

# A Finite Mixture Analysis of Beauty-Contest Data Using Generalized Beta Distributions \*

May 5, 2010

---

\*We thank the editor and two referees for insightful comments that helped improve the manuscript. Thanks are also due to the Spanish Ministerio de Educación y Ciencia for financial help under research projects SEJ2005-03891/ECON (AB-D), SEJ2006-135 and SEJ2007-64340, and by the Barcelona GSE research network, Generalitat de Catalunya.

## Abstract

This paper introduces a mixture model based on the beta distribution, without pre-established means and variances, to analyze a large set of Beauty-Contest data obtained from diverse groups of experiments (Bosch-Domènech et al. 2002). This model gives a better fit of the experimental data, and more precision to the hypothesis that a large proportion of individuals follow a common pattern of reasoning, described as iterated best reply (degenerate), than mixture models based on the normal distribution. The analysis shows that the means of the distributions across the groups of experiments are pretty stable, while the proportions of choices at different levels of reasoning vary across groups.

*Keywords:* Beauty-Contest experiments, decision theory, reasoning hierarchy, finite mixture distribution, beta distribution, EM algorithm.

# 1 Introduction

The paper applies a specific finite mixture model to identify patterns of belief formation and choice. The heterogeneity of subjects' decisions and beliefs favors clustering procedures to separate the observed outcomes, and mixture models are a convenient statistical tool for this type of investigation. Specifically, we analyze a data set collected from Beauty-Contest (BC) experiments by A. Bosch-Domènech, J.G. Montalvo, R. Nagel and A. Satorra (2002) using a finite mixture of generalized beta distributions. The data in Bosch-Domènech et. al. (2002) were obtained from seventeen different experiments. Often, experiments in economics draw their subjects from a student population and are typically run in laboratories. But the seventeen experiments whose data we are analyzing were performed in very diverse environments, involving different subject pools, sample sizes, payoffs, and settings: some data were collected in a laboratory and thus with high control, others in classrooms with undergraduate students, or in conferences, by e-mail and, most numerous, through newsgroups or among newspaper readers, a new source of data collection, enriching the growing area of field experiments.<sup>1</sup> We are, therefore, dealing with a rich and heterogeneous data set.

In a basic BC game, each player simultaneously chooses a number in an interval. The winner is the person whose number is closest to  $p$  times the mean of all chosen numbers, where  $p$  is a predetermined and known number.<sup>2</sup> The BC game facilitates an evaluation of the ‘agents reasoning’ and their beliefs on the other players’ strategies. A nice feature of the game is that players are not guided by social norms, like fairness or altruism, which are often invoked when payoff-maximizing solutions cannot describe the observed behavior. The game is thus a game of pure competition. Another advantage of the game is that the high number of players that can participate in it makes collusion or cooperation difficult, therefore

---

<sup>2</sup>For surveys of BC experiments see Camerer (2003), Nagel (1998, 2004).

simplifying the interpretation of the decisions. Rational-expectations equilibrium “solves” the game by assuming common knowledge. That solution implies that all agents choose the lowest possible number, after applying the process of ‘iterated elimination of weakly dominated strategies (IEDS)’ starting from 100. But as can be seen from Figure 1, this is not what necessarily happens in the seventeen experiments reported here, where  $p = 2/3$  and the interval, in sixteen out of the seventeen experiments, is  $[0, 100]$ ; in one experiment the choice set is  $[1, 100]$ .<sup>3</sup>

————— Figure 1 about here —————

Alternatively to IEDS, a reasoning process that appears to describe better the observed behavior is the so-called Iterated Best Reply with degenerate beliefs (i.e., the belief that the choices of all others are at one precise value), denoted by IBRd, which classifies choices according to the depth, or number of levels, of reasoning.<sup>4</sup> Specifically, IBRd postulates that a Level-0 player chooses randomly in the given interval  $[0, 100]$ , with the mean being 50. At other levels, it is assumed that every player believes that she is exactly one level of reasoning deeper than the rest of players. Therefore, a Level-1 player gives best reply to the belief that everybody else is a Level-0 player and thus chooses  $50p$ . A Level-2 player chooses  $50p^2$ , a Level- $k$  player chooses  $50p^k$ , and so on. Finally, a player who takes infinite steps of reasoning, and believes that all players take infinite steps, chooses zero, the rational-expectations equilibrium. The hypothesis that players follow the reasoning process described as IBRd, together with  $p = 2/3$ , and an interval  $[0, 100]$ , predicts that choices (in addition to random and haphazard choices, corresponding to Level-0 players) will be on the values

---

<sup>3</sup>In the experiments with interval  $[0, 100]$ ,  $p < 1$  and the number of players greater than two, the only solution surviving the process of iterated elimination of weakly dominated strategies is to pick 0. Obviously, when the interval is  $[1, 100]$ , the rational solution is at 1.

<sup>4</sup>See, e.g., Nagel (1995), Stahl (1996) or Bosch-Domènech et al. (2002).

33.33, 22.22, 14.81, 9.88, ... and, in the limit, 0.<sup>5</sup>

Starting with Nagel (1995), the analysis of the data generated by BC experiments uses diverse statistical procedures. In their seminal papers, Stahl and Wilson (1994, 1995) had the insight to connect the theoretical model of iterated levels of reasoning with the statistical method of mixtures, and based their analysis of a data set from  $3 \times 3$  normal form games on this insight.<sup>6</sup> Later on, Stahl (1996) used the mixture model on data from Nagel's (1995) repeated BC games. In his paper he was interested in finding a learning rule and, to this end, he fitted a mixture model with normally distributed stochastic errors with means and variances highly restricted, so that the dynamics of the individual "learning" processes could be assessed. Specifically, he assumed that, at period 1, the individual choices in each Level- $k$  were distributed with means specified at  $50p^k$ , and all variances followed a decreasing rule. Stahl's (1996) model included a uniform distribution to take care of the haphazard choices. Since his data came from experiments with students who seldom chose the equilibrium, he did not have to account for an important accumulation of choices at or near zero, and could postulate a model with a small number of iterations that did not include a final iteration to the equilibrium. In fact, the statistical procedure allowed him to choose between models with three or four levels of iteration, but was not designed to account for equilibrium (Level- $\infty$ ) choices.

Our data, instead, come from a number of *one-period* experiments including a diversity of people in different settings, totaling more than 8,000 observations, which we organize in six groups, according to the type of experiment that provided them, namely Lab, Classroom,

---

<sup>5</sup>Because the process of iterated reasoning is similar to the one mentioned by J. M. Keynes in the context of a beauty-contest thought experiment (Keynes, 1936, p.155), the class of  $p$ -mean-games and its variations have been called 'Beauty Contest games'.

<sup>6</sup>Mixture models have a long history in statistics, and a comprehensive description of the statistical theory of finite mixture modeling can be found in Titterton et al. (1992) and McLachlan and Peel (2000).

Take-home, Theorists, Internet, and Newspaper experiments (see Table 1).<sup>7</sup> As a result, we had data all over the range of possible choices and, in particular, at and around zero. With the same data set, in Nagel, Bosch-Domènech, Satorra and García-Montalvo (1999) (see also footnotes 26 and 28 in Bosch-Domènech et al. (2002)) we fitted a mixture model similar to Stahl (1996) to the one-period data, with the *difference* that we did not constrain the means and variances of the composing distributions and, in addition, we included the Level- $\infty$  (equilibrium) as a component of the model. This Level- $\infty$  was a normal distribution truncated at zero. Building on this previous analysis of ours, we propose a model that, in addition to contemplating the Level- $\infty$  and letting the means and variances free, benefits from the higher degree of flexibility provided by assuming that the stochastic errors follow a beta distribution. Contrary to the normal model, the beta distribution does not impose symmetry and adds the elegance bonus of using a single family of distributions in the mixture, as the uniform distribution is a specific beta distribution. Equally important, the beta distribution allows a more flexible representation of the Level- $\infty$  component than the truncated normal distribution.<sup>8</sup>

In the meantime, other papers have followed in the approach of Stahl and Wilson (1994, 1995), fitting data from a variety of experimental games, notably Costa-Gomes, Crawford, and Broseta (2001), Camerer, Ho, and Chong (2004), Costa-Gomes and Crawford (2006), and Crawford and Iriberri (2007a). Also Ho, Weigelt and Camerer (1998) specify a model in which the mean and variance of Level- $k$  choices are functions of the mean and variance of choices at the previous level, so that the only parameters of the model are the mean and variance of Level-0 choices. This highly restricted model is then estimated by maximum

---

<sup>7</sup>For details of the six groups see Bosch-Domènech et al. (2002).

<sup>8</sup>In economics the use of the beta distribution is not new. McKelvey and Palfrey (1992), for instance, use it in a different context, assuming that the heterogeneous beliefs of the participants in a centipede game are independently drawn from a beta distribution. In econometric analysis of labor and income distribution data, the beta distribution has a long tradition, see e.g. Heckman and Willis (1977) or McDonald and Xu (1995) and, more recently, Bognanno (2001) or Dastrup et al. (2007).

likelihood. In addition, Stahl (1998) estimated a levels-of-reasoning model assuming a non-degenerate distribution of beliefs about other players choices. In a similar vein, Camerer, Ho and Chong (2004) assumed that subjects believe that no other player uses as many levels of reasoning as themselves and that players guess the relative proportion of other players at the lower levels of reasoning, arguing that the Poisson distribution is a reasonable parametric distribution of other players reasoning levels. While this model fits well some samples of data from different games, it does not account for stochastic responses, as in all other models described above. Recently, Harrison and Rutström (2009) use a mixture model to propose a statistical reconciliation between two dominant theories of choice under risk, EUT and Prospect Theory. Their paper offers an insightful alternative to the debate over the competing models by assuming that the data analyzed are generated by a mixture of decision rules associated to both theories.

From the computational perspective, all of the above applications use general-purpose optimization algorithms, such as the simplex method of Nelder and Mead (1965).<sup>9</sup> But when handling finite mixture models, such algorithms require to carefully monitor the starting values to ensure proper convergence. Instead, in the present paper we use the Expectation Maximization (EM) algorithm (Dempster, Laird, and Rubin, 1977) that takes full advantage of the form of the likelihood function. Moreover, as a by-product of the EM algorithm, a Bayes rule classification method for assigning cases to the different levels of the reasoning process is made available.

---

<sup>9</sup>We thank a referee for pointing out an older literature in statistics showing that the beta distribution can be well approximated by the logistic transformation of the normal, a useful fact since in many settings there exists code that works for the normal distribution, thus with existing software a simple non-linear transformation could be used to estimate the beta. See Lesaffre, Rizopoulos and Tsonaka (2007) for an updated review of the logistic transformation of the normal, and Andersen, Harrison, Hole and Rutström (2009) for novel methods for analyzing non-linear mixed logit models.

## 2 Data description

The histogram for the whole distribution, when all the groups are pooled together (see Figure 1), shows that the peaks closely correspond to the numbers chosen by individuals who would have reasoned according to the IBRD hypothesis, at levels one, two, perhaps three, and infinity. In addition, inspecting the choices for each group, as depicted in Figure 3 of Bosch-Domènech et. al. (2002), we see substantial variation across groups. The first group, Lab-experiments with undergraduates, is clearly distinguished from the rest, because the Nash equilibrium is rarely selected. Yet, when subjects have some training in game theory, the proportion of subjects choosing the equilibrium increases. The highest frequencies are attained when experimenting with theorists, in which case, the greater confidence that others will reach similar conclusions may be reinforcing the effect of training. In Newspapers, the frequency of equilibrium choices falls somewhere in between, as should be expected from the heterogeneous level of training of their readers.

## 3 Finite mixture model and estimation procedure

The basic problem in fitting a statistical model to the BC data is the existence of unobserved heterogeneity (the different levels of reasoning), in addition to the multiple-group structure. This section develops the interpretation of the BC data as a mixture of beta distributions and provides the statistical strategy to estimate such a model.

To begin, the components of the mixture are anchored at the different levels of reasoning: 33.33 for Level-1, 22.22 for Level-2, 14.81 for Level-3,  $\dots$ , 0 for Level- $\infty$ . In addition, choices at Level-0 are captured by one specific beta distribution: the uniform distribution at (0, 100).

### 3.1 A finite mixture model based on beta distributions

A variable  $X$  is said to belong to the family of beta distributions if its probability density function (pdf) is

$$f_X(x) = \frac{1}{B(\alpha, \beta)} x^{\alpha-1} (1-x)^{\beta-1} I_{(0,1)},$$

$\alpha > 0$  and  $\beta > 0$ ; here,  $B(\alpha, \beta) = \int_0^1 x^{\alpha-1} (1-x)^{\beta-1} dx$  is the *beta function*, and  $I_{(0,1)}$  is an indicator function. We say that  $X$  is a standard beta distribution,  $X \sim \text{Beta}(\alpha, \beta)$ . In this paper we use the generalized beta distribution  $Y \sim \text{Beta}(\alpha, \beta, a, h)$  arising from the linear transformation  $Y = a + hX$ ,  $X \sim \text{Beta}(\alpha, \beta)$  and  $h > 0$ , where the support of variables  $X$  and  $Y$  are  $(0, 1)$  and  $(a, a + h)$  respectively. The shape of the distribution is dictated by the values of  $\alpha$  and  $\beta$ . When both  $\alpha$  and  $\beta$  are  $> 1$ , the distribution is unimodal; when  $\alpha < 1$  (or  $\beta < 1$ ) then  $f_Y(y) \rightarrow \infty$  when  $y \rightarrow a$  (or when  $y \rightarrow a + h$ ). When both  $\alpha$  and  $\beta$  are  $< 1$ , the density function is U shaped and tends to  $\infty$  both when  $y \rightarrow a$  and when  $y \rightarrow a + h$ . Since the distribution has bounded support, all its moments exist; the mean and variance of  $\text{B}(\alpha, \beta, a, h)$  are  $\mu = a + \frac{h\alpha}{\alpha+\beta}$  and  $\sigma^2 = \frac{h^2\alpha(\alpha+1)}{(\alpha+\beta)^2(\alpha+\beta+1)}$ , respectively.

We denote the multiple-group data in Table 1 by  $\{y_{ig}; i = 1, \dots, n_g\}_{g=1}^6$ , where  $y_{ig}$  is the number chosen by individual  $i$  in the group  $g$  of experiments, and  $n_g$  is the sample size of group  $g$ .

Associated to a model with  $L$  levels of reasoning, we consider the following  $L$ -component mixture probability density function for  $y$ :

$$f(y, \vartheta) = \pi_0 f_0(y) + \pi_1 f_1(y, \theta_1) + \dots + \pi_K f_K(y, \theta_K) + \pi_\infty f_\infty(y, \theta_\infty),$$

where  $K = L - 2$ .

- $f_0$  is the uniform distribution in 0 to 100; that is,  $f_0 \sim \text{Beta}(1, 1, 0, 100)$ , associated to

the Level-0 of reasoning.

- $f_k \sim B(\alpha_k, \beta_k, a_k, h)$ ,  $k = 1, \dots, K$ , where  $a_k = ((\frac{2}{3})^k H) - h/2$  are fixed values determined by the model specification, and  $\alpha_k$  and  $\beta_k$  are free parameters, to be estimated, that determine the shape of the distribution. Note that  $f_k$  has support  $(a_k, a_k + h)$ , so  $a_k + h/2$  is the midpoint of the support, called the *anchor point* of component  $f_k$ . As explained below, the *width*  $h$  of the support of  $f_k$  is taken to be 20.  $H$  is the number at which the reasoning process of an individual – who is not Level-0 – starts. The value of  $H$  will be 50 or 100 depending on whether we adopt the IBRD or the IEDS theories to model this reasoning process.
- $f_\infty \sim B(\alpha_\infty, \beta_\infty, 0, h)$ , with  $\alpha_\infty$  and  $\beta_\infty$  being parameters to be estimated, associated to the Level- $\infty$  of reasoning.
- The  $\pi_k$ 's are the mixing proportions. They are positive numbers and add up to 1, i.e.  $\sum_{k=0}^K \pi_k + \pi_\infty = 1$ . The mixing proportions are the weights of the different components of the mixture distribution.

Moreover,  $\vartheta = (\pi, \theta)'$ , where  $\pi = (\pi_0, \pi_1, \dots, \pi_K, \pi_\infty)$ ,  $\theta = (\theta_1, \dots, \theta_K, \theta_\infty)$  and  $\theta_k = (\alpha_k, \beta_k)$ . The different components of the mixture accounts for the (unobserved) levels of reasoning, from the uniform distribution in  $(0, 100)$ , accounting for Level-0, to the  $f_\infty$  accounting for Level- $\infty$ . The analysis estimates both the ‘weights’  $\pi_k$  of the different components of the mixture and the shape parameters  $\theta_k = (\alpha_k, \beta_k)$ .

Concerning the analysis of the different groups, we consider two models. One sets the vector of mixing proportions  $\pi$  as well as the vector of shapes  $\theta$  to be specific for each group. The second model sets the vector  $\theta$  (the shapes) as well as the vector of mixing proportions  $\pi$  equal across groups.

The participants in the Newspaper experiments were asked to provide comments about their decision process. We use this information to fix the width  $h$  of each of the beta distributions as well as the number  $L = K + 2$  of levels of reasoning. The comments of the participants in the experiment indicate that subjects who declared to be at level of reasoning  $k > 0$  gives numbers deviating no more than 10 units from the corresponding anchor point  $a_k + h/2$ , the center of the support of the  $k$ th component. This suggests a range of 20 for  $h$ .<sup>10</sup> Were the true range smaller, this would be picked up by the fit, since  $\alpha$  and  $\beta$  are free parameters to be estimated. Accordingly, except for Level-0, that has range 100, we assign  $h = 20$  to all the other components. We decided to start at  $L = 4$  because the received comments showed a very small number of Level-3 participants (below 5%). We now proceed to describe the estimation of the model.

### 3.2 Model Fitting

We estimate the mixture model by maximum likelihood (ML). From the previous subsection, it follows that the log-likelihood function is

$$\ell(\vartheta) = \sum_{i=0}^n \log \left( \sum_{k=0}^{K+1} \pi_k f_k(y_i; \theta_k) \right), \quad (1)$$

where  $i$  varies across sample units,  $k$  varies over all components of the mixture, and  $f_{K+1} = f_\infty$  and  $\pi_{K+1} = \pi_\infty$ . This log-likelihood function is highly non-linear, so its maximization using standard optimization routines may be difficult. Instead, we resort to the EM algorithm, which exploits the fact that when the  $\pi$ 's are given, the likelihood function is trivially optimized.

Consider the data augmented with an unobserved multinomial class-membership or vec-

---

<sup>10</sup>Only a small number of players at Level- $\infty$  (less than 3% of the whole sample) deviate more than the range of 20.

tor of indicators  $d_i = (d_{i0}, d_{i1}, \dots, d_{iK}, d_{i\infty})'$ , where  $d_{ik} = 1$  or  $0$  and  $\sum_{k=0}^{K+1} d_{ik} = 1$ . The vector  $d_i$  is assumed to have a multinomial distribution with parameters  $\pi = (\pi_0, \dots, \pi_K, \pi_\infty)$ . The (complete-data) log-likelihood is thus

$$\ell_C(\vartheta) = \sum_{i=1}^n \sum_{k=0}^{K+1} d_{ik} (\log \pi_k + \log f_k(y_i; \theta_k)) .$$

The EM approach computes ML estimates using the following algorithm:

**E-step:** From current estimates  $\pi_k^{(t)}$  and  $\theta_k^{(t)}$  of the parameters (at  $t$ th iteration), compute the expected value  $Q = Q(\theta)$  of the (complete data) log-likelihood  $\ell_C(\theta)$ . This expectation turns out to be

$$Q = \sum_{i=0}^n \sum_{k=0}^{K+1} \hat{\pi}_{ik} (\log \pi_k + \log f_k(y_i; \theta_k)) , \quad (2)$$

where

$$\hat{\pi}_{ik} = \frac{\pi_k^{(t)} f_k(y_i; \theta_k^{(t)})}{\sum_{k=0}^{K+1} \pi_k^{(t)} f_k(y_i; \theta_k^{(t)})} . \quad (3)$$

Note that  $Q$  can be written as:

$$Q = \sum_{i=1}^n \sum_{k=0}^{K+1} \hat{\pi}_{ik} (\log \pi_k) + \sum_{k=0}^{K+1} \left( \sum_{i=1}^n \hat{\pi}_{ik} \log f_k(y_i; \theta_k) \right) . \quad (4)$$

**M-step:** We update  $\pi_k^{(t)}$  and  $\theta_k^{(t)}$  with the maximizers of  $Q$  of (2). This is accomplished by

- updating  $\theta_k^{(t)}$  with

$$\theta_k^{(t+1)} = \arg \max \sum_{i=1}^n \hat{\pi}_{ik} \log f_k(y_i; \theta_k), \quad (5)$$

- updating  $\pi_k^{(t)}$  with

$$\pi_k^{(t+1)} = \sum_{i=0}^n \hat{\pi}_{ik} / n \quad (6)$$

( $\hat{\pi}_{ik}$  as defined in (3)).

EM iterate steps 1 and 2 till convergence is achieved.

Note that the M-step implies the simple maximization with respect to  $\theta_k$  of a one-component likelihood function with a weighted sum of individual log-likelihoods (see (5)); in contrast to the usual log-likelihood of the mixture model, this is easily accomplished with basic optimization routines.

In addition to providing a convenient algorithm, the EM procedure gives, for every subject, the posterior probabilities of belonging to each of the components (or levels of reasoning). From a Bayesian perspective, the  $\hat{\pi}_{ik}$  of (3), at the end of the iteration, can be interpreted as the estimated conditional probabilities of case  $i$  belonging to component  $k$ , while the  $\hat{\pi}_k$  of (6) are the marginal probabilities of each component. By averaging the conditional probabilities  $\hat{\pi}_{ik}$  within each group, we obtain the marginal probabilities  $\hat{\pi}_{kg}$  of each component in each group  $g$ th,  $g = 1, \dots, G$ . Both, the marginal probabilities for all the groups and conditional for each group are reported below.

Since the EM algorithm produces maximum likelihood estimates, we can compute the maximum log-likelihood ( $\log L$ ) of the data, that is the value of (1) evaluated at the ML parameter estimates. To compare the fit of competing models, we suggest the Akaike Information Criteria (AIC)  $AIC = -2 \log L + 2q$ , where  $q$  is the number of parameters of the estimated model.<sup>11</sup>

---

<sup>11</sup>See, e.g., Bozdogan (1987) for a review on AIC and other alternatives.

## 4 Results of the Analysis

We fit the model, separately, for the whole sample and for each of the six groups. The results are presented in Table 2 which shows the estimates of the means and variances of the composing distributions, as well as the estimates of the mixing proportions across groups. Standard errors (se) of all the sample estimates have been computed using bootstrap (see, e.g., Efron and Tibshirani (1986)).<sup>12</sup> About 30% of the choices in the overall sample correspond to a Level-0 of reasoning. The remaining choices are distributed among levels 1, 2 or  $\infty$  in different proportions. Not surprisingly, a large number (62%) of “Theorists” choose Level- $\infty$ , while only 4% of “Lab” subjects reach this level of iteration.

The standard errors for the estimates of the various components’ weights give a (95% confidence interval) variation of a tight  $\pm 0.05$  for the Newspaper experiment, and a much more variable  $\pm 0.10$  for the smaller sample size experiments. A similar pattern arises when computing the 95% confidence intervals for means and variances.

————— Table 2 about here —————

—————Figure 2 about here —————

Figure 2 shows the density functions of the four components of the mixture model for the overall sample as well as the fitted mixture. To test whether each group should be analyzed separately, we compute the log-likelihood ratio test for the null hypothesis of a single-group model versus a model with parameters specific for each group. From the values in the last column of Table 2 we obtain  $\chi^2 = 234.76$  with 10 degrees of freedom,  $p$ -value  $< .0001$ . For

---

<sup>12</sup>We used 200 as the number of bootstrap samples.

model comparison, a different option that is free from sample size dependence and applies also to non-nested models is an information criteria such as the AIC. The AIC difference for the “all sample” model and the model with parameters specific for each group equals 134.7, favoring again the multiple-group model. The maximized log-likelihood values and the estimates of  $\pi$ s and  $\theta$ s for each group are reported in Table 2.

An interesting feature is the increasing variance from Level-1 to Level- $\infty$ . With few exceptions, people who reach Level-1 choose tightly around 33. Those reaching Level-2 choose around 22, but, in general, not so tightly. Level- $\infty$  presents, in general, a higher variance.<sup>13</sup> This observation is supported even when taking into account the variation of the standard errors of the variances, shown in Table 2. A plausible interpretation of this result is that as subjects take further steps of reasoning they become more and more aware of the complexity of the game, and assume that the rest of participants may make more dispersed choices.

We also want to assess whether the IBRd model (where  $H = 50$ ) fits better the data than the (not nested) IEDS model (where  $H = 100$ ). For the same number of levels of reasoning, IBRd clearly outperforms IEDS for all samples. Table 3 shows, in particular, the AIC differences when comparing IBRd with four levels of reasoning ( $K = 2$ ) to IEDS with five levels ( $K = 3$ ). Since the difference is positive, the preferred model is IBRd.<sup>14</sup>

Finally, for the IBRd model, the AIC taking into account the number of components shows no gain when increasing from  $K = 2$  ( $L = 4$  components) to  $K = 3$  ( $L = 5$  components).

---

<sup>13</sup>This is in contrast with Ho et al. (1998) and Stahl (1996), where variances were postulated to follow a decreasing pattern, but in accordance with the observations of Kübler and Weizacker (2000) and Goeree and Holt (2004).

<sup>14</sup>The same conclusion is obtained if the model comparison is based on the likelihood principle, or if the Schwarz information criterion is used instead of the AIC.

These results compare favorably with our previous specification in Nagel et al. (1999) which uses (truncated) normal distributions instead of beta distributions, where we obtained for the Newspaper data a maximized log-likelihood of  $-32,045.7$  (see Table 4 in that paper) for the best fitting model, a model with five components, a value that is 528.7 less (worse) than the one in the present model (see second row of Table 2), with only four components based on beta distributions, a more parsimonious model.<sup>15</sup> For the same data and the same number of components, the approach of Stahl (1996) would yield an even smaller likelihood than the reported likelihood of Nagel et al. (1999), since Stahl’s model imposes additional restrictions on the means and variances of the composing normals and does not add the Level- $\infty$  component.<sup>16</sup>

## 5 Conclusions

This paper provides an analysis of a finite mixture of beta distributions, without pre-established means and variances, for data obtained from experiments on the BC game, with diverse samples of subjects amounting to more than 8,000 observations. In contrast with the mixture of normal distributions, that imposes symmetry or truncation on the composing distributions, the mixture of beta distributions allows varying shapes for the composing distributions of the mixture. Therefore, for our specific experimental data, the beta family of distributions confers more flexibility to the statistical analysis, thus providing a better fit

---

<sup>15</sup>In relation to the estimated proportions, we do not obtain noticeable differences in both approaches for Level-0, Level-1 and Level-2 (27, 11, 23 in the normal versus 30, 9, 22 for the beta); thus Level-3 plus Level- $\infty$  for the normal case gives the same proportion as the Level- $\infty$  of the beta model (39%). Also the beta model gives a variance more than six times smaller than the normal approach for Level-1, while the variances are similar for Level-2, but for Level- $\infty$  the variance is almost twice as large for the beta approach (as Level-3 disappears in the beta model)

<sup>16</sup>Since Camerer et. al. (2004) model does not contain a stochastic random term, their approach cannot be compared with ours in terms of log-likelihood. Costa-Gomes, Crawford (2006) and Costa-Gomes, Crawford, and Broseta (2001) analyze the data from  $3 \times 3$  normal form games, thus providing insights about a different sort of strategic behavior than the one confronting BC players.

to this set of BC data than previous attempts based on a mixture of normals.

Our model assumes that all individuals playing the BC game share a common pattern of reasoning, described as iterated best reply (degenerate), and the composing distributions are anchored according to the specifications of the theoretical model. However, their means and variances are let free, to be estimated, and so are, obviously, the proportions of choices at the different levels of reasoning. Similarly, the number of distributions involved is not predetermined. The estimation shows that about 30% of our 8,000 subjects use Level-0, 10% Level-1, 20% Level-2 and 40% Level- $\infty$ . Thus, it appears that once a player has moved up from Level-0 she, most often, tends to further proceed beyond Level-1. The analysis indicates that the hypothesis that individuals reason according to the Iterated Best Reply (degenerate) model fares well when compared to the Iterated Elimination of Dominated Strategies model. It also shows that, in the Beauty Contest game, the number of Level-3 choices is not large, suggesting that most players who manage to reach Level-3 decide to jump from there to the equilibrium solution.

As a general conclusion for wider application, it appears that for some experimental data, the beta distribution can be a useful alternative to the normal and, as it avoids truncation and restrictions of symmetry, it yields a simpler analysis with better fit, at no added computational cost.

Figure 1: Histogram for the aggregate of all the experiments. The points Level -1, Level-2, Level-3 and Level- $\infty$  correspond to the choices of subjects with first, second, third and infinite levels of reasoning.

Figure 2: The graph shows the fitted probability density functions of the components for levels of reasoning 0, 1, 2 and  $\infty$  (All sample). Level-0 is the straight line parallel to the  $x$ -axis, Level-1 is centered at 33.33 and Level-2 at 22.22, Level- $\infty$  is the density more in the left. The probability density for Level-1 is shown truncated for clarity of presentation of the whole graph. The graph shows also the probability density function of the fitted mixture that results from applying the (fitted) weights .31, .09, .22 and .39 on components 0, 1, 2 and  $\infty$ .
