The diffusion of Internet: a cross-country analysis^{*}

Luis Andrés, David Cuberes,
Mame A. Diouf and Tomás Serebrisky^{**}

Abstract

This paper analyzes the process of Internet diffusion across the world using a panel of 214 countries during the period 1990-2004. Countries are classified as low and high-income and it is shown that the diffusion process is characterized by a different S-shape in each group. The estimated diffusion curves provide evidence of very slow “catching up”. The paper also explores the determinants of Internet diffusion and shows that network effects are crucial to explain this process. One important finding is that the degree of competition in the provision of Internet contributes positively to its diffusion.

Keywords: Technological diffusion, Internet, S-shape curve, Network externalities, Digital divide

JEL Classification: O14, O33, O57

^{*} We would like to thank Makhtar Diop, Georgeta Dragoiu, Antonio Estache, J. Luis Guasch, Aitor Lacuesta-Gabarain and Juan Ortner for useful comments and support. We also thank Luis Díaz-Serrano, Antonio Manacorda and Tommaso Valletti for sharing their estimation codes with us. The authors gratefully acknowledge partial financial support from the FPSI Small Research Grants. Cuberes thanks the financial support of the Ministerio de Ciencia y Tecnología (project SEJ2007-62656) and the Ivie.

1. Introduction

The process of technological adoption and diffusion has been extensively studied in the literature.¹ A casual look at data on the diffusion of different technologies reveals that, at a given point in time, there are significant differences in the degree of diffusion or adoption across countries.² This paper studies those differences for one technology in particular: the Internet. Understanding the process of Internet adoption and diffusion as well as the main determinants of cross-country differences in this process seems to be of particular interest since, as it has long been acknowledged, the Internet is a key tool of economic development (Röller and Waverman, 2001; Sánchez-Robles, 1998; Kenny, 2003).

Figure 1 illustrates the significant disparity in Internet diffusion in five countries during the 1990-2004 time interval. Although the number of Internet users per capita was very low in the United States in 1990 (0.8%), the use of this technology increased to 22 percent in 1997, and jumped to 63 percent by 2004. France had a low adoption rate for most of the time interval covered here, but this rate grew very rapidly, especially after the year 2000, reaching 39 percent in the year 2004. These accelerations were clearly not observed in the three other countries of Figure 1. Brazil had a modest rate of 12% by the end of the period. In China, although Internet use grew very rapidly – from a level of 0.03 percent in 1997 to 7.2 percent in 2004, the penetration rate was still remarkably low in that year. Finally, Internet adoption in Tanzania was virtually zero in 1997 and it only increased to 0.9 percent by 2004. The observed difference in the levels of Internet adoption across countries raises important policy questions. Of particular interest to policymakers in developing countries is the need to understand the process of diffusion in order to anticipate if their countries will eventually catch up and close the digital divide and, more generally, to implement the right policies to increase the speed of Internet adoption.

This paper makes use of a comprehensive dataset to study the process of Internet diffusion in a large set of countries for the period 1990-2004. The analysis includes both developed and developing countries and provides separate results for distinct income levels. The paper is broken down into two parts. We first show that, confirming previous studies, the process of Internet diffusion across the world is well described by an S-shape pattern. An important advantage of the dataset used in this exercise, which distinguishes it from many previous papers, is that it includes data for the initial years in which Internet was adopted and hence it facilitates the estimation of a complete S-shape curve. We estimate these curves for different groups of countries and find that low-income countries have a much steeper adoption profile and their curve lies to the right of that of high-income countries. This finding provides support to the hypothesis that Internet adoption follows a leader-follower model whereby low-income countries, as followers, have lower adoption costs.³

¹ See for instance Keller (2001), Comín and Hobijn (2004), Caselli and Coleman (2001), Comín, Hobijn, and Rovito (2006), Barro and Sala-i-Martin (1997), and Jovanovic and Lach (1989).

² Chinn and Fairlie (2007) show that, in the year 1993, many developing countries had computer and Internet penetration rates that were 1/100th of the rates found in North American and Europe.

³ This hypothesis is developed in Chong and Micco (2003).

The second part of the paper identifies variables that explain the differences in cross-country patterns of Internet diffusion. Our most innovative finding is the presence of significant network effects in Internet diffusion: the number of Internet users (in a given country) in the previous year is a powerful determinant of the number of Internet users in the current year. The presence of network effects as a determinant of Internet adoption has been largely ignored in existing literature⁴-- a striking fact considering that the utility derived from Internet consumption is clearly affected by the number of people using it (Shy, 2001). In addition, the paper studies one determinant that has not been much explored in the literature: the competition in the market for the provision of Internet services. Controlling for different relevant variables, the results suggest that in countries where there is more competition in the distribution of Internet, the number of users increases more rapidly.

The remainder of this paper is organized as follows. Section 2 briefly summarizes the existing literature on technology diffusion and, in particular, on Internet diffusion. Section 3 describes the main dataset used throughout the paper. The empirical estimation of Internet diffusion curves is presented in Section 4. Section 5 explores the determinants of Internet diffusion across countries. Finally, Section 6 offers concluding remarks.

2. Related Literature

There exists a vast literature exploring the process of technology diffusion across countries. Since the emphasis of the present paper is empirical, the following summary will omit most of the theoretical analysis.⁵

The majority of the empirical papers on technological diffusion focus on identifying variables that can explain some features of the diffusion process of different technologies. For instance, Gort and Klepper (1982) trace the history of diffusion for 46 new products and correlate it with several economic indicators. Caselli and Coleman (2001) analyze the case of personal computer adoption and provide a comprehensive cross-country analysis that attempts to identify its main determinants. Finally, Pohjola (2003) studies observed investment in information and communication technology in 49 countries during the period 1993-2000.

Furthermore, there are plenty of empirical studies on the determinants of Internet usage.⁶ Chinn and Fairlie (2007) use panel data of 161 countries for the years 1999-2001 to

⁴ Estache, Manacorda, and Valletti (2002) is an exception as these authors include a lagged variable of Internet users but find it not significant as a determinant of Internet adoption.

⁵ A summary of the theoretical literature can be found in Keller (2001). His review argues that "technology" has been mostly modeled as "technological knowledge". The main theories belong to two groups. The first one (endogenous technological change) views technological change as the outcome of intentional private actions (Aghion and Howitt, 1992; Grossman and Helpman, 1991; Romer, 1990; and Segerstrom, Anant, and Dinopoulos, 1990). The other group of theories model technological change as a pool of available resources to the entire world (Mankiw, 1995; Parente and Prescott, 2000).

identify the determinants in cross-country disparities in the usage of personal computers and Internet. Although income differences play a major role in explaining the digital divide, they show that there are other important determinants such as regulatory quality and the level of infrastructure. Estache, Manacorda, and Valletti (2002) also analyze the determinants of differences in Internet usage across countries and use their results to provide some policy recommendations for the Latin America region. Chong and Micco (2003) study the spread of Internet in Latin America and argue that, in spite of being latecomers, Latin American countries have the advantage of lower costs of adoption and could easily catch up with technological leaders. They also find that a country's capacity to innovate helps explain the extent to which Internet is adopted. In a similar framework, Beilock and Dimitrova (2003) find that per capita income is one of the most important factors behind these differences. Their results also suggest that this effect is non-linear, with income differences having a larger effect in the use of Internet at lower income levels. Finally, Guillén and Suárez (2005) focus on the effect of economic, political and sociological factors on Internet usage.

On the other hand, several authors have studied the fact that technology diffusion follows an S-shaped pattern. This empirical recurrence is documented by Griliches (1957), Davies (1979), Gort and Klepper (1982), and Mansfield (1961), and is theoretically modeled in Jovanovic and Lach (1989) among others. More recently, Comín, Hobijn, and Rovito (2004, 2006) study the diffusion processes of several technologies in different countries over the last 200 years. They find that, once the intensive margin of technological diffusion is accounted for, the evolution of the level of technology in a country typically departs from an S-shaped pattern.

Finally, another strand of the literature has analyzed the positive effect of technology adoption and, in particular, the adoption of Internet on the growth performance of a country and on the digital divide across countries—the gap in access to information technologies between developed and developing countries. Some interesting studies along these lines are Röller and Waverman (2001), Gramlich (1994), World Bank (1994), Sánchez-Robles (1998), Norris (2000), OECD (2001), and Kiiski and Pohjola (2002).

This paper is intended to fill several gaps present in the literature. First, we use data that includes the initial years of Internet adoption, thus facilitating the estimation of complete S-shape curves. Moreover, by including both developed and developing countries, we can explicitly analyze differences between income level countries. The paper also studies the effect that competition and network externalities have on Internet adoption - two factors that have thus far been neglected in most previous studies.

⁶ We do not attempt to provide a comprehensive account of these papers here. An incomplete list includes Canning (1999), Klobas and Clyde (1998), Kiiski and Pohjola (2002), Quibria, Ahmed, Tschang, and Reyes-Macasaquit (2002), Liu and San (2006), Zhao, Kim, Suh, and Du (2007) and Leiter and Wunnava (2009).

3. The Data

Technological diffusion is defined in Gort and Klepper (1982) as “the spread in the number of producers engaged in manufacturing a new product.” Given the nature of the Internet, the paper adapts this definition, whereby diffusion refers to the number of consumers of Internet. Although one could think of many indicators of Internet diffusion⁷, the two most widely used are: the number (absolute and in per capita terms) of Internet users and that of Internet subscribers.⁸ Tables 1 and 2 present descriptive statistics for the total and per capita number of Internet users. Conceptually, Internet *users* and *subscribers* are different variables since the former include intra-household access to the Internet as well as people who access Internet in public places (universities, libraries, cafes). The results using both measures of Internet diffusion are qualitatively similar. Hence, in what follows, we only report the results for Internet users.

The main dataset used in this paper is from the International Telecommunication Union Data (2006). This dataset contains information on 214 countries for the period 1990-2004.⁹ By including both developed and developing countries in the sample we take into account the importance of problems of sample selection raised by De Long (1988) in the context of the literature on growth convergence.¹⁰

One important aspect of note is that, for most technologies, the relevant measure of diffusion is the ratio of *actual* to *potential* users. Measuring potential users is problematic since it requires access to micro data, which is unavailable for most of the countries in our sample. However, as noted by Dasgupta, Lall, and Wheeler (2001), in the case of Internet, human capital requirements to use its basic applications (electronic mail and information search) are relatively low. Therefore, it seems reasonable to assume, as the paper does, that the entire population is a potential user. We therefore define number of Internet users per capita as simply the ratio of users in a country to its total population.

⁷ Press (2000) provides a long list of such indicators: connectivity, host count, number of web sites, language distribution, compound indices of pervasiveness, geographic dispersion, sectoral absorption, connectivity infrastructure, organizational infrastructure, and sophistication of use.

⁸ Ideally, one would also like to have measures of the quality and the intensive use of the Internet but this information is not available for a large enough group of countries. It is well-known that developing countries might have a very slow connection to the Internet. For example, in the spring of 1999, Cuba’s total international bandwidth was 832 kb/s, which is much less than a home with high-speed DSL service or cable modem. Furthermore, connectivity was concentrated in Havana and limited to relatively few people, almost exclusively through their work (see Martínez, 1999). The picture is much worse in many African countries (see Jensen, 2009).

⁹ We replace zeros with missing values if a country has had positive figures for a large number of years preceding the missing value. On the other hand, initial missing values are replaced by zeros. The rationale for the latter is that, in most cases, the initial values are quite small, suggesting that initial missing values correspond indeed to zeros.

¹⁰ In order to control for outliers, in all specifications below we drop from our dataset the observations that correspond to countries with GDP growth above 9.2% or below -4.9% (which represent three standard deviations away from the mean GDP growth). As a robustness check we also run the regressions using the whole sample. The estimates of those regressions are similar to the ones we present in the main text and are available upon request.

Finally, the paper uses the *World Bank Country Classification* to study potential differences in diffusion patterns across countries with different income levels. The World Bank classifies countries in the year 2005 into four different groups according to their GNI per capita. These groups are *low-income*, *lower-middle-income*, *upper-middle-income*, and *high-income* economies.¹¹ A list of countries included in each group is shown in the Appendix. The paper follows the World Bank classification, but has opted to group countries into two categories: (i) Low-income and lower-middle-income countries and (ii) upper-middle-income and high-income countries, redefined as “low-income” and “high-income”, respectively. This grouping provides more degrees of freedom for the estimations.

4. An Estimation of the Diffusion Process of Internet

As noted in Jovanovic and Lach (1989), there exists strong empirical evidence to support the view that the diffusion path of both new processes and product innovations follows an S-shaped or logistic pattern.¹²

This paper presents two contributions to this stylized fact. First, we estimate the hypothesis that Internet diffusion follows an S-shape curve for low and high-income groups of countries. There are theoretically sound reasons to believe that the diffusion process of a given technology should be significantly different for poor and rich countries (see Barro and Sala-i-Martin, 1997).

Second, we use of a comprehensive dataset, which allows us to study the diffusion process of Internet since the initial years in which it started to spread in the leading country—the U.S. This clearly overcomes the selection problem present in most of the existing studies. As acknowledged in Comín and Hobijn (2004), most of these papers lack data for the initial years in which the innovation (or new product) was adopted.¹³ This translates into important differences in the estimation of diffusion. In particular, we show that the omission of the initial years leads to S-shape curves that grow “too fast” during the early introductory phase.

Figure 2 plots the actual number of Internet users per capita in the two income groups. It is clear from this graph that, at any point in time, the degree of Internet adoption is much lower in less developed economies than in more developed ones. The use of Internet in low-income countries did not commence until 1994, whereas it had already done so by 1990 in several high-income countries. In 2004, about 40 percent of the population of high-income countries enjoyed Internet services, while the percentage was less than 3

¹¹ The income thresholds are: low income, \$875 or less; lower middle income, \$876-\$3,465; upper middle income, \$3,466-\$10,725; and high income, \$10,726 or more.

¹² Kotler (1986) interpreted this fact as evidence in favor of the existence of four phases for technology adoption: introduction, growth, maturity, and decline.

¹³ This lack of data is due to the fact that, in most cases, information on the use of a given new technology starts to be collected only after it has been widely adopted. Comín and Hobijn (2004) mention the example of the telephone, which was invented by Alexander Graham Bell in 1876 but most countries did not publish official statistics on its diffusion until the early years of 1900s.

percent in low-income ones. In other words, the diffusion curve of low-income countries can be roughly described as a right shift of the one displayed by high-income ones. This stylized fact seems to support the leader-follower model presented by Chong and Micco (2003).

In order to estimate the diffusion process of Internet we use a logistic function. This functional form has often been used to approximate the S-shaped diffusion process due to its relative simplicity.¹⁴ Equation (1) presents the expression of the logistic function used in the estimations:

$$Y_{it} = \frac{\delta_0}{1 + e^{-(\delta_1 + \delta_2 t)}} + \varepsilon_{it} \quad (1)$$

where Y_{it} represents the number of internet users per capita in country i at period t , and ε_{it} is a white noise.¹⁵ The parameter δ_0 reflects the long-run level of diffusion, i.e. the limit of Y_{it} when t goes to infinity, δ_1 is a constant of integration that positions the curve on the time scale, and δ_2 reflects the speed of adoption. Equation (1) is estimated using a nonlinear least squares procedure.

The results of the estimation are displayed in Table 3. The first column presents the estimates for the entire world. Columns 2 and 3 show the estimates for low and high-income countries, respectively. First, the long run level of diffusion is much higher in high-income countries. Second, the parameter of the speed of adoption (δ_2) is higher for low-income countries than for high-income countries. This difference suggests that low-income countries have a higher adoption speed, which is consistent with the hypothesis that low-income countries are ‘catching up’, and that followers tend to adopt technologies faster than leaders.

Figure 3 displays actual and predicted number of Internet users per capita in the world during the years 1990-2004, while Figures 4 and 5 display the same variables for low-income and high-income countries respectively. The first thing to notice is that the data and the model display a very clear S-shape pattern, particularly for high-income countries. While the diffusion of Internet is very slow in the initial years it speeds up in the middle years, and then finally slows down. As mentioned above, the fact that the dataset contains information from the very first years of Internet diffusion helps explain why we obtain a complete S-shape curve while most of the related literature does not. Figures 4 and 5 show that in low-income countries, diffusion of Internet accelerates in the last years of the sample, while in high-income countries the process significantly flattens out. This graphical evidence also suggests that low-income countries are at a prior stage of the diffusion process and should eventually catch up with high-income countries in the diffusion of Internet.

¹⁴ Other S-shaped functions used include the cumulative normal and the Gompertz model.

¹⁵ Estimations using the total number of users as a dependent variable yield qualitatively similar results.

A striking result of Table 3 is the estimate of δ_0 , which suggests a lack of long term convergence in Internet diffusion between low and high-income countries. High-income countries converge to an adoption rate of 41.03 percent, whereas low-income ones reach a much lower adoption rate of 7.28 percent in the long run. Provided that the estimation indicates that low-income countries are catching up as their speed of adoption is higher, a relevant question is: in this scenario, how many years would it take for low-income countries to reach the long-term adoption rate of high-income countries? To answer this we estimate equation (1) imposing the restriction that the δ_0 coefficient for low-income countries equals 41.03, the estimated long run adoption rate of high-income countries. The result of this counterfactual experiment is shown in Figure 6. According to the estimates, low-income countries would take 14 years to reach a penetration rate of 40% (in year 2017) and 54 years (year 2057) to exactly converge to 41.03%, the long-term level of high-income countries. We conclude from this simple exercise that the implied rate of convergence is rather slow.

The importance of including the first years of data

Comín and Hobijn (2004) point out that the absence of the first years of data may have important consequences in the estimation of the diffusion process. The lack of public official statistics during the initial years in which a new technology is being used has been a problem in the vast majority of technologies that they study. As it is stated in their paper “[...] *This selection effect therefore implies that data do not tend to cover the introductory phase.*” Our study has the advantage of using data on the introductory phase for most countries.

In order to quantify the effect of including the initial years of data when estimating S-shapes, we borrow the methodology used in Comín, Hobijn, and Rovito (2008), henceforth CHR. In their paper they use three different calculations to argue that the logistic model fits the data much less so when they take into account the intensive margin of technological use. Their first strategy is to show that the computer routine to estimate the logistic curve does not converge in many cases once they control for this margin. Second, the estimate of the time parameter δ_2 is often negative, which is a direct violation of the logistic function.¹⁶ Finally, they use the fact that the logistic curve predicts that diffusion of a given technology will reach 1% approximately at period $t = \frac{-\ln(0.99) - \delta_1}{\delta_2}$. They find that this date is systematically over or understated once the intensive margin is controlled for.

¹⁶ Logistic curves increase monotonically and hence the parameter δ_2 must be positive. Another consequence of this monotonicity is that the R^2 are artificially high and cannot be used as an informative measure of goodness-of-fit.

Our strategy is to show how our estimation changes once a given fraction of the initial years of data is omitted. In particular, we choose to eliminate the data below the 25th percentile of Internet users in every country.

We find, as in CHR, that some countries lose so many observations that their “restricted” estimation takes longer to converge or does so very inaccurately.¹⁷ However, unlike in their case, this is not the norm. Most of the times the “unrestricted” estimation (the one that contains all years of available data) takes longer to converge. This seems reasonable since the computer routine has to work with a considerably larger amount of information when the sample is unrestricted. We believe the usual failure to converge in CHR once one includes the intensive margin is due to the fact that the shape of the curve is fundamentally changed due to this inclusion. In our case though, the shape of the curve is truncated, but not drastically altered. For the same reason we never find countries (or groups of countries) with a negative estimate of δ_2 .

However, we are able to show that the prediction of the period at which Internet diffusion reaches 1% significantly changes when one omits the initial years of data: there is a very clear tendency to underestimate the number of periods necessary to reach this level. The intuition for this finding is clear. By losing the introductory phase of Internet diffusion, the estimated S-shape tends to display an artificially large slope, which evidently implies that the 1% level of adoption is reached much earlier than what the actual data shows. Table 4 shows this in more detail. The table shows the estimates of the “1% date” for each country using the unrestricted and the restricted sample (columns 2 and 3, respectively), their difference (column 4), and the actual date at which the country has reached at least 1% of users (column 5).¹⁸ The first thing to notice is that, perhaps not surprisingly, the difference between the two estimates is virtually always positive.¹⁹ As discussed above, this indicates that, if one considers all the available data, the resulting S-shape has a lower slope and so the 1% level is predicted to be reached later in time. We then calculate the bias of these estimates by subtracting the estimated data from the actual one.²⁰ In the unrestricted sample (column 6) there is a tendency to underestimate the 1%-date, leading to “too pessimistic” predictions. The median bias is -2.84 years. The restricted sample (column 7) has a median bias of 2.51 years, leading to “too optimistic” predictions of when a country will reach the 1% level. While the two biases are similar in magnitude, these results show that including or excluding the initial years has important implications for the way one should interpret the estimates. In particular, the widespread omission of the initial years leads to predictions that are too generous. Figures 7-12 in the Appendix illustrates this point for three developing countries. It is apparent that, by omitting the initial years of data, the slopes of the S-curves are much steeper in the “initial phase” and hence Internet is predicted to spread much faster than it actually does.

¹⁷ In some cases the non-linear-least-squares estimator fails to produce standard errors for some or all of the parameters and the R^2 's are missing too.

¹⁸ In this exercise we find that 62 countries never reach the 1% diffusion level and are therefore omitted from the calculations.

¹⁹ Only in two out of the 143 countries the difference is negative.

²⁰ Similar results are obtained when we group countries in four different groups or when we use a different percentile to truncate the data. These results are available from the authors upon request.

5. The Determinants of Internet Adoption

To identify the main determinants of Internet adoption, this paper follows Estache et al. (2002) and Caselli and Coleman (2001) and estimates the following reduced form model: p

$$\ln IU_{it} = \alpha + \beta_1 \ln Y_{it} + \beta_2 \ln P_{it} + \beta_3 \ln L_{it} + \beta_4 \ln C_{it} + \eta_i + \varepsilon_{it} \quad (2)$$

where IU_{it} represents the number of Internet users per capita in country i and period t , Y_{it} is the real GDP per capita, P_{it} represents the real cost of a local phone call, and L_{it} and C_{it} are the number of phone lines and computers per capita, respectively. The last two variables are intended to capture the level of telecommunication infrastructure and the availability of infrastructure facilities needed to access the Internet of a country at a given point in time, respectively. Finally, η_i is a country fixed effect and ε_{it} is a standard error term.

One would expect β_1 to be positive since a higher income level is naturally associated with better technological infrastructure and a higher purchasing power of goods and services associated with the Internet. The coefficient of the cost of a local phone call (β_2) is expected to be negative and its magnitude would depend on the price elasticity of the demand for Internet usage. Both the effects of the number of phone lines (β_3) and the number of computers (β_4) should be positive, since they are necessary inputs to use the Internet.²¹ Moreover, one would expect a strong positive complementarity between computer and Internet use.

Some studies have added additional explanatory variables to equation (2), including a country's level of human capital -proxied by the number of years of education-, its degree of trade openness, the percentage of urban population, and the extent of property rights protection.²² These variables are not incorporated here since the data suggests that, in most cases, they display very little variation in the time interval covered in this paper. The inclusion of a country fixed effect in the estimation should be able to capture most of the cross-country differences explained by these variables.²³

One variable that deserves special mention is the quality of institutions. One of the most established facts in the comparative telecommunications literature is that institutions are important determinants of the diffusion of telecommunications technologies.²⁴ In results not reported here we demonstrate that the same is true in our sample. When one

²¹ A possible criticism to the specification of the model is the inclusion of the cost of local phone calls given the increase in alternative technologies to access the Internet (for instance broadband access). However, up to 2004 the participation of alternative technologies was very low, especially in low income countries.

²² See Chinn and Fairlie (2007), Wallsten (2005), Kiiski and Pohjola (2002), and Chong and Micco (2003).

²³ Interestingly, the coefficients associated to these variables have often been found non significant or controversial in Internet adoption models. This is the case of education in Kiiski and Pohjola (2002) and Chinn and Fairlie (2007), and openness and property rights protection in Caselli and Coleman (2001).

²⁴ Levy and Spiller (1996) and Henisz and Zelner (2001) provide theoretical reasons why this should be the case. Empirically, Andonova and Díaz-Serrano (2009), Andonova (2006), and Guillén and Suárez (2005) show a positive relationship between a country's institutional framework and its diffusion of different technologies, Internet in particular.

estimates (2) *in growth rates* the quality of institutions (measured by the lag of the *level of constraints on executive discretion*) have a significant positive effect on the growth rate of the number of per capita Internet users and hosts.²⁵ However, the effect of institutions becomes insignificant when one estimates the equation *in levels*. Our interpretation of this result is that the level of Internet usage in a given country is better explained by country fixed effects or by its level of infrastructure (number of computers and telephone lines per capita), as the estimates below suggest.

The results of estimating (2) using OLS are presented in Table 5.²⁶ All the coefficients are highly significant and have the expected signs. The levels of income and telecommunication infrastructure (lines and computers per capita) have significant positive effects on Internet adoption and are similar in magnitude. A ten percent increase in per capita GDP is associated with a 21.5 percent increase in the number of Internet users per capita. Similarly, increases of 10 percent in the number of lines and computers per capita drive up the number of internet users per capita by 21.3 and 23.2 percent respectively. On the contrary, the higher the cost of a local call, the lower is the percentage of population that uses Internet, although this coefficient is significantly smaller.

5.1. The diffusion model

Specification (2) has often been criticized because it does not account for the process of diffusion in Internet adoption. Following Estache et al. (2002), our next regression includes the lag of the number of Internet users (in logs) as a right-hand-side variable:

$$\ln IU_{it} = \alpha_i + \beta_1 \ln Y_{it} + \beta_2 \ln P_{it} + \beta_3 \ln L_{it} + \beta_4 \ln C_{it} + \beta_5 \ln IU_{it-1} + \eta_i + \varepsilon_{it} \quad (3)$$

Equation (3) is the reduced form of a Gompertz model of technology diffusion with a constant speed of adjustment. In such a model, the change in the number of users (from the current period to the next one) is expressed as a fraction- the speed of adjustment- of the gap between the number of users in equilibrium and the number of current users. Hence, the number of new users who adopt a certain good or service in a given period depends on both the number of existing and potential users, which is itself determined by demand-side variables (income, costs, etc.), and other factors affecting the demand or supply conditions or the technological infrastructure in each country i (see Stoneman, 1983; Kiiski and Pohjola, 2002; and Estache et al., 2002 for more details).

²⁵ In our sample institutions are a significant explanatory variable when one uses system GMM, but not when one uses standard GMM techniques. This is consistent with Andonova and Díaz-Serrano (2009), who claim that the former technique is more adequate in this framework.

²⁶ In all the OLS regressions that follow we use robust standard errors to account for potential heteroskedasticity of the unbalanced panel. We also add year effects to control for time-varying macroeconomic shocks. The inclusion of these regressors do not change any result significantly so we do not show their associated coefficients here in order to save space. The inclusion of continent effects (as in Estache et al. 2002) is also irrelevant for our findings.

The coefficient β_5 measures the importance of network externalities in the diffusion of Internet. In the absence of diffusion, β_5 should not be significant. When β_5 is positive and smaller than 1, the diffusion model is accepted: the number of users in the current period helps explain the number of Internet users the subsequent year.

As it is well known, including the lagged dependent variable in the right hand side of equation (3) creates an endogeneity problem. By construction, the regressor $\ln IU_{it-1}$ is correlated with the error term ε_{is} for $s < t$, so the standard fixed effects estimation is not consistent (see Wooldridge, 2002). To correct this problem, we use the instrumental variables (IV) procedure proposed by Arellano and Bond (1991) where the lagged values of the dependent variable are used as instruments. Table 6 presents the results of the OLS and IV estimations (specifications (1) and (2) respectively).

First of all, the diffusion coefficient (the lag of the dependent variable) is positive, smaller than one, and highly significant with a similar magnitude in both regressions, indicating that the diffusion model cannot be rejected. A ten percent increase in the number of Internet users per capita in the current year leads to an increase of about 5 to 6.8 percent in the number of Internet users the next year. In the OLS regression (column [1]) income and the number of computers per capita have a positive effect on diffusion. It is interesting to note that the size of these estimates becomes much larger once we take into account the endogeneity problems and use an instrumental variables procedure (column [2]). Another difference between the two specifications is that the number of telephone lines per capita is statistically significant and has the expected sign only when one uses instruments. Finally, it is worth mentioning that, if one includes a year-effect to capture macroeconomic shocks, the coefficient on the real GDP per capita turns insignificant. Interestingly, this does not happen to the other variables that have clearly increased in the time period studied, namely the number of telephone lines and computers per capita. This suggests that we should interpret the positive coefficient on income with caution, since it seems to be picking -at least partly- the time trend.

The importance of the lagged dependent variable is in line with the results of several papers including Goolsbee and Klenow (2002) and Kiiski and Pohjola (2002). However, it contradicts the results of Estache et al. (2002) where the diffusion hypothesis is rejected. There are several reasons why our results differ from theirs. The first one is that the sample used here is considerably larger. In particular, there are 74 countries which are included in our sample but not in theirs. Moreover, for many countries they do not have access to data for the initial years. Additionally, our time span is longer- we include the 2000-2003 period, whereas their sample ends in 1999. Finally, from an econometric point of view, we use the Arellano-Bond GMM estimator, which is known to be more efficient than the Anderson-Hsiao IV estimator that they use.

The main new result of this section is that network externalities drive Internet diffusion and are indeed one of its most important determinants. The fact that in both the OLS and the IV specifications the lagged dependent variable is one of the significant explanatory variables, gives strong support to this hypothesis.

Tables 5 and 6 provided results on the determinants of Internet diffusion at the world level. However, Section 4 presented conclusive evidence that the process of Internet diffusion is far from being uniform across countries. Thus, the question that needs to be answered next is whether the variables that explain this process differ between low and high-income countries. Only by identifying differences in the explanatory power of factors that influence the diffusion process in the two groups, will it be possible to adopt policies aimed at reducing the digital divide.

5.2. Does the magnitude of Internet diffusion explanatory variables vary with the level of income?

The benchmark model showed that the level of income is positively and highly correlated with internet adoption. However, this result does not provide information about the existent varying processes of Internet adoption across countries with different levels of income. To assess whether there are significant differences in the explanatory power of the variables that are more likely to account for the Internet diffusion process, we now estimate equation (3) dividing the sample into two groups: low and high-income countries.

Table 7 displays the estimation results for the two different groups of countries. The table shows that the number of users in the previous period is significant for both groups of countries.²⁷ This result confirms that network effects are one of the main drivers of Internet diffusion.

The estimates indicate that network effects are larger in high-income countries. A ten percent increase in the number of Internet users in high-income countries in one year leads to an increase of almost 6 percent in the number of users the following year, which is 1.5 percent more than in low-income countries. One possible explanation for this finding may be related to the way in which developed economies are structured. The relative importance of services -usually high intensive in Internet usage- in these economies, is higher than in less developed ones. Accordingly, high-income countries may have more Internet-demanding and network-demanding jobs, hence enhancing the importance of network effects.

It is also interesting to note that, while income level- measured by GDP per capita- is a very important determinant of Internet adoption for low-income countries, it is not significant for high-income countries. In other words, when we consider countries that already have a high-income level, changes in GDP per capita do not have a significant impact on the level of Internet adoption. This result is similar to the one in Beilock and Dimitrova (2003), who show that income differences have a larger effect in the use of Internet at lower income levels.

²⁷ For the remaining of the paper we rely on the IV estimation only.

In addition to studying the determinants of Internet adoption dividing countries by income level, it is important to understand whether the differential effect at different levels of income is constant through time. In order to do so, we divide the sample in two sub-periods: 1985-1998 and 1999-2004. The results are presented in Table 8.

First, the model of diffusion is accepted in both sub-periods and for both income categories. Moreover, the table also shows that the importance of network effects has increased over time for the two groups. Between the years 1985 and 1998, an increase of ten percent in the number of Internet users per capita in low-income countries in one year produced a 3.2 percent increase in the number of users the next year. During the 1999 to 2004 period the boost was 4.8 percent. A similar result holds for high-income countries--the diffusion coefficient increases from 0.51 for the period 1985-1998 to 0.56 for the period 1999-2004. Worldwide the increase is from 0.42 to 0.48. Interestingly, these estimations are consistent with the S-shape curves estimated for each income category in Section 4. The value of the lagged number of internet users captures the average contribution of network effects to the speed of adoption and thus shows that the speed of diffusion increases between the two periods considered in this exercise. This indicates that one is identifying the first phase of the Internet adoption process. These results also show how low-income countries are following a similar adoption path than the one observed for high-income countries; the diffusion coefficient for the 1999-2004 period for low-income countries is very close in magnitude to the one obtained for the period 1985-1998 for the group of developed countries (0.48 vs. 0.51).

The cutoff dates used in Table 8 to divide periods are clearly arbitrary. Indeed, one could easily argue that they should differ between the two groups of countries, reflecting the fact that they are at different stages of the diffusion process. In results not reported here we show that the same qualitative results hold if one uses different splitting years (1995, 2000) for low and high-income countries.

We conclude from this section that the diffusion model is accepted in virtually all cases, regardless of the cutoff used or the income group chosen.²⁸ When one chooses the cutoff of 1995 it is still the case that the importance of network effects increases over time. However, this is not the case when the dividing year is set to be the year 2000. One interpretation of this result is that these effects have tended to vanish by the end of the studied period, perhaps because of the fading impact of the IT revolution in the nineties and the economic crisis after the burst of the dot-com bubble.

5.3. Impact of the level of competition on Internet diffusion

As mentioned in the introduction, there is plenty of evidence that the adoption of information and communication technologies in general and Internet in particular significantly contribute to economic growth and development (for a summary of this literature see Grace, Kenny, and Zhen-Wei Qiang, 2004 and Zhen-Wei Qiang, Pitt, and

²⁸ The coefficient on the lag is insignificant when one chooses the cut-off 1995 for low income countries. The most likely reason is that the number of observations drastically drops to 13.

Ayers, 2004). Thus, a key policy question centers on what low-income countries can do to accelerate Internet diffusion. One potentially positive policy is to liberalize telecommunication markets, with the hope that more competition drives prices down and facilitates the diffusion of Internet. To assess the validity of this argument, we analyze the impact of the number of Internet Service Providers (ISP) operating in a country on the speed of diffusion. The sample is decomposed into two groups: countries with a low level of competition—with a number of ISPs less or equal than 4, and countries with a high level of competition—with a number of ISPs larger than 4.²⁹ Then, we estimate equations (2) and (3) for each group, also distinguishing between low and high-income countries. Provided the lag variable of internet users is, *ceteris paribus*, a proxy for the average speed of diffusion, we are interested in determining if a more competitive ISP market structure leads to a higher estimate of the lag internet users variable.

The results are displayed in Table 9. First, once again one cannot reject the model of diffusion. Network effects are a significant determinant of Internet adoption for all income categories and degrees of competition. Second, competition has a larger impact on diffusion in high-income countries. In low-income countries increasing the number of ISPs from 4 or less to 5 or more increases the diffusion coefficient from 0.41 to 0.55, while for high-income countries the jump is from 0.38 to 0.72. Supporting this finding, specifications [3] and [6] show that, when one uses the interaction between high competition (proxied by the dummy variable *ISP_5*, which takes a value of one if there are five or more ISP providers) and lagged Internet users, a high degree of competition significantly increases the average speed of diffusion in high-income countries while the effect is insignificant in low-income countries. This approach seems to be more informative than the one used in Estache et al. (2002) and Wallsten (2005), who simply added a dummy variable on the right hand side of their regression to account for the existence of competition and/or regulation. In fact, this latter work only allows the intercept to adjust for the conditions on the telecommunication market while our approach allows all coefficients to adjust for the degree of competition.

6. Conclusions

This paper provides a detailed empirical study of the process of adoption and diffusion of Internet in a large sample of countries for the period 1990-2004. In the first part of the paper it is shown that Internet adoption follows an S-shape pattern, but that this pattern is different for low and high-income countries. Internet diffusion in low-income countries started with a lag but is now enjoying a faster adoption speed. However, our estimates suggest that the digital divide, in absolute terms, is still impressive and it might take low-income countries several decades to eliminate it.

²⁹ The median of the number of ISPs for the world is 5. We adopted this threshold to define countries with low and high competition. In unreported results we test whether changing the definition this cutoff value has any effect on the results. Changing the threshold to 4 (the median number of ISPs for low income countries) or to 17 (the median number of ISPs for high income ones) does not have a significant qualitative impact on our estimates.

A major feature that distinguishes our work from previous papers in the literature on diffusion of new technologies is that our data set covers the first years in which the innovation (i.e. Internet) was adopted. This allows us to provide more realistic estimations on the actual diffusion process.

The second part of the paper explores the main determinants of Internet diffusion and finds that national network effects -measured as the lag of the number of users per capita in a given country- are a crucial determinant of Internet adoption. Our results show that this network effect is very robust and stronger in high-income countries, implying that low and high-income countries clearly were in different phases of the process of Internet adoption during the period 1990-2004. The paper also explores potential differences in this process across time and finds that low-income countries are following the path of high-income countries. A positive reading of these results is that low-income countries are, albeit at a very slow pace, converging to the levels of Internet usage present in high-income countries. Finally, our results show that increasing the number of Internet providers has a positive effect on the spread of Internet. An important policy implication of this findings is that, in order to help close the digital divide, policymakers may want to implement policies to liberalize the telecommunications markets.³⁰ However, further analysis is needed to design a proper strategy to do so.

³⁰ As argued in Estache et al. (2002), such policies have been recently implemented in several Latin American countries, like Chile, Argentina, and Mexico.

Western Samoa	20,62	11,94	8,69	12	-8,62	0,06
Yugoslavia	10,79	3,81	6,99	11	0,21	7,19

The difference is calculated by subtracting restricted estimated date from the unrestricted one. The bias is defined as the difference between the actual date and the predicted one.

Table 5: Benchmark Model

log real GDP per capita	2.15*** (0.51)
log real cost	-0.2*** (0.08)
log lines per capita	2.13*** (0.27)
log computers per capita	2.32*** (0.13)
constant	-11.44*** (4.7)
Method of estimation	OLS
Number of observations	949
R ²	0.91

*The dependent variable is the log number of Internet users per capita. Robust standard errors in parentheses. *, **, *** denote significance at the 10%, 5%, and 1% level, respectively.*

Table 6: OLS and Instrumental Variable Estimations of the Diffusion Model

	[1]	[2]
log real GDP per capita	0.866*** (0.02)	2.03*** (0.42)
log real cost	0.01 (0.02)	0.04 (0.05)
log lines per capita	0.01 (0.14)	0.3* (0.16)
log computers per capita	0.52*** (0.08)	0.995*** (0.1)
lag Internet users	0.676*** (0.02)	0.496*** (0.02)
constant	-6.69*** (2.43)	-15.33*** (3.86)
Method of estimation	OLS	IV
Number of observations	881	759
R ²	0.97	-

*The dependent variable is the log number of Internet users per capita. Robust standard errors in parentheses in specification [1] and standard errors in parenthesis in specification [2]. *, **, and *** denote significance at the 10%, 5%, and 1% level, respectively.*

Table 7: Impact of Income Categories on the Diffusion Process

	Low-Income [1]	High-Income [2]
log real GDP per capita	2.69*** (0.88)	0.6 (0.42)
log real cost	0.13* (0.07)	-0.14** (0.06)
log lines per capita	0.82*** (0.29)	-0.04 (0.21)
log computers per capita	0.89*** (0.14)	0.998*** (0.13)
lag Internet users	0.44*** (0.03)	0.59*** (0.03)
constant	-16.17** (7.3)	-5.44 (4.26)
Method of estimation	IV	IV
Number of observations	356	399

*The dependent variable is the log number of Internet users per capita. Standard errors in parenthesis. *, **, and *** denote significance at the 10%, 5%, and 1% level, respectively*

Table 8: World Diffusion and Diffusion by Income Category: 1985-1998 and 1999-2004

	Low-Income		High-Income		World	
	1985-1998	1999-2004	1985-1998	1999-2004	1985-1998	1999-2004

World Bank income classification³¹

Low-income countries: Afghanistan, Bangladesh, Benin, Bhutan, Burkina Faso, Burundi, Cambodia, Central African Republic, Chad, Comoros, Congo (Dem. Rep), Cote d'Ivoire, Eritrea, Ethiopia, Gambia, Ghana, Guinea, Guinea-Bissau, Haiti, India, Kenya, Korea (Dem Rep.), Kyrgyz Republic, Lao PDR, Liberia, Madagascar, Malawi, Mali, Mauritania, Mongolia, Mozambique, Myanmar, Nepal, Niger, Nigeria, Pakistan, Papua New Guinea, Rwanda, Sao Tome and Principe, Senegal, Sierra Leone, Solomon Islands, Somalia, Sudan, Tajikistan, Tanzania, Togo, Uganda, Uzbekistan, Vietnam, Yemen, Zambia, Zimbabwe.

Lower-middle-income countries: Albania, Algeria, Angola, Armenia, Azerbaijan, Belarus, Bolivia, Bosnia and Herzegovina, Brazil, Bulgaria, Cameroon, Cape Verde, China, Colombia, Congo (Rep), Cuba, Djibouti, Dominican Republic, Ecuador, Egypt, El Salvador, Fiji, Georgia, Guatemala, Guyana, Honduras, Indonesia, Iran, Iraq, Jamaica, Jordan, Kazakhstan, Kiribati, Lesotho, Macedonia, Maldives, Marshall Islands, Micronesia, Moldova, Morocco, Namibia, Nicaragua, Paraguay, Peru, Philippines, Sri Lanka, Suriname, Swaziland, Syrian Arab Republic, Thailand, Tonga, Tunisia, Turkmenistan, Ukraine, Vanuatu, West Bank and Gaza.

Upper-middle-income countries: American Samoa, Argentina, Barbados, Belize, Botswana, Chile, Costa Rica, Croatia, Czech Republic, Dominica, Equatorial Guinea, Estonia, Gabon, Grenada, Hungary, Latvia, Lebanon, Libya, Lithuania, Malaysia, Mauritius, Mayotte, Mexico, Northern Mariana Islands, Oman, Palau, Panama, Poland, Romania, Russian Federation, Seychelles, Slovak Republic, South Africa, St. Vincent and the Grenadines, Trinidad and Tobago, Turkey, Uruguay, Venezuela.

High-income countries: Andorra, Antigua and Barbuda, Aruba, Australia, Austria, Bahamas, Bahrain, Belgium, Bermuda, Brunei Darussalam, Canada, Cayman Islands, Cyprus, Denmark, Finland, France, French Polynesia, Germany, Greece, Greenland, Guam, Hong Kong (China), Iceland, Ireland, Israel, Italy, Japan, Korea (Rep), Kuwait, Liechtenstein, Luxembourg, Macao (China), Malta, Monaco, Netherlands, Netherlands Antilles, New Caledonia, New Zealand, Norway, Portugal, Puerto Rico, Qatar, San Marino, Saudi Arabia, Singapore, Slovenia, Spain, Sweden, Switzerland, United Arab Emirates, United Kingdom, United States, Virgin Islands (U.S.).
