April 19, 2005

Abstract

The paper explores dynamics of inflation in Ukraine in the period of relative macroeconomic stability. The analysis of interrelationship between inflation, money growth, wage growth, and a proxy for devaluation expectations is based on impulse responses and variance decomposition of a vector autoregression model. We find that changes in devaluation expectations appear to be the most important factor driving price development, while money supply growth has negligible impact on inflation. In addition, our results evidence of high degree of inflation inertia in the economy, which may reflect the specific institutional settings of Ukrainian economy.

1 Introduction

As many other transition economies of the Central and Eastern Europe (CEE), Ukraine passed through years of sharp economic decline, rising unemployment, and hyperinflation, which were followed by a period of relative macroeconomic stability. While there is some conformity among researchers regarding causes of high inflation in the economies passing through initial stage of deep economic transformation (see, for example, Ghosh, 1997; Fischer et al., 1996), the driving forces of price development during stabilization period vary from country to country. There is evidence that in some cases import prices is the only factor driving prices on other goods inside the country, while traditional monetary factor plays very limited role (results obtained by Kutan and Brada (1999) for the Czech Republic, Hungary, and Poland). In other economies money growth along with exchange rate movements play important role for inflation development, see Ross (2000) for Slovenia. Thus, depending on an institutional context peculiar to a particular economy inflation can be driven by different factors.

The purpose of this paper is to reveal which of the possible factors cause inflation development in Ukraine. We do this by exploring dynamic interrelationship between inflation and other macroeconomic indicators that may affect price dynamics. The choice of possible determinants grounds on analysis of macroeconomic relationships in the country. It shows us that apart from commonly investigated factors of inflation, such as money supply and wage growth, peoples expectations towards exchange rate may have strong influence on price growth in the Ukrainian economy. The role of expectations for determining inflation path is fully recognized in theoretical literature; however, attempts to verify it empirically is usually hindered by unavailability of data, the problem especially acute in transition economies. Here we tackle the data problem by using information available from foreign currency cash market for approximating expectations. Thus, to the best of our knowledge this paper will be a first attempt to investigate the influence of expectations on inflation dynamics in transition economies. Apart from deeper understanding of the inflationary process in Ukraine, the evidence provided here will help to figure out the role of monetary policy in managing inflation and, consequently, to draw some lessons as to the feasibility of inflation targeting regime in Ukraine.

The paper proceeds as follows. In the next section we briefly summarize findings of previous research regarding determinants of inflation in transition economies. The economic development in Ukraine with some implications for econometric modelling are examined in Section 3. The data are described in Section 4. In Section 5 we explain the methodology and report the obtained results. The final section concludes.

2   Inflation in transition economies: empirical evidence

There exist a number of studies that look at the inflation dynamics in the CEE countries such as Albania (Haderi et al., 1999), the Czech Republic, Hungary, and Poland (Kutan and Brada, 1999), Slovenia (Ross, 2000), Croatia (Payne, 2002), *inter alia*. The common among these studies is that they try to determine which factors have been contributing to the inflation dynamics in the respective countries by means of the impulse response functions and the forecast error variance decompositions.

Despite the common technique and similarities of transition process to market-economy, the results of mentioned studies differ substantially. Haderi et al. (1999) find that remittances from Albanians working abroad have substantial influences on the exchange rate and inflation in the economy. At the same time, the response of inflation to money supply growth is small and quickly dies out. Kutan and Brada (1999) undertake an attempt to examine causes of successful disinflation in three transition economies: the Czech Republic, Hungary, and Poland. Their main finding is that in all three cases reduction of inflation was due to lower import prices rather than due to success of disinflationary monetary policy. According to Payne (2002), in Croatia inflation was driven mainly by wage growth and currency depreciation, while money supply growth again appeared to be unimportant determinant. In addition, there is evidence that inflation inertia in Croatia is rather low, whereas other authors find it to be quite substantial. In contrast to the cited literature, money growth is found to have significant effect on inflation in Slovenia (Ross, 2000). Ross (2000) finds a strong linkage between growth rate of broad money and inflation as well as between changes in exchange rate and inflation, while inflation response to shock in wage growth is found to be insignificant.

This diversity of empirical results for transition economies makes it obvious that drawing general con-

clusion is an impracticable task and investigation of inflationary process in each particular country is necessary. Among very scarce literature that examines inflation in Ukraine the impulse response and variance decomposition analysis is used by Piontkivsky et al. (2001), who apply vector autoregression analysis to investigate effect of budget deficit on inflation in 1995 - 2000. They find that budget deficit (even not monetized) has significant albeit small effect on price development, whereas inflation response to shock in monetary base is the weakest. The other study by Lissovolik (2003) tests two theoretical models of inflation on Ukrainian data - a mark-up model and a money market model. The results evidence that the mark-up model, in which inflation is determined by fluctuations in costs of production (labor and raw materials costs) and changes in a mark-up is more applicable in Ukrainian context than the money market model which envisages close relationship between money and inflation. In this paper we tackle the problem from different standpoint than the previous studies did. Instead of concentrating on specific role of one of the possible macroeconomic variables on inflation or testing applicability of a particular theoretical model, we take more general approach, which allows examining influence of various factors on inflation development Ukraine without imposing specific restrictions.

3 Stylized facts about inflation and other macroeconomic indicators in Ukraine

Similar to other post-Soviet economies, the first years of Ukraine's independence were marked by a sharp decline in real output, accompanied by severe impoverishment of population and hyperinflation. In 1991 - 1995 prices were growing at an average monthly rate of 28% sometimes increasing more than thrice during a month.

The relative macroeconomic stability, including slowdown of inflation, was achieved only in 1996, in a year when new currency, the hryvnia, was introduced. Binding hryvnia to the US dollar by the exchange rate corridor stabilized people's expectations helping in this way Ukrainian government to further reduce turbulent price growth. As a result, the 12-month inflation rate reduced to a modest two-digit level

in 1996 and continued to fall later on. The decline in output also became less severe due to gradual implementation of structural reforms initiated several years before.

Notwithstanding these achievements, in 1996 - 1997 fiscal balance remained negative at the level of 5% of GDP. To cover the persistent budget deficit government started to borrow heavily from domestic and foreign investors. Monetization of the budget deficit was often in practice as well, fuelling inflation against a background of stable exchange rate (see Figure 1).

Figure 1 is about here

The situation became dangerous after 1997 Asian crisis, which negatively affected foreign investors' perception of emerging market economies and provoked a rapid outflow of foreign capital from many of them, including Ukraine. Despite the efforts of Ukrainian monetary and fiscal authorities to stabilize the situation, the confidence in domestic economic policy has not been restored. The continuous capital outflow, difficulties in servicing state debt, and the spill-over effect of 1998 Russian crisis resulted in a financial crisis in Ukraine. Hryvnia was devalued sharply causing considerable loss of people's confidence in national currency and further progress of dollarization process. Growth of prices accelerated substantially as well.

Only in the second half of 2000, foreign exchange market was eventually stabilized. At that time Ukraine officially proclaimed a switch from managed peg to free floating exchange rate regime. However, de-facto the National Bank of Ukraine (NBU) has been keeping the exchange rate at almost constant level with respect to the US dollar. Thus, even after the official regime change the monetary policy remained almost fully subordinated to the exchange rate policy and growth rate of money supply was determined by current account and capital account balances. Accordingly, large current account surplus in the year 2000 and later on promoted considerable monetary expansion. Notwithstanding sizeable growth rates of money supply of 40-45% per year, inflation has remained at a quite low one-digit rate.

Besides describing basic economic trends, it is worth paying attention to administrative regulation of commodity prices and wages. Ukrainian economy is characterized by quite high degree of state interven-

tion in the price formation mechanism, which concerns first of all commodity prices and to lesser degree wages. Control over commodity prices takes different forms from explicit fixing of prices and tariffs for some goods and services to indirect administrative regulation through bans on exports, firms mark-up constraints, etc[1]. As to the wage setting mechanism, wages are not linked to inflation development through official backward indexation. State interventions in private sector takes a form of administrative increases in minimum wage, which is rather binding, while wages in budget sector are regulated more heavily by direct setting of salaries for employees of all ranks.

In light of the described facts several inferences important for modelling should be emphasized here: influence of exchange rate and devaluation expectations on inflation development, relationship between money and prices, and regulation of wages and prices.

First, as suggested by Figure 1, there is a close link between exchange rate development and inflation. However, taking into account that imported goods are mainly energy materials, prices on which are regulated by various bilateral intergovernmental agreements with supplying countries, and that imported goods comprise tiny share in the consumer basket (about 10%)[2] most likely this link works through peoples expectations. In rather scarce formal theoretical literature devaluation expectation affect prices through raising current wage demands (Himarios, 1987). We strongly believe, however, that different link operated in the transition economy of Ukraine. After the break-up of the Soviet Union inflation and devaluation were for a long time parallel processes both caused by uncontrolled monetary expansion. Since general public is primarily concerned with easily observable exchange rate and price developments rather than with difficult-to-access money supply statistics, it is very likely that in people's mind devaluation and inflation became closely associated phenomena, while the major cause of them was ignored. Thus, expecting national currency to devalue people automatically expected prices to go up.

Second, the relationship between money supply and inflation was subject to changes. While the developments of monetary aggregates and prices were not characterized by large discrepancies before 2000, the fact that rapid monetary expansion did not evoke acceleration of price growth after 2000 undermines the traditional money-inflation link.

Third, since commodity prices and wages are regulated differently, the development of wages is likely to have an autonomous influence on prices in the short-run. We will make use of these inferences when building a model.

4   Data and variables

Data used in this study are monthly spanning January 1996 – November 2003 (92 data points). We start with the year 1996 as it was marked by relative stabilization of macroeconomic indicators compared to severe economic decline and hyperinflation observed in earlier periods. Basing on our conclusions from the previous section and following the empirical studies for transition economies (Haderi et al., 1999; Kutan and Brada, 1999; Payne, 2002; Ross, 2000), we have chosen the following variables[3]:

Consumer price index, in logs: $LCPI_t$

Average wage per capita, in logs: $LAVW_t$

Money supply

broad monetary aggregate M2, in logs: $LM2_t$

Proxy for expected devaluation

cash market spread: $Spread_t$

for out modelling purposes. The data are displayed in Figure 2. We do not include budget deficit as done by Piontkivsky et al. (2001) since it affects inflation either through money supply or through expectations both used in our model.

Figure 2 is about here

An important determinant of inflation could be exchange rate. However, there are two major reasons not to include official exchange rate as an endogenous variable in the model. First, over the period of investigation official exchange rate of Ukrainian hryvnia to US dollar was under NBU control and, thus, development of exchange rate variable is more comparable to deterministic process rather than to the

stochastic one. Second, as explained above, changes in the exchange rate are likely to propagate into prices through stirring up expectations; hence, some expectation proxy would be more relevant here.

To approximate people's expectations towards future devaluation in countries where forward markets are undeveloped researchers use a differential (spread) between the official and black market rate. The relevance of this proxy is confirmed by Pozo and Wheeler (1999), who find that expectations of devaluation cause movements in black market spread in three of the four investigated developing countries (Argentina, Brazil, and Mexico). Himarios (1987) uses black market spread as an expectations proxy in the cross-country study of inflationary effects of devaluation and devaluation expectations. His results strongly support the argument that expectations of devaluation intensify inflation. Since, to the best of our knowledge, black market rate series is not available for Ukraine, we use similar measure, the cash market spread variable, calculated as a difference between average ask exchange rate on the cash market for foreign currency and official exchange rate. Intuitively, the higher the spread the stronger people's believe that hryvnia will devalue soon[4].

The relationship between wages, commodity prices and money supply require additional attention. Since wage is basically a price for labor, wages along with commodities prices should be affected by the same long-term factors like money supply growth. However, as explained before due to administrative regulation the wage setting mechanism in Ukraine differs from the commodity price formation. Thus, the development of wages is likely to have an autonomous influence on prices over the short time period as ours. This indicates that wage growth affects inflation independently from money supply growth and may enter the model as a separate variable. It also worths noting that we do not tend to interpret average wage as a pure cost-push factor of inflation. The reason for this is a relatively low share of wages in the production costs (about 18%) on the one hand, and its high share in households income (about 50%) on the other. Thus, in interpreting effect of wages on inflation it is rather difficult to separate its demand-pull and cost-push components[5].

The question of state intervention in the process of commodity prices formation also should be addressed here. High degree of price regulation may pose problems for econometric modelling of inflation, since

it undermines the relationship between price growth and development of other macroeconomic variables and introduces distortions not easily caught by econometric model. However, one justification would be that administratively regulated prices react to shocks as well, albeit with lag and by smaller amount than market prices. Bearing this justification in mind, we will embark on estimation.

5   Methodology and empirical results

Our estimation procedure comprises several steps. First, we test for the order of integration of time series at hand and address the cointegration properties of the data. Then we explore the pairwise causality between the employed variables by means of the Granger causality test. Grounding on the findings of these preliminary tests, we formulate a vector autoregressive (VAR) model, which we further use to evaluate direction and strength of relationship between economic variables based on the orthogonalized impulse response functions (IRF) and on the orthogonalized forecast error variance decompositions (FEVD).

Table 1 is about here

The results of the ADF test suggest that all the variables are I(1), see Table 1. Hence, the next step is to determine whether there are any cointegration relations exist between these variables. For this purpose we apply the Full Information Maximum Likelihood (FIML) method of Johansen (1995). We find that there is no firm evidence for the existence of the long-run equilibrium relations in the data of interest[6]. Therefore, for the further analysis and final conclusions we consider only the first difference transformation of the variables, subsequently denoted as $DLM2_t$, $DLCPI_t$, $DLAVW_t$, and $DSpread_t$. In addition, we use the deterministic seasonal dummies in order to account for seasonality and the impulse dummy - for the financial crisis in September 1998.

Table 2 is about here

The next exploratory step for determination of the strength and direction of causality between the economic variables is provided by the Granger causality test. We report the results for lag length from one

to twelve in Table 2. As evident from first row of each panel, growth of monetary aggregates, change in average wage and change in devaluation expectations all Granger cause growth of prices, indicating that all three variable are potentially good determinants of inflation. At the same time, as shown in panel three of the table, the reverse causality is not revealed for money and wages, although inflation Granger causes changes in expectations.

Below we specify the VAR model and use it to identify the IRF and FEVD. In this approach we follow Ross (2000), who also considered orhtogonalized IRF and FEVD. In particular, we used the following ordering of the variables: $DLM2_t - DLCPI_t - DLAVW_t - DSpread_t$. It is, however, well known that the estimated IRF and FEVD depend on the ordering of the variables in the VAR model unless the estimated residual covariance matrix is diagonal. As shown below, the estimated residual covariance matrix has no large off-diagonal elements. Therefore our results reported for this particular ordering are rather robust to the alternative orderings of the variables.

Estimation of the VAR model starts by determining its lag order. It is interesting to observe that the various information criteria have selected the optimal lag length rather differently, i.e. the Akaike Information Criterion (AIC) 12 lags, the Final Prediction Error (FPE) and the Hannan-Quinn (HQ) - 1 lag, and the Bayesian (BIC) - 0 lags. The outcome of the order selection procedure is consistent with the strength of the penalty a particular information criterion imposes on the extra parameters. Thus, the AIC, which imposes the least penalty, selects the largest order, whereas the BIC, which imposes the strongest penalty - the smallest.

This poses us with a dilemma. On the one hand, imposing the zero lag order on the VAR suggests that all the variables are random walks (with drift) and there are no interrelations among these economic variables themselves as well as their past, which contradicts the results of the unit root and of the Granger causality tests. In addition, by selecting the VAR(1) model we risk to omit the higher-order dynamics, whose presence is also indicated by the results of the ADF and of the Granger causality tests. On the other hand, by selecting VAR(12) model, as the AIC criterion suggests, we run into the 'curse of dimensionality' problem. This means that for the given sample size the number of estimated parameters is too large,

which results in overfitting of the model. Hence, as the compromise between these two extremes we specify a subset VAR using the VAR reduction technique (e.g. see Brüggermann and Lütkepohl, 2001).

Tables 3 and 4 are about here

In particular, we sequentially eliminate the regressors with the smallest absolute values of the $t-$ratios until the remaining regressors are significant at the 1% level[7]. In this way, we do not restrict the dynamic interaction between the variables by considering e.g. only one lag of the dependent variables, and at the same time, we solve the 'curse of dimensionality' problem by deleting the insignificant variables. We check the statistical adequacy of the estimated subset VAR model using the standard battery of the diagnostic tests reported in Table 3. As seen, there is no evidence of model misspecification. In addition, the correlation of the residuals is reported in Table 4. As seen, none of the estimated correlation exceeds 0.30 in the absolute value. This fact ensures that the orthogonalized IRFs and FEVDs (reported below) are rather robust to the alternative ordering of the variables in VAR. Hence we can base our subsequent analysis on this model.

Figures 3 and 4 are about here

The estimated IRFs along with the bootstrapped 95% confidence intervals are reported in Figures 3 and 4. Each row of the figure demonstrates response of a particular variable to one standard deviation shocks in all the other variables of the model. The dying out IRFs, reported in panel (a), indicate stability of the model. As becomes evident from the second row of each panel, the response of inflation to shocks in other variables is positive, as expected. While innovation in money variable produces very small, quickly subsiding and insignificant effect on price growth, shock in growth rate of wages as well as in devaluation proxy has more prolonged significant impact on inflation dynamics. At the same time, the FEVDs reported in Table 5 demonstrate that major part of the forecast error variance in inflation can be attributed to its own innovation. Nevertheless, it is interesting to note that among the explored variables innovation in the devaluation proxy has the largest proportion in inflation FEVD, while proportion of money supply growth innovation is close to zero.

Table 5 is about here

Absence of close relationship between the variables may point to high degree of inflation inertia in the economy, partially caused by high degree of administrative control over prices. The unimportance of money supply growth for inflation dynamics as indicated by insignificant IRFs and tiny proportion in variance decomposition is rather consistent with our inferences from Section 3 as well as with previous empirical findings for Ukraine (Piontkivsky et al., 2001; Lissovolik, 2003) and demonstrates very low sensitivity of price dynamics to monetary policy actions. In contrast, the fact that expectations play important role in determining development of inflation is quite interesting and indicates that inflationary process may be sensitive to changes in peoples' projection as to future devaluation of national currency.

6 Concluding remarks

This paper was aimed at exploring dynamic interrelationship between inflation and three other macroeconomic variables: money growth rate, wages growth rate and changes in devaluation expectations in the transition economy of Ukraine. The analysis based on impulse response functions and forecast error variance decompositions of the VAR model gives grounds for several conclusions. First, there is evidence of substantial inflation inertia, which can be partially attributed to high degree of price control in the country. Second, among the explored variables the effect of money supply growth on price dynamics is the weakest. This finding is consistent with the results of previous research and indicates low power of monetary policy in controlling inflation. This, in turn, points out that adoption of inflation targeting regime in Ukraine, an option considered by local monetary authorities as desirable and feasible in the medium-run, remains questionable, at least unless control over inflation is regained by the central bank. Finally, changes in the devaluation expectations have the strongest impact on price growth. Although this finding should be treated with caution because of imperfection peculiar to any approximation procedure, it gives grounds to believe that people's expectations is an important factor fuelling inflationary process in transition economies, the fact that should not be overlooked when formulating economic policy.

Footnotes

[1] In such case a core inflation index would, definitely, be more appropriate for econometric analysis. However, the core inflation index is not calculated by Ukrainian statistical authorities and deriving a measure of it is beyond the scope of this paper.

[2] According to the information of official representatives of the State Statistics Committee of Ukraine during the round table "Macroeconomic Indicators in Ukraine: Methodological Aspects", December 8, 2001, Kiev, Ukraine.

[3] Data on consumer prices and average wages are from the monthly reports of the State Statistics Committee of Ukraine. Monetary aggregate as well as official exchange rate and ask rate on a cash market used for calculation of cash market spread variable are from the National Bank of Ukraine.

[4] It should be acknowledged that the cash market spread variable has several shortcomings because of restrictions sporadically imposed and abolished by the central bank on cash foreign exchange operations. In addition, it is subject to seasonal fluctuation related to vacation and holidays periods, which, however, are believed to be captured by seasonal dummies included in the model.

[5] The way out would be to use households' income, which more certainly affects inflation from the demand side; however, the due to drastic changes in the methodology of calculating income, time series data for the income variable that is comparable for the whole period is not available.

[6] Not reported for the sake of exposition conciseness.

$DLCPI_t$	[0.967]	[0.988]	[0.903]	[0.127]	[0.116]
$DLAVW_t$	[0.562]	[0.426]	[0.680]	[0.831]	[0.674]
$DSpread_t$	[0.225]	[0.684]	[0.524]	[0.121]	[0.174]
System	[0.696]	[0.649]	[0.427]	–	[0.371]

Note: Table reports the $p-$values of the following residual diagnostic tests: LM - $F-$test of no residual autocorrelation, ARCH - $F-$test of no residual autoregressive conditional heteroscedasticity, Doornik-Hansen - χ^2-test for normality of the residuals.

Table 4: Subset VAR(12) model: residual correlation matrix.

	$DLM2_t$	$DLCPI_t$	$DLAVW_t$	$DSpread_t$
$DLM2_t$	1.392	0.108	0.256	-0.212
$DLCPI_t$	0.108	0.919	0.277	0.242
$DLAVW_t$	0.256	0.277	1.639	0.284
$DSpread_t$	-0.212	0.242	0.284	0.776

Note: Observe that the standard deviations of the appropriate equation residuals are reported on the diagonal.

Table 5: Subset VAR(12) model: Orthogonalized Forecast Error Variance Decomposition.

Proportions of forecast error in $DLM2_t$ accounted for by:

forecast horizon	$DLM2_t$	$DLCPI_t$	$DLAVW_t$	$DSpread_t$
1	1.00	0.00	0.00	0.00
12	0.72	0.08	0.20	0.00
24	0.69	0.08	0.22	0.01

Proportions of forecast error in $DLCPI_t$ accounted for by:

forecast horizon	$DLM2_t$	$DLCPI_t$	$DLAVW_t$	$DSpread_t$
1	0.01	0.99	0.00	0.00
12	0.01	0.91	0.02	0.06
24	0.01	0.90	0.03	0.06

Proportions of forecast error in $DLAVW_t$ accounted for by:

forecast horizon	$DLM2_t$	$DLCPI_t$	$DLAVW_t$	$DSpread_t$
1	0.07	0.06	0.87	0.00
12	0.10	0.07	0.81	0.03
24	0.10	0.07	0.79	0.04

Proportions of forecast error in $DSpread_t$ accounted for by:

| forecast horizon	$DLM2_t$	$DLCPI_t$	$DLAVW_t$	$DSpread_t$
1	0.04	0.07	0.09	0.80
12	0.08	0.22	0.07	0.63
24	0.08	0.23	0.09	0.60

Figure 1: Development of official exchange rate and consumer prices in Ukraine in 1996-2003

Figure 2: The variables: $LCPI_t$ - consumer price index, in logs, $LM2_t$ - broad monetary aggregate M2, in logs, $LAVW_t$ - average wage per capita, in logs, $Spread_t$ - cash market spread.
