in earnings due to variation in working hours and do not want to lose the final wave throughout the analysis, we prefer to work with ‘interview stayers’.

tion at zero and some thinning in the distribution below zero. However, a purely static descriptive analysis of the shape of the earnings change distribution does not prove the existence of downward nominal wage rigidity, since the thinning of the distribution below zero may simply reflect a peculiar shape of the ‘notional’ (or ‘counterfactual’) distribution of earnings changes. As is evident from the exposition of the econometric models in Section 2, the existence of downward nominal wage rigidity can only be detected by considering the joint variation of location and shape of the earnings change distribution.

Figure 1

In the literature, usually the median is used as measure of location. However, care must be taken in selecting a measure of location which is not affected by downward nominal wage rigidity. Besides productivity growth, the main determinant of the location of the earnings change distribution is inflation. As can be seen in Figure 2a, inflation has been rather low in many EU countries during the second half of the 90s. As a consequence, in some countries and years (e.g. Denmark in 1999) the median includes zero earnings changes, thereby making it unsuitable as measure of location (see Figure 2b). Throughout the analysis we therefore have to use higher percentiles as measure of location. In Figure 1 for example, the sixty percent percentile of the earnings change distribution (marked by a thin vertical line) is used as measure for location.

Figure 2

The descriptive evidence can be used to illustrate the principle of joint variation of location and shape of the earnings change distribution. Greece turns out to be an excellent example for marked joint variation of location and shape. In Greece in the mid-nineties the sixty percent percentile lies between 12 and 15 percent because of high inflation. When Greece curbed inflation in order to meet the requirements for the introduction of the Euro, the sixty percent percentile also declined and amounted to only around 3 percent in 2000. This leftward shift of the location of the earnings change distribution is accompanied by a more pronounced pile-up at zero and an increased asymmetry of the distribution due to thinning in the left tail of the distribution.

As a second example, consider Portugal. The marked asymmetry of the earnings change distribution seems to point to pronounced downward nominal wage rigidity. However, there is hardly any variation of the location of the earnings-change distribution. When we apply the histogram-location approach to the Portuguese data, it will turn out that it is not possible to obtain robust estimates of the extent of downward nominal rigidity for this country on the basis of an isolated national econometric model. Since the same problem also holds for other countries, such as France and Germany, we extend the histogram-location approach (as discussed in Section 2) and estimate pooled models in which the cross-country variation in the

location of the earnings-change distribution is used as additional information for the identification of the extent of downward nominal wage rigidity.

As a final example the earnings change distributions for Spain are considered. Spain stands out as the only country in which pronounced changes in location are not accompanied by corresponding changes in the asymmetry of the distribution. Descriptive evidence therefore suggests that Spain is a country where downward nominal wage rigidity seems to play hardly any role, which may come as a surprise.

5 Empirical implementation and results

In this section we present estimated national and aggregate European degrees of downward nominal wage rigidity. The focus is on results from a reference specification, but we also report the results of systematic robustness checks and relate our results to the literature.

Reference specification

The overall reference specification comprises four categories of definitions concerning the reference subsample, reference histogram construction, reference econometric model and reference estimation set up, which in turn each are defined by selected values for a number of characteristics within these categories. The structure of the definition of the reference specification is illustrated in Table 3.

Table 3

The *reference subsample* results from definitions with respect to the concept of job stayer, the socio-economic characteristics of employees, and the measure of earnings used, and has already been discussed in detail in Section 3.

Constructing histograms of annual relative wage changes is the first step in applying the histogram-location approach, and it involves a number of decisions with respect to the treatment of the data. In the *reference histogram construction* exact percentage changes, a bin width of two percentage points, and a standardization based on a measure of location $l_{t,i} = q_{60,t,i}$ and a measure of dispersion $v^{IPR80/60}$ are used. As in other applications in the literature, e.g. Kahn (1997), exact percentages, rather than log percentages are used, since the transformation implied by using log percentages are of no consequence due to the non-parametric nature of histograms. The two percent bin width is a compromise between the one percent bin width used in the rest of the literature and even wider bin widths suggested by the usual rules, given the numbers of observations per year and country in our sample. On the one hand, there are the necessities to have sufficiently frequent changes of bin status and to have a sufficiently detailed picture of the potential effects of rigidity, both favoring narrower bins. On the other hand there is also the need for reasonably smooth histograms that necessitates the use of wider

bins. Considerations of data quality, especially rounding, also tend to favor wider bins. The main consideration behind the use of the unconventional standardization of wage changes is the need to use measures of location and dispersion that are unaffected by rigidity, as explained in Section 2.

The proportional, pooled, closed model with bins $r=1\dots 10$ is used as the *reference model* for estimating an econometric model of these histograms in the second step of the histogram-location approach. As discussed in detail in Section 2, this model is best suited for the cross-country analysis. The range of bins chosen is somewhat larger than suggested by the range of bins with status changes, $r^{\min}=1$ and $r^{\max}=7$, in order to be able to use the same model in variations of the reference specification where this range increases (narrower bin width).

Finally, our *reference estimation procedure* is iterated weighted least squares (WLS), where weighing is by equation, i.e. by bins. As a consequence, the smaller bins further out in the left tail of the distribution tend to be estimated more accurately.⁶ Along with the different dimensions of the reference specification, all selected values for its characteristics are reported in Table 3.

Reference results

National and European estimated degrees of rigidity for the reference specification are reported in the first column of Table 4. Degrees of rigidity are highly significant in all of the twelve individual countries included in the sample. While in a majority of seven countries the rigidity coefficient lies between 25 and 50 percent, there are also four countries with lower and one with even higher degree of rigidity, within an overall range of 7 percent (Spain) to 66 percent (Italy). EU wide estimated degrees of rigidity are based on the data of twelve 'old' EU countries, Euro area estimates are based on the data of ten members of the monetary union; both are shown in the lower part of Table 4. The standard specification results in highly significant estimated rigidity coefficients of 36 per cent and 37 per cent for these two aggregates.

Table 4

Taking these figures literally means that more than one third of the notional nominal wage reductions for job stayers in the euro area do not take place because of the presence of downward nominal wage rigidity. However, because of the reporting errors typical for survey data, and because of the attenuation effects of these on the observable distribution of per cent wage changes discussed in Knoppik and Beissinger (2003), we interpret these results as constituting lower bounds of true degrees of downward nominal wage rigidity in the respective

⁶ Iterated seemingly unrelated regression (SUR) is used in Kahn (1997), but was shown to lead to unstable results because of the relatively short length of longitudinal surveys in Beissinger and Knoppik (2001).

countries or areas. Actual degrees of downward nominal wage rigidity may turn out to be even larger.

Variation of specification and robustness

The picture that emerges from the reference specification is corroborated by the estimation results from alternative specifications that generally exhibit rather little variation in the estimated degree of downward nominal wage rigidity. The right part of Table 3 summarizes these alternative specifications that result from partial variation of characteristics along almost all dimensions of the reference specification. The corresponding estimation results are summarized in Table 4 as a range for the estimated degrees of rigidity. In addition, they are discussed in more detail in Appendix B which also provides detailed tables with estimation results. Only in the case of the countries with the lowest degrees of rigidity are there some alternative specifications with insignificant rigidity coefficients ρ . Overall, estimated degrees of rigidity tend to be quite insensitive to changes in the specification.

Comparison with literature

If one tries to put these results in perspective using earlier studies, one encounters the very difficulties that motivate the present project, i.e. difficulties of comparison, in particular (but not only) across method and data, and the scarcity of quantitative European analysis. Nevertheless, it seems worthwhile to see whether and where in the overall spectrum the results do fit in; where there is sufficient overlap with preexisting studies with respect to data and method one can also find corroboration or contradiction. The following considerations are based on the reference specification discussed above. They deal first with the cases where econometric approach and regional coverage overlap and are then completed by the discussion of other European and US evidence. Throughout, the discussion focuses on quantitative econometric rather than purely descriptive or qualitative evidence.⁷

As far as Europe or European countries are concerned, the histogram-location approach has only been applied to German data. Beissinger and Knoppik (2001) analyze data of different type, the IAB Beschäftigtenstichprobe, which is a subsample of official social security data, and find degrees of rigidity for blue and white collar workers that are somewhat below the result for Germany found here. Even more closely related are Knoppik and Dittmar (2002) and Decressin and Decressin (2002), since both studies not only use the histogram-location approach, but apply it to GSOEP data that is the basis of the German part of the ECHP (see Appendix A). For a comprehensive measure of earnings, Knoppik and Dittmar (2002) find

⁷ A count of zero nominal wage changes is used as the indicator of downward nominal wage rigidity in Dessy (2002); no further identification or econometric estimation of the degree of rigidity are used. In the analyses of UK data of Smith (2000) and Nickell and Quintini (2003) evidence on the extent of DNWR is not based on econometric models; both find small amounts of DNWR.

degrees of rigidity for blue and white collar workers that are close to the results found here. The figures in Decressin and Decressin (2002) are slightly lower. We interpret the German evidence with far reaching overlap with respect to econometric approach and regional coverage as corroboration of the present analysis.

All other econometric European studies of the extent of DNWR use variants of the earnings-function approach introduced by Altonji and Devereux (2000). This approach deals explicitly with measurement error and changing sample composition and claims to yield actual degrees of downward nominal wage rigidity, rather than only lower bounds, which is one reason why estimates should tend to be higher than our ECHP based estimates.⁸ The earnings-function approach comes in different variants and with a corresponding spectrum of results. Of these variants, the proportional model due to Knoppik and Beissinger (2003) can most easily be compared to results from the histogram-location approach, since it contains a rigidity parameter that can be interpreted in exactly the same way as parameter ρ in the histogram-location approach. Using the mixed measurement error variant of the proportional model, Devicienti (2003) found exactly the same degree of rigidity for Italy as here. With the alternative contaminated mixed measurement variant of the proportional model Knoppik and Beissinger (2003) found more rigidity for Germany than in the present study. Both results are compatible with the interpretation of present results as lower bounds. Ekberg (2004) is an application of the proportional model without any explicit model of measurement error to Swedish data (arguably free of measurement error). Fehr and Goette (2000) is an application of the threshold model to two sets of Swiss data. Both report very high degrees of rigidity for these two European countries outside of our sample. Recently an unsettled issue has emerged within the earnings-function approach, whether and how real wage rigidities should be integrated into the analysis. European studies employing this variant of the earnings-function approach are Fehr, Goette and Pfeiffer (2002) and Bauer, Bonin and Sunde (2003) for Germany, Devicienti, Maida and Sestito (2003) for Italy, and Schweitzer and Barwell (2004) for the UK, which tend to find relatively low degrees of nominal rigidity.

A comparison with US evidence is easiest with Kahn's application of the histogram-location approach to PSID data, which are survey data similar to the ECHP. Kahn distinguishes between different types of employees with different compensation systems. She finds no rigidity for salaried employees, but a degree of rigidity of 40 percent for workers who are paid by the hour. The average of these figures is therefore lower than our result for Europe. The opposite is true for a comparison with the results of Lebow, Saks and Wilson (2003), another application of the histogram-location approach. Even in their version with the most comprehensive earnings measure, estimated degrees of downward nominal wage rigidity are

⁸ Note that the (partial) renunciation on identification by joint variation of location and shape goes along with heavily relying on functional assumptions for identification which may constitute similarly severe problems as the assumptions that are meant to be replaced.

comparable with average European ones and higher than those of anglo-saxon countries in the ECHP European sample. The data in that study is, however, derived from a survey of businesses and therefore not as directly comparable as in the case of the Kahn study. Finally, Altonji and Devereux (2000) use the threshold variant of the earnings-function approach to analyze downward nominal wage rigidity in the PSID to find very high degrees of rigidity.⁹ Overall, there is no conclusive evidence to suggest systematic differences between Europe and the US with respect to downward nominal wage rigidity.

In the few cases, where econometric approach and regional coverage overlap sufficiently for comparisons, our results fit well into the overall picture of existing evidence. Beyond these cases, the European evidence is substantially extended, at the same time allowing consistent cross-country comparisons due to uniform method and uniform data.

6 Summary, conclusions, and outlook

This paper analyzes existence and extent of downward nominal wage rigidity in the European Union, which is a question of great significance, both from a theoretical and from a policy perspective. Up until now, evidence on existence and extent of downward nominal wage rigidity in Europe has been limited to only a few countries and, if available, has been hard to compare because different data sources and methodologies have been used. The available evidence has now been substantially extended by the first-time econometric analysis with respect to these questions using employee micro data from the European Community Household Panel (ECHP) for twelve of the EU's current member states.

We develop and apply a pooled multi-country version of the histogram-location approach which exploits variation in the location of the standardized earnings-change distributions over time and over countries and infers existence and extent of downward nominal wage rigidity from the corresponding variation in the shape of observed histograms. This approach allows the estimation of the degree of downward nominal wage rigidity, which is the percentage of notional wage cuts prevented by downward nominal wage rigidity in relation to all notional wage cuts. National and EU wide estimates of this rigidity parameter support the view that downward nominal wage rigidity is a rather widespread phenomenon within the European Union and the Euro Area. Modifications of our reference specification with respect to subsample selection, histogram construction and econometric model reveal that our estimation results are quite robust to changes in the specification. For example, the estimated degree of downward nominal wage rigidity for the Euro area only varies between 0.31 and 0.40, i.e. between 31 and 40 percent of employees in stable jobs in the Euro area are affected by rigidity. As is argued in the paper, the estimated degree of downward nominal wage rigidity in the

⁹ Other US evidence based on the PSID are McLaughlin (1994) and Christofides and Stengos (2001), which both do not provide quantitative estimates of the degree of downward nominal wage rigidity.

histogram-location approach provides a lower bound of the true extent of rigidity, implying that downward nominal wage rigidity in the Euro Area may be even more pronounced.

The estimation results on the national level make evident a considerable variation in the degree of downward nominal wage rigidity across countries despite the comparable data and uniform methodology used. This observation raises the question what determines this country-specific heterogeneity. In the literature, psychological or institutional factors are put forward as possible causes of downward nominal wage rigidity. In a companion paper we strive to identify the role of these factors as possible causes of downward nominal wage rigidity.

Appendix A Data Selection

In Germany and the UK, the first three waves of the ECHP ran parallel to existing national panels, namely the German Socio-Economic Panel (GSOEP) and the British Household Panel Survey (BHPS).¹⁰ In 1997 (i.e. the fourth wave of the ECHP) the original ECHP surveys were stopped in these countries. Instead, it was decided to integrate ex-post-harmonized national panels into the ECHP. Comparable data were derived from the GSOEP and BHPS back from 1994 onwards. Consequently, two sets of data are available for the years 1994 to 1996 for Germany and the UK. In our analysis, we use the “long series”, i.e. the GSOEP and BHPS data for Germany and the UK, respectively.

To make scientific use of the ECHP data possible, Eurostat constructed an anonymised and user-friendly version of the data (the User’s Database; UDB) from the original data (the Production Database; PDB). In this process, variables have been reorganized and standardized across waves, no more strictly reflecting the structure of the questionnaire. In the following, the data selection from the UDB database, which has been described in Section 3, is documented in more detail.¹¹ The numbering of the following headings corresponds to the entries of Table 1 in the main text.

a) Classification of job stayers

a1) Employment relationship of job stayers

Full-time working employees are selected by using the following conditions for UDB variables describing the main activity status and working time:

PE001 = 1 The interviewed person defines the main activity status as working with an employer in paid employment (15+ hours/week). Other per-

¹⁰ There was the same situation in Luxembourg, but as has already been explained in Section 3, the data for Luxembourg cannot be used because relevant information is missing.

¹¹ For a detailed data dictionary, codebook and information about data differences between countries and waves see Eurostat (2003a).

sons, as e.g. persons in paid apprenticeship or the self-employed, are left out.

PE005C = 1 The main job is classified as full-time job
 $30 \leq \text{PE005A} \leq 60$ The working time in the main job (including paid overtime) comprises at least 30 hours and at most 60 hours.

The above criteria are applied to all stayer types. For type-II and type-III stayers we additionally compare the variable PE005A with PE005, the latter variable containing information on the total number of hours worked per week in main and additional jobs. We require that $\text{PE005} \leq \text{PE005A}$ in order to select employees who hold only one job.

Job stayers do not change the job between interviews. It is checked that the current job started before or in the month of the preceding interview by use of the following UDB variables:

PG006 Month of the personal interview
 PG007 Year of the personal interview
 PE012 Month of start of current job
 PE011 Year of start of current job

a2) Interview distance in months

The interview distance is calculated by using the variables PG006 and PG007 (see above).

a3) Absence from work in days

PE038 Absence from work (in days) in the last four working weeks (not counting holiday weeks) because of illness or other reasons.

This information is completely missing for the UK BHPS data and is not available for the Netherlands in 1994. For these countries and years the value of this variable is not checked.

a4) Monthly activity calendar

In the UDB the main activity status in month 1, 2, ..., 12 of the year preceding the wave year is documented in the variables PC001, PC002, ..., PC012. For stayer types II and III we use this information in order to check that the respective person has been in paid employment in each month between interviews without interruptions.¹² Consider as an example a person who has been interviewed in July 1996 and in June 1997. For the period from July 1996 to December 1996 we checked the information coded in the variables PC007 to PC012 of the wave year 1997. For the period from January 1997 to June 1997 we checked the information coded in the variables PC001 to PC006 of the wave year 1998.¹³ Since the calendar information about

¹² The fact that the person staid with the same employer between interviews (i.e. the person is a job stayer) is checked by the variables described in a1).

¹³ We also took account of „special cases“, in which the interview for wave year ($t-1$) and/or for wave year t took place in the year following the respective wave year.

monthly activity refers to the year preceding the wave year, the main activity status can not be checked for the final wave. For type-II stayers we leave the final wave in the subsample and do not require a check of the activity calendar for the observations of the final wave. For type-III stayers a check of the monthly activity calendar is required for all observations implying that the final wave is lost for type-III stayers.

b) Socio-economic characteristics and other conditions

b1) Age

PD003 Age

b2) Sex

PD004 Sex

b3) Sector

PE007C Main activity of the local unit of the business or organization in current job (agriculture, industry or services)

b4) Type of employment contract

PE024 = 1 Permanent employment contract in main job

b5) Mode of interviewing

PG008 = 1 or = 2 There has been a face-to-face personal interview (with or without computer aid)

Since it is missing or wrongly coded, this information could not be checked for France and the Netherlands for any year and neither for Portugal in 1994.

c) Earnings

c1) Type of earnings

PI221M Current monthly net wage and salary earnings

PI211MG Current monthly gross wage and salary earnings

c2) Change in working hours

PE005A Hours worked in main job (including paid overtime)

Appendix B Robustness checks

This appendix analyses whether the estimation results for the degree of downward nominal wage rigidity presented in Section 5 are robust to variations in the specification. Those estimates were based on a reference specification which is characterized by definitions of (i) reference subsample, (ii) reference histogram construction, (iii) reference econometric model, and (iv) reference estimation.¹⁴ In the following, the robustness of results is checked by varying one by one the various characteristics of the reference specification, while the others are kept identical with the reference specification.¹⁵ For ease of comparison, the first column of each of the following tables contains the results of the reference specification.

Ad (i): Variation of subsample selection

Table B.1 presents estimates which have been obtained by varying the subsample selection. From the upper part of the table it can be seen which component of the reference subsample selection has been changed. As a reminder, the first column repeats the specification of the reference subsample which is based on type II stayers, the socio-economic category B and earnings measure 2. Column 2 reports estimation results if type I stayers are considered instead.¹⁶ In contrast to type II stayers, no restrictions are imposed for type I stayers with respect to interview distance, absence from work and the monthly activity calendar. Column 3 reports estimation results for type III stayers who face even stronger restrictions with respect to interview distance and absence from work than type II stayers. Consider as an example Denmark. If type I stayers instead of type II stayers are considered, the estimated degree of downward nominal wage rigidity changes from 0.35 (in the reference specification) to 0.39. If type III stayers are considered instead, the respective value changes to 0.34. If one also compares the other entries in columns 2 and 3 with column 1, it becomes evident that neither weaker nor stronger restrictions with respect to the stayer definition have a significant impact on the results.

Table B.1

Column 4 presents estimation results for the socio-economic category A instead of category B. In this case female employees are included in the analysis. Moreover, there are weaker (or no) restrictions with respect to sector, type of employment contract and mode of the interview. One would perhaps expect that in this case the extent of downward nominal wage rigidity will be less pronounced. However, with the exception of Italy, where the estimated degree

¹⁴ The reader is referred to Table 3 in the main text for an overview over the various categories of the reference specification. Detailed information on the definition of a reference subsample can be found in Section 3, whereas reference histogram construction and reference econometric model are explained in Section 5.

¹⁵ The estimation procedures are not varied.

¹⁶ All other aspects of the reference specification, including the other components of the reference subsample definition, remain unchanged.

of downward nominal wage rigidity declines from 0.66 in the reference specification to 0.53, the other estimates tend to remain very close to the estimates of the reference specification and for some countries are even higher. Similar conclusions can be drawn with respect to the results for the more restrictive socio-economic category C (see column 5). Since in this category only male employees working in industry are considered, one would perhaps expect that downward nominal wage rigidity will be more pronounced. However, only in the case of Belgium, Greece and Austria significantly higher estimates are observed whereas the estimates for all other countries are close to the estimates in the reference specification. In column 6 results are reported for earnings measure 1, i.e. in contrast to the reference specification it is not checked whether a change in working hours occurred. In most countries, the estimates of the degree of downward nominal wage rigidity are only slightly lower, with the exception of Italy where the estimated degree of downward nominal wage rigidity changes from 0.66 in the reference specification to 0.53. In column 7 gross earnings instead of net earnings are considered. It might be suspected that this change in data selection will considerably modify the earnings change distributions and therefore have a huge impact on the estimation results. However, it is evident from the table that only for four countries the change in estimated wage rigidity seems worth mentioning, with increases in estimated wage rigidity in Denmark and UK, and decreases in Italy and Greece. Overall, from the results documented in Table B.1 it can be concluded that the estimates of the reference specification are quite robust to changes in subsample selection.

Ad (ii): Variation of histogram construction

Table B.2 presents estimates of the degree of downward nominal wage rigidity which were obtained by varying some aspects of histogram construction. As can be seen from the upper part of the table, the reference histogram construction is based on the sixty percent percentile as measure of location, the difference of eighty and sixty percent percentile as measure of dispersion (used for standardization) and a bin width of 2 percent. Column 2 shows that estimates remain basically the same if, all other things being equal, the difference $q_{75} - q_{60}$ is used as measure of dispersion. Columns 3 and 4 present estimates based on histograms with lower or higher bin width (i.e. a bin width of 1.5 percent or 2.5 percent instead of 2 percent). Though the shape of histograms may be influenced by choice of bin width, it is evident from the results that the choice of smaller or larger bins barely affects the estimates. Finally, columns 5 to 7 document that the estimates are quite robust to changes in the measure of location which is used for standardization of histograms.¹⁷ All in all, it can be concluded from the results in Table B.2 that our estimates for the reference specification are robust to changes in histogram construction.

¹⁷ Note that for some countries the median must not be used as measure of location because it is affected by downward nominal wage rigidity. For completeness, the results for the median are nevertheless documented.

Table B.2

Ad (iii): Variation of econometric model

Table B.3 presents estimates of the degree of downward nominal wage rigidity which were obtained by varying some aspects of the econometric model. As can be seen from the upper part of the table, the reference econometric model is based on the pooled closed model described in Section 2 and comprises bins 1 to 10. The second column of the table reports the results of the estimation of isolated national models. Because of insufficient variation of location, the estimation could not be performed for Germany, France, UK and Portugal. The estimates for Ireland and Spain are insignificant. For the remaining countries (with the exception of Belgium) the estimated degree of downward nominal wage rigidity turns out to be higher.

Table B.3

Columns 3 and 4 report the results of estimations which include different bin ranges. As can be seen from the table, a change in the number of bins included (and hence in the number of equations estimated) does barely affect the estimates. The final column presents the results of estimations in which the model has not been closed (see Section 2 for details). This has consequences for the estimation results. For instance, the estimates for Denmark and France are much lower and insignificant. For other countries the significant estimates are considerably higher (UK, Greece, Portugal) or lower (Italy, Germany, Austria, Finland). We conclude that the conventional histogram-location approach in which models are *not* closed may lead to biased estimates of the extent of downward nominal wage rigidity.

Restrictiveness of sample selection	low	middle	high
b1) Age	21-65	21-65	25-60
b2) Sex	all	male	male
b3) Sector	all	industry and services	industry
b4) Type of employment contract	no restriction	permanent ^(c)	permanent ^(c)
b5) Mode of interview	no restriction	no restriction	face to face personal interview ^(d)
c) Earnings	Earnings measure 1	Earnings measure 2	Earnings measure 3
Restrictiveness of sample selection	low	high	high
c1) Type of earnings	monthly net earnings	monthly net earnings	monthly gross earnings
c2) Change in working hours	no restriction	not allowed ^(e)	not allowed ^(e)

Notes: Details on the variables used for data selection can be found in Appendix A. The reference subsample consists of type-II stayers meeting the requirements of category B and earnings measure 2.

(a) Absence from work in the last 4 weeks (not counting holiday weeks) due to illness or other reasons. Absence is not checked for UK since information is not available

(b) With a check of the monthly activity calendar provided by the ECHP it can be secured that the respective person has been in paid employment in each month between interviews. The calendar information always refers to the year preceding the respective wave year. In order not to lose the data of the final wave, we do not perform a calendar check for the final wave (the year 2001) for type-II stayers. For type-III stayers a check is required.

(c) The type of employment contract is not checked in 1994 since in that year the information is missing in all countries.

(d) Since it is missing or wrongly coded, this information could not be checked for France and the Netherlands for any year and neither for Portugal in 1994.

(e) Change in reported working hours in comparison to preceding interview.

UK	—	947	974	929	927	877	819	935	6,408
Σ	—	11,117	10,674	10,919	9,383	9,007	7,996	11,143	70,239

Notes: The table contains the number of observed per cent changes of monthly net earnings between two consecutive interview dates in the reference subsample which consists of type-II stayers meeting the requirements of category B and earnings measure 2 as defined in Table 2. For cells marked with an X the respective wave is not available. In cells marked with a dash observations are missing since information on the preceding year is not available.

^(a) Sweden, Luxembourg and the Netherlands are excluded from the analysis (see text).

^(b) We leave the year 2001 in the reference subsample though the monthly activity calendar cannot be checked for the final wave. This explains the rise in observations for the last wave.

^(c) The low number of observations in Belgium in 1999 and 2000 is due to the fact that in 1999 the sector information is missing in most cases.

^(d) The low number of observations in Finland in 1998 is due to the fact that the spell between interviews exceeded the upper limit of 16 months for most observations in 1998.

TABLE 3: REFERENCE SPECIFICATION AND SYSTEMATIC VARIATION OF SPECIFICATION

	Reference specification	Variation of specifications
Subsample		
Stayer type	II	I, III
Socio-economic category	B	A, C
Earnings measure	2	1, 3
Histogram construction ^(a)		
Per cent annual changes	exact percentage	-
Bin width b	.020	.015, .025
Location l	q_{60}	q_{50}, q_{55}, q_{65}
Dispersion v	$q_{80}-q_{60}$	$q_{75}-l$
Model ^(b)		
Pooling	yes	no
Closed	yes	no
Bins explicitly covered	$r = 1..10$	$r = 1..8, 1..12$
Small changes	no	-
Estimation ^(c)		
Estimator	WLS	-

Notes: The overall reference specification is made up of the definitions for the reference subsample, the reference histogram construction, the reference model and the reference estimation, which in turn each are defined by selected values for a number of characteristics within these categories. For the category ‘subsample’ the characteristics are actually groups of characteristics, see Section 3. The influence of choosing the selected values for the reference specification over alternative values is explored by (partially) varying almost all of them. The corresponding alternative values are listed in the second column. See also discussion in text.

- (a) The use of dispersion and location for standardization of earnings changes are explained in Section 2; q_x denotes the x -th percentile.
- (b) Versions of the model are explained in Section 2. In the reference subsample and histogram construction $r^{\min} = 1$ and $r^{\max} = 7$. The somewhat larger model with $r = 1..10$ was chosen in order to be able to estimate the same model on histograms with smaller bin width.
- (c) Uniform starting values and iteration patterns were used in all estimations.

TABLE 4: ESTIMATED DEGREES OF DOWNWARD NOMINAL WAGE RIGIDITY

		Degree of rigidity		Range of degree of rigidity ^(b)
		ρ	<i>t</i> -values	ρ
		(1)	(2)	(3)
National	Austria	^(a) 0.45	(16.36)	[0.41, 0.52]
	Belgium	0.47	(13.47)	[0.41, 0.68]
	Denmark	0.35	(12.49)	[0.31, 0.60]
	Finland	0.46	(12.99)	[0.36, 0.52]
	France	0.23	(7.54)	[0.20, 0.28]
	Germany	0.28	(9.42)	[0.19, 0.33]
	Greece	0.43	(16.86)	[0.36, 0.64]
	Ireland	0.18	(7.03)	[0.00, 0.20]
	Italy	0.66	(22.38)	[0.45, 0.89]
	Portugal	0.41	(15.13)	[0.37, 0.54]
	Spain	0.07	(2.60)	[0.00, 0.10]
	UK	0.14	(5.32)	[0.10, 0.24]
European	EU ^(c)	0.36	(25.17)	[0.30, 0.37]
	Euro area ^(c)	0.37	(24.19)	[0.31, 0.40]

Notes: Column 1 contains estimated national and aggregate rigidity coefficients ρ from closed pooled models for the reference specification. The coefficient ρ captures the degree of downward nominal wage rigidity in the sense that it measures the share of counterfactual wage cuts that are prevented by nominal rigidity. Column 3 contains the range of ρ that results from systematic variation of the reference specification. The reference specification and its variations consist of definitions with respect to subsample used, histogram construction, econometric model, and estimation that are detailed in Table 3 and the text.

^(a) Assumption of measure of location greater than (nominal) zero violated at least in one year; see also Section 2.

^(b) Ranges for the degree of rigidity consist of the minima and maxima of estimated ρ over the variations of the reference specification, except the inconsistent estimates from the non-closed model. Insignificant estimates in the case of Ireland and Spain are represented by a zero lower bound of the range.

^(c) The European Union (EU) estimate is based on twelve of the fifteen old European Union countries (without Luxembourg, the Netherlands, and Sweden). The Euro area estimate is based on ten of the twelve current member states of the European monetary union (without Luxembourg and the Netherlands).
