Abstract

We use multivariate Markov switching models to characterize the time-varying linkages among the Irish stock market, one of the top world performers of the 1990s, and the US and UK stock markets. We find that two regimes, characterized as bear and bull states, are required to capture the dynamics of excess equity returns both at the univariate and multivariate level. The regimes driving the small open economy stock market are largely synchronous with those typical of the major markets. In fact, despite the existence of a persistent bull state in which the correlations among Irish and UK and US excess returns are low, we find that state co-movements involving the three markets are so relevant to reduce the optimal mean-variance weight carried by ISEQ stocks to at most one-quarter of the overall equity portfolio. We compute time-varying Sharpe ratios and recursive mean-variance portfolio weights and document that a regime switching framework produces out-of-sample portfolio performance that outperforms simpler models that ignore regimes. These results appear robust to endogenizing the effects of dynamics in spot exchange rates on excess stock returns.

JEL Classification: G11; F30; F37; C32.
Keywords: International portfolio diversification; multivariate regime switching; national stock markets co-movements; Sharpe ratios.

1. Introduction

Understanding the relationships between small open economies and major international stock markets and how linkages between these markets vary through time is of great importance for portfolio diversification. Standard finance textbooks usually argue that there are significant gains from international portfolio diversification. However, these claims are based on the existence of relatively low, constant correlations between national equity markets. There is now massive evidence that correlations are neither constant nor particularly modest. This feature seems particularly important for emerging markets representative of economies with strong trade and real (e.g., foreign direct investments) ties with economies that happen to host major international stock markets and financial intermediation centers: while the real ties work to make correlations higher, time-variation in such ties and business cycles conjure to make such correlations time-varying. Our paper investigates the case of an interesting small open economy—the Irish stock market as represented by its value-weighted index, the ISEQ—by exploring the ability of a flexible class of nonlinear models—multivariate Markov switching vector autoregressions—to capture dynamic patterns potentially useful to portfolio managers.

Recent empirical findings have shown that not only have correlations increased over time due to expanding capital market deregulation, increasing free trade, globalization, growth in the activities of multinational enterprises, the number of cross-listings, and cross-border merger and acquisitions, but that these correlations are also time-varying. Longin and Solnik (1995, 2001) show that correlations between markets increase during periods of high market volatility, with the result that correlations would be higher than average exactly in the moment when diversification promises to yield gains. Such changes in correlations imply that the benefits to portfolio diversification may be rather modest during bear markets (see Butler and Joaquin, 2002, and Baele, 2005). Despite a number of stylized facts regarding correlations, co-movement and integration of stock markets over time, much of the extant literature fails to encapsulate these facts in a genuine multivariate setting. Therefore in this paper we investigate the time-varying nature of the relationship between the equity market in a small open economy, Ireland, and the major Anglo-Saxon markets, the UK and the US, using a multivariate Markov switching (MMS) model.

Ireland seems to offer the ideal case of a small open economy with long-standing political and economic links with both the UK and US. For instance, prior to Ireland joining the European Monetary System in 1979, the Irish punt was held at parity with the UK pound sterling. Moreover, the majority of Irish firms are listed on the London stock exchange in addition to Dublin's exchange. Ties with the US have been increasing significantly over the past three decades. By 1994, nearly a quarter of the Irish workforce were employed by US owned firms and in 1999 US foreign direct investment accounted for virtually 90% of total investment (capital formation) in Ireland. Moreover, the degree of economic and financial dependence of Ireland on the US and the UK remains non-obvious throughout the entire 1978-2004 sample, in the sense that while Ireland joined the EMU in 1999, the UK (and obviously the US) did not, meaning no structural break affects the commonality of fundamentals in any of the pairs of countries under investigation.[1]

There are also good reasons arising from financial considerations that suggest that the Irish stock market ought to be strongly co-moving with other major international markets. First, all small size markets are prone to rebalancing-induced effects of large movements in major markets: when larger markets are bull (bear), diversification considerations suggest buying (selling) in smaller markets as well, thus spreading the bull (bear) state to them. In the specific case of the ISEQ, we have an additional effect caused by the choice of the majority of large Irish firms to be cross-listed on the ISEQ and the London Stock Exchange, which ought to accentuate the influence of the latter on the former. In fact, a number of papers have investigated the relationships between the Irish and UK equity markets (Gallagher, 1995, Kearney, 1998, and Alles and Murphy, 2001) providing evidence of substantial integration and significant spillovers, while Cotter (2004) highlights the influence of the US market on Irish stock returns. However, all of these studies fail to capture the time-varying nature of the relationship beyond simple sub-sample analysis. Using smooth transition regressions, Bredin and Hyde (2007) capture the relationship of the ISEQ with the UK and US through time in a univariate context and demonstrate the significant role that UK stock returns and in particular US stock returns have in determining Irish equity returns when there is an allowance for differing states. Although previous research clearly establishes a relationship between the small open economy, Ireland, and the major economies and markets of the UK and the US, it fails to capture the multivariate nature of the interrelationships and is silent on any commonality in state dependence.

We report a number of interesting results. First, the null of linear (either i.i.d. or vector autoregressive) Gaussian excess stock returns is severely rejected for all the markets under consideration, in the sense that univariate analysis reveals the presence of clearly interpretable regimes.[2] We find that the

[1] Gottheil (2003) discusses the causes for the "tiger-like" economic growth observed in Ireland between 1995 and 2000; see also The Economist, "Green is Good", May 17 1997, issue 8017.

[2]This is less than surprising in the light of the existing literature, even with reference to ISEQ returns. Among others, Lucey (2001) tests whether there is evidence of long memory—and hence of nonlinear dependence—in daily ISEQ returns using the Fractional Differencing Model of Geweke and Porter-Hudak. Hamill, Opong and

degree of 'synchronization' across markets is surprisingly high and that this finding also applies to Ireland, whose stock market strongly co-moves (both linearly, as measured by pair-wise correlation coefficients, and non-linearly) with US and UK equity markets. In fact, when truly multivariate models are considered, we obtain evidence that a simple two-state vector autoregressive model in which the regime is common across the three markets is sufficient to capture the salient properties of the data. Second, a formal (nonlinear) impulse-response analysis uncovers that - despite a VAR component is suggested by the data - the common wisdom that it is difficult to predict excess stock returns simply on the basis of past behavior is fairly accurate, especially when horizons exceeding 3-4 months are considered and for pairs of national equity markets. This result is consistent with the idea that linear patterns of interdependence are difficult to estimate with any accuracy and therefore hard to exploit in portfolio management. However, in a regime switching model, the linear channel is not the only one through which cross-market linkages appear: dynamic associations through commonality in regimes may be more important and can be accurately estimated. Third, we show this is the case by calculating mean-variance portfolio weights and documenting their usefulness in a recursive, pseudo-out-of-sample exercise in which portfolio performances based on alternative statistical models are compared. It turns out that using regime switching VAR models produces useful portfolio indications that maximize (average) realized Sharpe ratios. Fourth, we repeat some of the exercises when the log-changes in the spot exchange rate vs. the US dollar of Ireland and the UK affect the definition of the regimes and linearly forecast subsequent excess equity returns. Although the analysis is complicated by the higher dimensionality of the estimation problem, we obtain some evidence that implied portfolio indications are not qualitatively different from those that are based purely on excess stock return data.

All in all, our paper shows that the ISEQ parallels the real side of the Irish economy and therefore manifests a high association with returns and especially regimes characterizing US and UK markets. This makes Irish stocks a diversification vehicle that remains certainly useful, but that ought to receive an optimal weight that fails to reflect the "Tiger", emerging-like recent performance of the Irish economy. On the contrary, the negative skewness and fat-tailed properties of ISEQ excess returns contribute in the end to limit the importance of Irish stocks to weights that hardly reach one-quarter of the overall equity portfolio, even under the most favorable configurations of preferences and parameters (see Guidolin and Nicodano, 2007, for similar conclusions with reference to European small capitalization stocks).

Sprevak (2000) use a variety of statistical tools to test whether ISEQ returns are independently and identically distributed over time and reject the hypothesis in favor of fractionally integrated ARMA models.

A number of papers have employed regime switching techniques to model time-varying linkages among international stock indices. Ramchand and Susmel (1998) examine the relationship between correlation and variance in a regime-switching ARCH model estimated on weekly returns data for the US and a few major markets (in pairs). They find that correlations between US and other markets are 2 to 3.5 times higher when the US market is in a high variance state. Ang and Bekaert (2002) consider bi-variate and tri-variate regime models that capture asymmetric correlations in volatile and stable markets and characterize a US investor's optimal asset al.location under power utility. Butler and Joaquin (2002) characterize the consequences of asymmetric correlations in bear and bull markets in an international portfolio diversification framework and show that risk averse investors may want to tilt portfolio weights away from stock markets characterized by the highest correlations during downturns.[3] Sarno and Valente (2005) propose a regime switching vector error correction (VEC) representation that captures international spillovers across futures-spot index prices for the S&P 500, the FTSE 100 and the NIKKEI 225. The paper has the following structure. Section 2 introduces multivariate Markov switching models. After an introduction to the data, Section 3 reports the main body of empirical results of the paper, distinguishing between univariate and multivariate findings. Section 4 is devoted to the economic implications of our econometric results, in particular to examining the nonlinear impulse-responses implied by MMS models, to predicting Sharpe ratios useful in portfolio choice, and to calculating and assessing the recursive out-of-sample performance of portfolio strategies that rely on different statistical models. Section 5 concludes.

2. Models of Regimes in the Joint Return Process

A vast literature in finance has reported evidence of predictability in stock market returns, mostly in the context of linear, constant-coefficient models, see e.g. Fama and French (1989) and Goetzmann and Jorion (1993). This evidence on linear predictability and co-movements of asset returns has been extended to model dynamic linkages across international equity markets (see e.g. Kim *et al.*, 2005). More recently, some papers have found evidence of regimes in the distribution of returns on individual asset returns or pairs of these (e.g., Guidolin and Timmermann 2003, 2005, Schaller and Van Norden, 1997, Turner *et al.*, 1989). To our knowledge, there are very few applications of the class of multivariate Markov switching models studied by

[3] Butler and Joaquin (2002) simply define their three regimes (bear, normal, and bull) according to the level of domestic returns. Each regime is exogenously constrained to collect exactly one-third of the sample. In our paper the regimes are endogenously identified.

Hamilton (1993) and Krolzig (1997) involving relatively large vectors of national stock index returns.[4] On the contrary, and following the expanding macro-econometrics literature, in this paper we model the joint distribution of a vector of n (excess) stock index returns, $\mathbf{x}_t = (x_{1t},\ x_{2t}, \ldots,\ x_{nt})'$ as a multivariate regime switching process driven by a common discrete state variable, s_t, that takes integer values between 1 and k:

$$\mathbf{x}_t = \boldsymbol{\mu}_{s_t} + \sum_{j=1}^{q} \mathbf{A}_{j,s_t} \mathbf{x}_{t-j} + \boldsymbol{\varepsilon}_t. \tag{1}$$

Here $\boldsymbol{\mu}_{s_t} = (\mu_{1s_t}, \ldots, \mu_{ns_t})'$ is a vector of intercepts in state s_t, $\mathbf{A}_{j,s_t}$ is an $n \times n$ matrix of autoregressive coefficients at lag j in state s_t and $\boldsymbol{\varepsilon}_t = (\varepsilon_{1t}, \ldots, \varepsilon_{nt})' \sim N(0, \boldsymbol{\Sigma}_{s_t})$ is the vector of return innovations that are assumed to be joint normally distributed with zero mean and state-specific covariance matrix $\boldsymbol{\Sigma}_{s_t}$. Innovations to returns are thus drawn from a Gaussian mixture distribution that is known to provide a flexible approximation to a wide class of distributions, see Guidolin and Timmermann (2005). Importantly, it is well known that mixtures of conditionally Gaussian densities can approximate highly non-Gaussian unconditional multivariate distributions rather well. In our application, $n = 3$ (Ireland, UK, and US).

Moves between states are assumed to be governed by the $k \times k$ transition probability matrix, $\mathbf{P}$, with generic element p_{ji} defined as

$$p_{ji} \equiv \Pr(s_t = i | s_{t-1} = j), \quad i,j = 1, \ldots, k. \tag{2}$$

Each regime is hence the realization of a first-order Markov chain. Our estimates allow s_t to be unobserved and treated as a latent variable. This feature corresponds to the common observation that although non-stationarities and regime shifts seem to be pervasive, they remain extremely difficult to predict and even pin down once they take place.

(1) - (2) nest several popular models as special cases. In the case of a single state, $k = 1$, we obtain a linear vector autoregression (VAR) with predictable mean returns provided that there is at least one lag for which $\mathbf{A}_j \neq 0$. In the absence of significant autoregressive terms ($q = 0$), the discrete-time equivalent of the standard IID Gaussian model adopted by much of the mean-variance based literature obtains.

Our model can be extended to incorporate an $l \times 1$ vector of predictor variables, $\mathbf{z}_{t-1}$, comprising variables such as inflation and/or exchange rates that have been used in recent studies on predictability of stock returns from macroeconomic variables. Define the $(l + n) \times 1$ vector of state variables $\mathbf{y}_t \equiv (\mathbf{x}_t'\ \mathbf{z}_t')'$. Then (1) is readily extended to

[4]The only exception is Ang and Bekaert (2002) who model bi- and tri-variate vectors of national stock index returns (US and UK, US, UK, and Germany) although their focus is mainly on optimal asset al.location issues.

$$\mathbf{y}_t = \begin{pmatrix} \boldsymbol{\mu}_{s_t} \\ \boldsymbol{\mu}_{zs_t} \end{pmatrix} + \sum_{j=1}^{q} \mathbf{A}^*_{j,s_t} \mathbf{y}_{t-j} + \begin{pmatrix} \boldsymbol{\varepsilon}_t \\ \boldsymbol{\varepsilon}_{zt} \end{pmatrix}, \tag{3}$$

where $\boldsymbol{\mu}_{zs_t} = (\mu_{z_1 s_t}, \ldots, \mu_{zl s_t})'$ is the intercept vector for $\mathbf{z}_t$ in state s_t, $\{\mathbf{A}^*_{j,s_t}\}_{j=1}^{q}$ are now $(n+l) \times (n+l)$ matrices of autoregressive coefficients in state s_t and $(\boldsymbol{\varepsilon}_t' \ldots \boldsymbol{\varepsilon}_{zt}')' \sim N(0, \boldsymbol{\Sigma}^*_{s_t})$, where $\boldsymbol{\Sigma}^*_{s_t}$ is an $(n+l \times n+l)$ covariance matrix. This model allows for predictability in returns through the lagged values of $\mathbf{z}_t$.

MMS models are estimated by maximum likelihood. In particular, estimation and inferences are based on the EM (Expectation-Maximization) algorithm proposed by Hamilton (1993), a filter that allows the iterative calculation of the one-step ahead forecast of the state vector $\boldsymbol{\pi}_t$ given the information set, and the consequent construction of the log-likelihood function of the data. Maximization of the log-likelihood function within the M-step is actually made faster by the fact that the first-order conditions defining the MLEs may often be written down in closed form. Under standard regularity conditions (such as identifiability, stability and the fact that the true parameter vector does not fall on the boundaries) Hamilton (1993) and Leroux (1992) have proven consistency and asymptotic normality of the ML estimator. As a consequence, standard inferential procedures are available to test statistical hypothesis.

3. Empirical Results

3.1. The data

We use monthly series on Irish, US, and UK nominal stock returns for the period 1978:05-2004:12. In particular, we focus on continuously compounded total (inclusive of dividends and all distributions) returns on the Dublin ISEQ, the US S&P 500, and the UK FTSE 100 stock market indices. These data are supplemented by data on spot exchange rates for the Irish punt and the British pound vs. the US dollar. All data series are obtained from Datastream. Table 1 reports summary statistics for all series under consideration. Consistently with the literature on stock return predictability, we investigate the properties of *excess* equity returns. To make the table easy to read, the statistics refer to monthly percentage returns.

The three markets display similar median excess returns, in the order of 8-9 percent a year, i.e. values consistent with the debate on the high equity premium.[5] Some structural difference is displayed by the volatility coefficients, a textbook annualized value of 15 percent for the US index, 17 percent for the UK, and more than 18 percent for Irish excess stock returns. As a result the (median-based, annualized) Sharpe

[5]Mean (as opposed to median) excess equity returns are low (less than 1 percent) for the UK. This is caused by 2 extreme observations (of -19 and -16 percent) that lie more than 3 standard deviations away from the mean.

ratios range from 0.49 for the UK to 0.58 for the US (the Irish index is 0.53). However, should we add confidence bands around such values, we would fail to find significant differences among these reward-to-risk ratios, which appear to cluster around a 'typical' 0.5 per year. This feature suggests that in a portfolio logic, an investor might derive substantial benefits from a strategy that diversifies across the three equity portfolios. However, Panel A of Table 1 also shows that such a simplistic approach may be inappropriate, as the three indices display asymmetric, left-skewed, and fat-tailed distributions. In particular, excess Irish returns show a large and statistically significant negative skewness (-1.5) and a large kurtosis (12.4) that exceeds the Gaussian benchmark (three) with a negligible p-value. The values of skewness and kurtosis for UK and US excess returns are less impressive, but they still bring to stark rejections (using a Jarque-Bera test) of the null hypothesis that each of these univariate series may have a Gaussian marginal distribution.

Interestingly, such non-Gaussian features do not appear to be exclusively driven by the presence of volatility clustering (ARCH effects) in the three excess equity returns series. For instance, we calculate an eight-order Ljung-Box test statistics on squared excess returns and test whether there is any serial correlation structure in volatility. We find high p-values (0.91, 0.95, and 0.84 for Ireland, UK, and US, respectively) and very weak indications of ARCH.[6] On the other hand, while Irish excess returns appear to be highly serially correlated in levels, this is not the case for UK and US excess returns.[7] Section 3.2 considers another possible source of departures from (marginal) normality for the excess returns under consideration, the presence of regimes in the first two moments that equate the unconditional marginal densities to mixtures of normals.

Panel B of Table 1 reports summary statistics for log-changes in spot exchange rates, later used as predictors of excess stock returns. Means and medians indicate that while over our sample period the Irish punt has slowly depreciated against the US dollar (the annualized average rate is 0.32 percent), the British pound has shown no appreciable trend. In fact, while on 1978:05 the pound-USD spot rate was 1.94, on 2004:12 such rate was 1.93. However, spot rates show a non-negligible volatility, 9.4 and 8.8 percent per year, respectively. The UK pound-US dollar exchange rate is also highly non-normal, negatively skewed (-0.17) and fat-tailed (with kurtosis coefficient of 4.79). Panel C concludes by showing simultaneous correlation coefficients among excess equity returns and spot exchange rates. Excess stock returns are generally positively correlated, with coefficients between 0.54 (Ireland-US) and 0.70 (US-UK). Even such a

[6]This result is partially explained by the presence of a few influential observations in the 1980s, in particular the large, negative returns of October 17, 1987. In fact, when we test for clustering in squares in a 1988:01 - 2004:12 sample, we find p-values of 0.01, 0.54, and 0.01, i.e. some evidence of ARCH reappears, with the UK exception.

[7]The associated p-values for a eighth order Ljung-Box test on levels are 0.001, 0.41, and 0.51.

large value implies the existence of substantial international diversification opportunities. Spot exchange rate changes are essentially uncorrelated with excess equity returns, while shocks to the UK pound and the Irish punt seem to push the two currencies in opposite directions (their correlation is -0.76).

3.2. Regimes in national stock indices

To assess whether regime switching models are capable to provide an adequate fit of the asset return properties revealed by Table 1, in this Section we search for appropriate multi-state models for the univariate excess equity returns series. In practice, we fit a variety of MSIAH(k,q) models,

$$x_t^i = \mu_{s_t^i}^i + \sum_{j=1}^{q} a_{j,s_t^i} x_{t-j}^i + \varepsilon_t^i \quad \varepsilon_t^i \sim N(0, \sigma_{s_t^i}^i), \tag{4}$$

where i = ISEQ, FTSE100, S&P500 and also the latent, first-order Markov state variable s_t^i is assumed to be specific to each national stock market, as indexed by $i.$ In the acronym MSIAH(k,q) (see Krolzig, 1997), MS stands for 'Markov Switching', 'I' points to the fact that the intercept $\mu_{s_t^i}^i$ is regime-specific, 'A' to the regime-dependence in the AR(p) component, and 'H' to analog structure in the covariance matrix. Clearly, single-state, Gaussian IID models correspond to $k = 1$ and $q = 0,$ while simpler MS models can be easily derived by imposing restrictions on (4), e.g. MSIH(k,q) models in which $q \geq 1$ but the AR component of the conditional mean function fails to be regime-dependent or MSI(k) models in which $q = 0$ and the covariance matrix fails to be regime-dependent.

Based on the analysis in Section 3.1, we expect UK and US excess stock returns to display $q = 0$ and possibly require simple MSI(k) models, given the weak evidence of time-variation in second moments; Irish excess returns are likely to imply either a MSI(k,q) or a MSIA(k,q) model, given the evidence of serial correlation. We perform a specification search with reference to each of the excess stock return series using three information criteria (AIC, BIC, and Hannan-Quinn) and two different likelihood-ratio tests. The first type of LR test concerns the appropriate number of regimes k in (4). In particular, we would like to test whether the null of a single-state (also called "linear" in what follows) model ($k = 1$) can be rejected in favor of $k > 1.$ We use Davies' (1977) correction to the standard LR test to circumvent the problem of estimating the nuisance parameters under the alternative hypothesis and derive instead an upper bound for the LR test. The second set of LR tests is applied only to models with the same number of regimes k, i.e. the test is applied to standard restrictions that involve (e.g. on the autoregressive order q or on the regime-dependence of the variance in the case of MSIH(k,q) and MSIAH(k,q)). Detailed results are reported in

Guidolin and Hyde (2007). However, for all excess return series, the null of a single-state model is always rejected, even after applying Davis' (1977) correction. Although some ambiguities remain on the exact functional form, information criteria generally signal the need for two regimes and for an autoregressive component. For at least two stock markets, there is also strong evidence of regime-dependence in volatility.

Table 2 provides parameter estimates (along with implied significance levels) for a common MSIAH(2,1) model estimated for the three markets. For comparison, panel A of Table 2 also reports estimates for a single-state, Gaussian AR(1) model. Consistently with the discussion in Section 3.1, the conditional mean model is 'significant' (precisely, the autoregressive coefficient is) for ISEQ excess returns; for other markets, a simple AR(1) model provides no useful fit to the data.

The picture provided by panel B is radically different. For all markets, the two regimes have a natural interpretation as bear and bull states, although the regime-specific intercept μ^i_{bear} is (weakly) significantly negative only for US data (-1.2 percent per month). The bear states are characterized by negative and large unconditional, state-specific risk premia, with an extreme value of -31 percent in Irish case.[8] This means that the ISEQ is characterized by the possibility of crash states that inflict large losses to investors, as reflected by the large and negative skewness of -1.5 in Table 1. Moreover, the bear states are highly volatile, with annualized, unconditional state-specific volatilities between 2 and 3.4 times the unconditional AR(1) values.[9] In particular, the bear annualized volatility for the ISEQ is a whopping 60 percent. However, while for US and UK excess returns the implied bear state is persistent, with average durations between 7 and 11 months, in the Irish case such a state is as extreme as short-lived, with a duration barely in excess of 1 month.

The other regime is a bull state of positive and high unconditional, state-specific risk premia (between 7 percent for the ISEQ and 11 percent for US returns, in annualized terms) with moderate unconditional volatility between 8 and 15 percent. This is also the regime in which Irish returns are positively serially correlated, while also UK and US returns appear to have some mild linear structure, with some degree of mean-reversion built in the boom regime (i.e. the estimated serial correlation coefficients are negative). The bull state is rather persistent in all markets, with average durations of 25, 7, and 14 months for Ireland, UK, and US, respectively.

Such values are consistent with an equilibrium interpretation, since the regimes are unobservable and

[8]Unconditional, state-specific means are calculated as $E_{S^i}[x^i_t] = \mu^i_{s^i_t}/(1-a^i_{s^i_t})$ exploiting the simple AR(1) within-state structure implied by a MSIAH(2,1) model.

[9]Unconditional, state-specific variances are calculated as $Var_{S^i}[x^i_t] = (\sigma^i_{s^i_t})^2/[1-(a^i_{s^i_t})^2]$.

never perfectly predictable (in particular, the bear state is latent and—even when persistent–never perfectly anticipated) and the one-step predicted risk premium conditional on each of the two states,

$$E_t[x_{t+1}^i|bear] = (\mathbf{e}_1'\hat{\mathbf{P}}^i\mathbf{e}_1)\cdot\frac{\mu_1^i}{1-a_1^i} + (\mathbf{e}_1'\hat{\mathbf{P}}^i\mathbf{e}_2)\cdot\frac{\mu_2^i}{1-a_2^i}$$
$$E_t[x_{t+1}^i|bull] = (\mathbf{e}_2'\hat{\mathbf{P}}^i\mathbf{e}_2)\cdot\frac{\mu_2^i}{1-a_2^i} + (\mathbf{e}_2'\hat{\mathbf{P}}^i\mathbf{e}_1)\cdot\frac{\mu_1^i}{1-a_1^i},$$

is always positive, which is consistent with risk-aversion and standard preference specifications.[10]

Figure 1 shows the ex-post, full-sample smoothed state probabilities for each of three national stock markets under examination. Clearly, the structure and frequency of regime shifts differs when the ISEQ is compared to the UK and US markets. In fact, the bear state is a true crash regime in the case of Ireland: the state appears relatively infrequently and tends to be short-lived; well-known episodes of declining markets are identified, such as October 1987, the Summer of 1990 (the Iraqi invasion of Kuwait), the Russian crisis of the Summer 1998, and a few months surrounding the September 2001 terror attacks. On the other hand, the bear state is milder and much more persistent when inferred from UK or US data. Although the previous episodes are all identified by prolonged bear episodes also on UK and US data, a few more periods are ex-post fitted using the bear density, e.g. the oil shocks of the early 1980s, and the Spring of 2002 in correspondence to an international recession cycle. However, the visual impression provided by Figure 1 is not completely accurate: despite the difference frequency of the switches, the ISEQ smoothed probabilities of a bear/crash state are substantially correlated with the FTSE and (especially) the S&P 500 bear state probabilities, with coefficients of 0.29 and 0.47, both statistically significant at 5 percent.[11]

In conclusion, the brief analysis of regimes at univariate level shows that excess returns in the three national stock markets under investigation all display overwhelming evidence of recurring non-stationarities, in the form of shifts in risk premia as well as risk (volatilities). Moreover, the national regimes appear to be positively, although imperfectly correlated. Section 3.3 adopts a truly multivariate approach and models the *joint* density of excess stock returns using regime switching techniques. This strategy will allow us to explicitly ask whether bull and bear states are common across national markets.

3.3. A regime switching vector autoregressive model

---

[10] $\mathbf{e}_j$ is defined as a $k \times 1$ vector with zeros everywhere but in its j -th position, where a 1 appears.

[11] Less surprisingly, the FTSE and S&P 500 smoothed probabilities are also positively correlated (0.50) although we fail to detect any systematic difference vs. the association characterizing ISEQ probabilities with other markets.

Specification tests are performed for vector regime switching models as in (1) when $\mathbf{x}_t = (x_t^{ISEQ},\ x_t^{FTSE},\ x_t^{S\&P})'$ becomes the object of interest.[12] The null of a single regime is decidedly rejected in correspondence of all models estimated. We find no evidence that our small-open economy national stock market would command by itself the presence of specific states apt to describe its (less frequent) regime shifts between crash and normal/bull states. On one hand, this is consistent with our finding in Section 3.1 that—despite a few visual differences among the smoothed probability plots of the three markets–the univariate state probabilities display rather high correlations. On the other hand, the fact that a simple two-state, "bull & bear" model is sufficient to capture the nonlinear dynamic properties of $\mathbf{x}_t$ implies that it is easy to find "*what* tames (drives) the Irish market": the same underlying state variable that seems to characterize many stock markets in the world, and particularly the UK and US markets.

Table 3 reports parameter estimates for the selected model. Also in this case, panel A provides a benchmark by reporting the estimates of a single-state VAR(1) model. Visibly, a single-state model is not only resoundingly rejected in a statistical dimension (the LR statistic in this case exceeds 104), but provides a few puzzling implications: for instance, the ISEQ is significantly affected by lagged S&P 500 returns, but the corresponding coefficient estimate is economically negligible (a one standard deviation shock to lagged S&P 500 excess returns would move ISEQ excess returns in the same direction by 0.02 percent only); on the contrary, the FTSE100 seems to oddly react to lagged Irish excess returns, with a coefficient with p-value below 0.1 and economically important.[13]

Panel B shows the MMS EM-MLE estimates. The table confirms the interpretation of the two regimes provided at the univariate level. Regime 1 remains a bear (or normal), persistent state (average duration is 13 months) in which excess returns are characterized by a negative (albeit not statistically significant) intercept. This is confirmed by the within state unconditional (monthly) risk premia:[14]

$$E[\mathbf{x}_t|bear] = [\text{-1.20 0.21 -0.55}]'.$$

All of the indices display significant (partial) first-order serial correlation coefficients; Irish excess returns are highly serially correlated, while UK and US excess returns imply significant (and in the UK case, economically non-negligible) mean reversion. As one would expect, the ISEQ market is heavily influenced

[12]Detailed specification test results are not reported to save space and are available from the authors on request.

[13]In Tables 3 and 6 the VAR matrices have to be read by row, i.e. in each row we report the impact on the row variable of the lagged variables in the columns.

[14]These are calculated as $E[\mathbf{x}_t|S_t] = (\mathbf{I}_3 - \mathbf{A}_{s_t})^{-1}\boldsymbol{\mu}_{s_t}$.

by the recent levels of risk remuneration in the major, foreign reference markets, although past positive returns in the UK seem to depress the ISEQ index, while the opposite happens as a reaction to past positive US excess returns. Although the associated coefficients are small, the FTSE100 and the S&P500 show some (delayed) interdependence. At a simultaneous level, the same is true: all shocks to excess returns appear to be significantly and positively correlated in the bear state, with the FTSE-S&P coefficient particularly large (0.68). Finally, volatilities (both for VAR shocks and unconditionally, within state) are sensibly above the overall unconditional levels. As evidenced by scores of earlier papers (e.g. Longin and Solnik, 2001) bear, volatile states imply high contemporaneous correlation among international stock markets.[15]

The second regime is instead another relatively persistent (average duration is between 6 and 7 months) bull state in which excess returns all display positive intercept and positive and high within state unconditional (monthly) risk premia:

$$E[\mathbf{x}_t|bull] = [1.71\ 0.90\ 1.64]'.$$

Clearly, these mean excess returns correspond to double-digit annualized risk premia. ISEQ excess returns remain rather extreme in both regimes, switching from an annualized -14 percent in the bear state to +21 percent in the bull state. This fits the general awareness that a small open economy, emerging stock market may often be prone to jumps and sudden corrections. In this regime, only S&P 500 excess returns display a significant negative serial correlation coefficient. The ISEQ remains strongly affected by lagged excess returns in UK and US markets although the coefficients now display signs that run opposite those obtained in the bear state. Although the corresponding VAR coefficient estimates are from being economically negligible, the finding of opposite signs in the two states is consistent with our remark that a simple, single-state VAR(1) would produce statistically significant but rather small interdependence coefficients between the ISEQ and other major Anglo-Saxon markets.[16] For instance, notice that with reference to the lagged dependence of the ISEQ on the FTSE100, the Irish reaction to a past 1 percent FTSE return is

$$0.67 \times (-0.38) + 0.23 \times (0.64) = -0.11$$

(where 0.67 and 0.23 are the long-run, steady-state probabilities of the bear and bull state, respectively), which is not very different from the single-state VAR(1) coefficient estimate of -0.17 in panel in Table 3.

[15] There is evidence of this phenomenon concerning emerging markets, see e.g. Yang *et al.* (2003).

[16] For instance, a one standard deviation positive shock to the FTSE100 causes an excess return of +3.1 percent on the ISEQ, in the following month. The corresponding estimate for a one standard deviation shock to the S&P 500 is -2.5 percent.

Even more crucially, in the bull state shocks to excess ISEQ returns appear to be weakly correlated at best with similar, contemporaneous shocks to other national stock markets. This fact seems to be rather specific to the small open economy stock market, as the FTSE and the S&P indices anyway have a significantly positive correlation of 0.45. Additionally, the bull volatilities are systematically lower than the unconditional values, generally between one-half and two-thirds of the matching bear volatilities.

Figure 2 shows the full-sample smoothed probabilities implied by the model. The sequence of bear periods in which risk premia are negative or negligible accurately match the historical experience of the major world equity markets: 1978-1981 are characterized by two bear spells, coinciding to the oil shocks; 1983 is the period of high and volatile interest rates following the US monetarist, anti-inflationary experiment; the early 1990s identify a worldwide recession and the effects of the first Iraqi war; finally, since 1998 the world equity markets go in and out of the bear state (initially in correspondence to events such as the Russian debt crises), with acute bear episodes of a few consecutive months in 2001 and 2002. Matching recent experience, in 2003-2004 the three equity markets switch to a bull regime of high expected returns.

Figure 3 confirms that our two-state VAR(1) model really captures common regimes across the three national stock markets. In the three diagrams we have plotted the log-index levels for the ISEQ, the FTSE, and the S&P and–using a superimposed shading–the periods in which the smoothed probability from the model estimated in Table 3 assigns at least a 50% chance to a bull state. Consistently with our remarks above, the system is in a bull state roughly one-third of the time. Most of the shaded periods do correspond to well-visible (and easily recollected) bull phases–e.g., 1985, early 1987, the end of the first Iraqi War in 1991-1992, the dot.com explosion of 1995-1998, and the recent rebound of 2003-2004–which do characterize all markets under investigation.[17]

3.4. Diagnostic checks

Standard, residual-based diagnostic checks are made difficult within the MMS class by the fact that in (1), $\boldsymbol{\varepsilon}_t \sim$ i.i.d. $N(0, \boldsymbol{\Sigma}_{s_t})$ only within a given regime. Since for most times t, the vector of state probabilities $\hat{\boldsymbol{\pi}}_t$ will differ from $\mathbf{e}_s$ ($s = 1, \ldots, k$, i.e. there is uncertainty as to the current regime), the generalized residuals,

$$\sum_{s=1}^{k} (\mathbf{e}_s' \hat{\boldsymbol{\pi}}_t) \left(\mathbf{x}_t - \hat{\boldsymbol{\mu}}_s - \hat{\mathbf{A}}_s \mathbf{x}_{t-j} \right),$$

[17]There are short periods of upward trending markets which are not captured as a bull regime: a feature of our econometric framework is that only protracted periods of positive and high excess stock returns lasting at least 5-7 months may be captured by the corresponding regime.

will fail to be either i.i.d. or normally distributed. Therefore standard residual-based tests will fail if focused around testing the i.i.d. properties of the residuals and will anyway run into difficulties when tests rely on their normality. However, Krolzig (1997) shows that under the assumption of correct specification, one important property ought to pin down at least the one-step ahead forecast errors,

$$\boldsymbol{\eta}_{t+1} \equiv \mathbf{x}_{t+1} - \sum_{s=1}^{k} (\mathbf{e}_s' \hat{\mathbf{P}} \hat{\boldsymbol{\pi}}_t) \left(\hat{\boldsymbol{\mu}}_s + \hat{\mathbf{A}}_s \mathbf{x}_t \right)$$

(where $\hat{\boldsymbol{\pi}}_t$ is the vector of real-time, filtered state probabilities and $\mathbf{e}_s' \hat{\mathbf{P}} \hat{\boldsymbol{\pi}}_t$ is the one-step ahead prediction of the probability of state $s = 1, \ldots, k$): $\{\boldsymbol{\eta}_{t+1}\}$ should define a martingale difference sequence, i.e.

$$E[\boldsymbol{\eta}_{t+1} | \Im_t] = 0.$$

This hypothesis is testable in standard ways, i.e. looking at the ability of elements of the information set at time t, $\Im_t$ (e.g. current excess returns, short-term interest rates, their combinations, etc.), to forecast both elements of $\boldsymbol{\eta}_{t+1}$ as well as their powers (since $E[\boldsymbol{\eta}_{t+1} | \Im_t] = 0$ is more restrictive than $Cov[\boldsymbol{\eta}_{t+1}, Y_t] = 0$, where Y_t is any variable that belongs to $\Im_t$).

We implement two types of residual-based tests. In each case, we provide intuition for what a rejection of the null of the forecast errors being a martingale difference sequence would imply in economic terms. To gain additional insight, we apply tests to each of the elements of $\{\boldsymbol{\eta}_{t+1}\}$ in isolation (i.e. to the univariate series of forecast errors concerning national stock market excess returns). We start by testing whether any lags of excess returns predict current and future forecast errors. Rejections of the null of zero predictive power, would point to misspecification in the conditional mean function implied by our MMSIAH(2,1) model in particular (but not exclusively) in the VAR order (q). While for the ISEQ and the S&P, past excess returns fail to be correlated with current forecast errors, for the FTSE100 we find that at one lag such correlation is 0.24 and with a p-value below 0.05. This is hard to interpret because in Section 3.1 it became clear that at the univariate level (and even within a MSIH(2,0)) FTSE100 excess returns hardly required any AR component. Obviously, similar restrictions apply to the ability of past forecast errors to predict future errors, i.e. on the implied serial correlation structure of the forecast errors themselves. If past forecast errors help predict future errors, improvements of the model are possible. Here we find once more that while ISEQ and S&P errors have no appreciable serial correlation structure (e.g. their Ljung-Box order 12 p-values are 0.57 and 0.14, respectively), FTSE100 forecast errors are negatively serially correlated at lag one (-0.12), which is borderline significant. All in all, especially given that FTSE100 excess returns fail to display any autoregressive structure at the univariate level, we interpret this evidence as consistent with the absence of obvious misspecifications in conditional mean functions.[18]

Next, we examine the ability of variables in the information set to predict squared forecast errors. In case of rejections of the no predictability restriction, this test can be interpreted as a test of omitted volatility clustering and ARCH effects in the model. There is only borderline evidence of some positive and significant first-order serial correlation in squared forecast errors for UK and US excess returns, while both past own and cross-excess returns fail to predict subsequent squared forecast errors. All in all, there is no evidence of a need of specifying ARCH effects on the top of making $\boldsymbol{\Sigma}_{s_t}$ a function of the state.[19]

4. Economic Significance

4.1. Dynamic links across markets: impulse response analysis

Model (1) is of course amenable to computing impulse-response functions (IRFs) at several horizons of interest. For instance, assuming $q = 1$, in (1) a unit, standardized shock to the excess return of market i, $\mathbf{e}_i$ ($i = 1,2,3$), generates the impulse response function:

$$E[\Delta\mathbf{x}_{t+h}|\Im_t] = \sum_{s=1}^{k}(\hat{\boldsymbol{\pi}}_t'\hat{\mathbf{P}}^h\mathbf{e}_s)\hat{\mathbf{A}}_s E[\Delta\mathbf{x}_{t+h-1}|\Im_t] \quad h \geq 1, \tag{5}$$

with $E[\Delta\mathbf{x}_{t+1}|\Im_t] = \sum_{s=1}^{k}(\hat{\boldsymbol{\pi}}_t'\widehat{\mathbf{P}}\mathbf{e}_s)\hat{\boldsymbol{\Omega}}_s\mathbf{e}_i$, $\hat{\mathbf{P}}^h \equiv \prod_{i=1}^{h}\hat{\mathbf{P}}$ and $\Im_t = \{\mathbf{x}_q\}_{q=p}^{t}$. $\hat{\boldsymbol{\pi}}_t'\hat{\mathbf{P}}^h\mathbf{e}_s$ is simply the $h-$step ahead prediction of the probability of state $s = 1,\ldots,k,$ where $\hat{\boldsymbol{\pi}}_t$ is the vector of state probabilities. $E[\Delta\mathbf{x}_t|\Im_t] = \sum_{s=1}^{k}(\hat{\boldsymbol{\pi}}_t'\widehat{\mathbf{P}}\mathbf{e}_s)\hat{\boldsymbol{\Omega}}_s\mathbf{e}_i$ stresses that a unit standardized shock translates into a different return shocks, depending on the current regime, where $\hat{\boldsymbol{\Omega}}_s$ is the state s Choleski decomposition of the regime-specific covariance matrix, $\hat{\boldsymbol{\Omega}}_s\hat{\boldsymbol{\Omega}}_s' = \hat{\boldsymbol{\Sigma}}_s$.[20] Hats on all the matrices of interest stress that what we can calculate is purely an estimate of the impulse response function, based on MLE full-sample estimates of the

[18]We also examine the ability of lagged excess returns of market i to predict forecast errors of market j, $i \neq j$. There is some linear (cross-) structure only in FTSE100 errors; in particular, $t-1$ excess S&P returns predict time t FTSE100 errors.

[19]We formally test a regime switching ARCH(1) specification in which

$$\boldsymbol{\Sigma}_t = \boldsymbol{\Lambda}_{0s_t} + \boldsymbol{\Lambda}_{1s_t}\boldsymbol{\varepsilon}_t\boldsymbol{\varepsilon}_t'.$$

This specification implies specifying 18 additional parameters, the elements of the matrix $\boldsymbol{\Lambda}_{1s_t}$. A LR test resoundingly rejects this specification, consistently with our conclusion of no ARCH at the univariate level in Section 3.1.

[20]This implies that a unit, standardized shock to the excess return of national stock market i will be accompanied by contemporaneous shocks to the other markets, in accordance with the structure of the covariance matrix. The interpretation is that we must take into account that random influences on asset returns rarely appear in isolation, but tend instead to take the form of spreading bull or bear waves.

parameters. The formula has a clear recursive structure that reduces to the familiar VAR(1) impulse-response only when $k = 1$:

$$E[\Delta\mathbf{x}_{t+h}] = \hat{\mathbf{A}}^h\hat{\mathbf{\Omega}}\mathbf{e}_i.$$

(5) can be cumulated to record the total deviation of the vector of excess stock returns from their 'baseline' level, absent the assumed standardized, unit shock:

$$\sum_{f=1}^{h} E[\Delta\mathbf{x}_{t+f}|\Im_t] = \sum_{f=1}^{h}\left[\sum_{s=1}^{k}(\hat{\boldsymbol{\pi}}_t'\hat{\mathbf{P}}^f\mathbf{e}_s)\hat{\mathbf{A}}_s E[\Delta\mathbf{x}_{t+f-1}|\Im_t]\right] \quad h \geq 2.$$

These definitions obviously admit an immediate extension to the case of model (3).

An IRF analysis appears particularly justified in our study, as the presence of a VAR component in the model providing the best fit to the data implies in principle that delayed linkages exist across national markets. However, the structure of (1) should make it clear that pure shocks to national stock markets are hard to define and highly counterfactual: our estimates of $\hat{\mathbf{\Sigma}}_s$ in both regimes implies a positive (and in the bear state, substantial) correlation across markets that should be taken into account. Moreover, even though many VAR coefficients turned out to be statistically significant in Table 3, it remains to be seen whether the interactions among significant and insignificant coefficients delivers IRFs that are 'estimate' accurately enough to deliver economically meaningful results.

Figure 4 starts by showing the IRFs of a one-standard deviation shock to each of the three national stock markets when the initial state is bull. The figure contains nine distinct plots which should be read in the following way: each row of plots shows the effects of a one-standard deviation shock on the three markets. The graphs also report 95 percent confidence bands obtained using (parametric) bootstrapping methods.[21] Shaded areas inside the IRFs highlight horizons h for which the null of no statistically non-zero effect may be rejected (i.e. these are regions over which the confidence bands fails to be so wide to include the zero). In the bull state, very few shocks have persistent, cumulative impact. In particular, a one-standard deviation increase in US excess returns tends to be quickly absorbed by the US market and leave a small cumulative impact of only 0.1 - 0.2 percent after 2-3 months to then decline to an overall effect of approximately -0.2 percent, which is however not significantly different from zero. A US shock has instead a rather small and

[21] A large number (5,000) of IRFs are generated in correspondence of a given type of shock (and initial state): each IRF is computed by randomly drawing (for $h \geq 1$) both regimes and state-specific shocks from the estimated two-state models in Table 3. The 95 percent bands are obtained by reporting the 2.5 and 97.5 percentiles of the distribution of the responses in correspondence for each h.

transitory, but still significant positive effect on UK excess returns (roughly -0.2 percent at 2-3 months). Consistent with the small coefficient in Table 3, a US shock fails to significantly impact the ISEQ. Finally, a UK shock has only significant effect on itself, with an interesting sinusoidal shape in the cumulative effect, that starts with the same sign as the shock and then changes sign at a 2-3 month horizon. As expected, a Irish shock has effect only on the ISEQ, with a cumulative pattern similar to the US one, although the effect are larger (e.g. the long-run impact is -0.5 percent, not statistically significant).

Figure 5 repeats the experiments in Figure 4, when the initial state is bear. Results are qualitatively similar, although the magnitudes involved are much larger. This is fully consistent with the fact that many of the estimated VAR coefficients are larger in the bear state. For instance, a time 0 shock to excess ISEQ returns is persistent and generates a short-term effect of approximately 1.4 percent while the cumulative effect is just below 2.2 percent. We also produced (unreported) IRFs for the case in which the initial state is unknown and the state probabilities are initialized to their ergodic (long-run) counterparts. In this case the statistically significant responses are limited to the impact of shock in one market to the market itself.[22]

Overall, the result that weak (in the bear state) or ambiguous (in their statistical strength) cumulative responses follow sizeable shocks in the three stock markets is consistent with the commonly maintained notion that the linear (vector autoregressive) structure present in international stock returns hardly allows one to find low frequency evidence of systematic, delayed reactions of national stock markets to other markets (see e.g. Solnik and McLeavey, 2004). However, other patterns of co-movement have been isolated, patterns that essentially rely on bull and bear states being common across markets. The remaining sub-sections characterize these commonalities and explore the portfolio implications of our multivariate switching model.

4.2. Time-varying predicted risk premia and second moments

Another obvious way in which we can gauge the economic implications is by calculating the one-step ahead predictions of risk premia and volatilities characterizing the three stock markets. These are obviously crucial pieces of information relevant to portfolio mangers interested in international portfolio diversification when a rampant, high-return emerging market belongs to the menu. To this purpose, we proceed to the recursive estimation of our two-state regime switching VAR(1) model over the period 1995:01 - 2004:12. This means that the first estimation uses data for the interval 1978:05 - 1995:01 (i.e. 201 observations), the second for 1978:05 - 1995:02 (202 observations), etc. This recursive updating of the parameter estimates captures the

[22] Since the ergodic probability of the bear state exceeds the one for the bull state, the ergodic IRFs are similar to those obtained for the bear state.

learning of an investor who uses the model to characterize the properties of international equity markets.

Figure 6 shows one-step ahead predicted risk premia, volatilities, and correlations resulting from such a recursive updating process.[23] Clearly, risk premia tend to substantially fluctuate over time, and are sometimes negative even only for relatively short periods of time. In particular, two different periods can be easily isolated: during 1995 - 1998 and then again from mid-2003 to 2004, predicted risk premia are generally positive and scarcely volatile, always falling in the narrow range 0 - 3 percent per month; on the contrary, over 1999-2003 (and in particular in 2001 and 2002) risk premia appear extremely volatile and often turn negative, with one-month ahead spikes below -5 percent. Additionally, the predicted risk premia tend to move in a largely symmetric fashion across stock markets. Although the plot allows one to detect a few episodic differences, they never exceed 0.3-0.5 percent per month, in absolute value. This implies that in a two-state VAR(1) model, the specific emerging, small open economy features of the Irish stock market fail to be reflected in systematically higher or different risk premia.

The second panel of Figure 6 offers a similar picture for predicted monthly volatilities of excess returns in each of the three markets. Differently from risk premia, volatilities are systematically different across national markets: the ISEQ is always predicted to be most volatile market, with forecasts between 3.5 and 5.8 percent per month; the FTSE 100 follows and displays a considerably wider range of variation, 2.7 to 5.5 percent; the S&P 500 is more stable with modest fluctuations in the range 3 - 4 percent. A few differences appear to be related to time. For instance, the three volatility series start out relatively distinct in the mid-1990s, but after 1998 the UK stock market displays high variation and in some periods seems to mimic the high volatility dynamics of the ISEQ (e.g. 1999 and 2001), while in others it actually settles to the low volatility implied by the S&P 500 (e.g. from mid-2003 to 2004).

The last panel of Figure 6 shows the dynamics of the predicted, one-month ahead correlations between the ISEQ and the two major Anglo-Saxon stock markets.[24] Also in this case, while over 1995-1997 the anticipated correlation between ISEQ and FTSE 100 and S&P 500 were similar and relatively moderate (around 0.4), after 1998 the pairwise correlation with the FTSE 100 becomes systematically higher than the

[23]While predicted risk-premia are simply calculated as a predicted-probability weighted average of state-specific risk premia, predicted volatilities adjust for possible switches in means between t and $t+1$ as shown by Timmermann (2000). The same applies to the correlations presented later on.

[24]An equivalent plot concerning the pair-wise correlation between FTSE and S&P excess returns is omitted to save space and is available upon request. It shows a pair-wise correlation that oscillates in the narrow range 0.4-0.6.

one with the S&P. While the former correlation is generally high and often exceeds 0.5, the latter gravitates around 0.3, and in some months it drifts towards zero. This means that for most of the sample the ISEQ appears to offer appreciable hedging benefits vs. the US national stock market and moderate ones vs. the UK market. Interestingly, our model fails to imply that the correlations between the Irish market and the two major markets would be drifting up in time; to the contrary, the end-of-sample implied correlations of 0.3 - 0.4 are similar to those characterizing the mid-1990s and may imply enormous diversification benefits.

Once values for predicted risk premia and volatilities are available, it becomes natural to proceed to recursively calculate one-month ahead predicted Sharpe ratios, which give an indication for the recursive behavior over time of the expected reward-to-risk ratio. In the following we specialize to the viewpoint of a US investor, i.e. compute the predicted Sharpe ratio as:

$$\widehat{SR}^{i}_{t+1}|\Im_t = \frac{E[x^i_{t+1} + r^i_t|\Im_t] - r^{US}_t}{Var[x^i_{t+1}|\Im_t]}, \tag{6}$$

where $E[x^i_{t+1} + r^i_t|\Im_t]$ and $Var[x^i_{t+1}|\Im_t]$ are computed using $\hat{\boldsymbol{\pi}}_t \in \Im_t$, the vector of recursive state probabilities. $E[x^i_{t+1} + r^i_t|\Im_t] - r^{US}_t$ converts local currency net stock returns into excess returns in the perspective of a US investor, with both r^i_t and r^{US}_t known at time t.[25]

Given our finding in Section 4.2 that the predicted risk premia are relatively close to each other over our sample while heterogeneity exists in the dynamics of predicted volatilities, it seems clear that Sharpe ratio forecasts will be mostly driven by the time variation in the latter. However, since (6) comes in the form of a ratio and not of a simpler difference, it is unclear whether heterogeneous volatility dynamics will be sufficient to induce large differences. Results in Guidolin and Hyde (2007) show that the ratios fundamentally inherit the dynamic behavior of predicted expected returns. In practice, between 1995 and mid-1998 the predicted Sharpe ratios remain positive in the three countries and oscillate around an average of approximately 0.4, which seems to be a rather typical value for bull markets. If any, over this period it is the UK market that displays the highest Sharpe ratio, although differences are generally small, between 0.05 and 0.2. From mid-1998 and until the end of the sample (but the peak is reached in 2002-2003), the predicted reward-to-risk ratio becomes highly volatile and often breaks into the negative numbers.

These results suggest two preliminary conclusions. First, the ISEQ seems to compensate risk in ways that are perfectly consistent with the ratios that are typical of major, developed markets. This means that the

---

[25]Notice that $\widehat{SR}^{i}_{t+1}|\Im_t$ is in fact the ratio of two predicted moments (or functions thereof) and not a direct implication of the two-state model.

differences in volatilities apparent in Figure 6 are in the end small enough to go undetected by the corresponding Sharpe ratio. Second, a situation in which correlations are systematically below 1 (between 0.3 and 0.6, see Section 4.2) and in which Sharpe ratios are essentially similar across markets suggests the existence of enormous potential for international portfolio diversification. Section 4.4 tests this conjecture.

4.3. Implications for optimal portfolio decisions

In this section we proceed to the recursive calculation of optimal mean-variance portfolio weights and assess the comparative (pseudo) out-of-sample portfolio performance of our two-state regime switching model vs. a few benchmarks of common usage. Assume an investor has preferences described by a simple mean-variance functional:

$$\begin{aligned} V_t &= E_t[W_{t+1}] - \frac{1}{2}\lambda Var_t[W_{t+1}] \\ W_{t+1} &= \omega_t^{ISEQ}(1 + x_{t+1}^{ISEQ} + r_t^{IRL}) + \omega_t^{FTSE}(1 + x_{t+1}^{FTSE} + r_t^{UK}) + \omega_t^{S\&P}(1 + x_{t+1}^{S\&P} + r_t^{US}) \\ &\quad + (1 - w_t^{ISEQ} - w_t^{FTSE} - w_t^{S\&P})(1 + r_t^{US}) \end{aligned} \tag{7}$$

where λ is interpreted as coefficient of risk aversion that trades-off (conditional) predicted mean and variance of the one-step ahead wealth. At each time t in the sample, the investor maximizes V_t by selecting weights $\boldsymbol{\omega}_t \equiv [\omega_t^{ISEQ} \;\; \omega_t^{FTSE} \;\; \omega_t^{S\&P}]'$ when the predicted moments are calculated using some reference statistical model, e.g. our two-state model. Simple algebra shows that:

$$\tilde{\boldsymbol{\omega}}_t = \frac{1}{\lambda}\hat{\boldsymbol{\Sigma}}_t^{-1}\left(\hat{\boldsymbol{\mu}}_t + \hat{\mathbf{A}}_t\mathbf{x}_t + \mathbf{r}_t - r_t^{US}\boldsymbol{\iota}_3\right),$$

where the time index appended to the matrices $\hat{\boldsymbol{\Sigma}}_t$, $\hat{\boldsymbol{\mu}}_t$, and $\hat{\mathbf{A}}_t$ reflects the possibility that parameters may be a function of the state. $\mathbf{r}_t$ is a 3×1 vector that collects the short-term yields for each of the three markets. As in Section 4.3, we solve the problem from a US viewpoint, which explains why (after calculating predicted one month local returns, $\hat{\boldsymbol{\mu}}_t + \hat{\mathbf{A}}_t\mathbf{x}_t + \mathbf{r}_t$) we are subtracting r_t^{US} from predicted mean returns on all markets. Clearly, since exchange rates are ignored, this representative investor is assumed to be able to perfectly hedge her equity positions in foreign currencies. Portfolio weights are calculated recursively using the recursive parameter estimates underlying Sections 4.2-4.3.[26] (7) is solved both without and with restrictions on the admissible range for $\boldsymbol{\omega}_t$; in particular, in what follows we compute and discuss weights that prevent the investor from selling any securities short, i.e. such that $\boldsymbol{\omega}_t'\mathbf{e}_j \in [0,1] \;\; \forall t$ and $j = ISEQ$, $FTSE$, $S\&P$.

[26]For instance, $\tilde{\boldsymbol{\omega}}_{1995:01}$ is based on estimates obtained using data for the interval 1978:05 - 1995:01, etc.

As hinted at earlier, we extend weight calculations to a range of common benchmarks:

- A simple, myopic IID model,

$$\mathbf{x}_t = \boldsymbol{\mu} + \boldsymbol{\varepsilon}_t \quad \boldsymbol{\varepsilon}_t \sim N(0, \boldsymbol{\Sigma}), \tag{8}$$

in which $q = 0$, $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ are constant. Clearly, $\boldsymbol{\mu}$ and $\boldsymbol{\Sigma}$ will have to be recursively estimated over time as the vector of sample means and the sample covariance matrix, respectively.

- A single-state, VAR(1) model (see e.g. Campbell and Viceira, 1999)

$$\mathbf{x}_t = \boldsymbol{\mu} + \mathbf{A}\mathbf{x}_{t-1} + \boldsymbol{\varepsilon}_t \quad \boldsymbol{\varepsilon}_t \sim N(0, \boldsymbol{\Sigma}), \tag{9}$$

in which only risk premia are predictable according to the simple law $E_t[\mathbf{x}_{t+1}] = \boldsymbol{\mu} + \mathbf{A}\mathbf{x}_t$. In this case, variance and covariances are restricted to be constant over time.

Figure 7 starts by showing plots of recursive, one-month ahead predicted Sharpe ratios for each stock market and under each of the three models investigated. Independent of the stock market under investigation, the plots show the existence of striking differences between the IID Sharpe ratios and ratios implied by models that account for predictability. While the former model generates ratios that are small (generally between 0 and 0.15) and that change smoothly over time as a consequence of recursive updating, the predictability models induce substantial variation in Sharpe ratios, which are actually often predicted to be negative. Some differences exist also between regime switching and VAR Sharpe ratios, as the latter tend to be less volatile than the MMS ratios. Moreover, periods can be found in which the two models imply heterogeneous ratios and hence different portfolio prescriptions.

We also compare the evolution of portfolio weights induced by the three different models in the case $\lambda = 0.5$ (a plot appears in Guidolin and Hyde, 2007). Table 4 provides summary statistics. Differences are striking: the IID model generates almost no demand for stocks, independently of whether short sales are admitted or not; the only positive (but small) weights are obtained for the S&P 500 index. Clearly, this is not surprising since equities have (for instance) end-of-sample monthly Sharpe ratios of 0.05 (for the S&P 500) and lower (essentially zero for the FTSE 100). A single-state VAR(1) model generates a higher demand for stocks, although it remains moderate: 3-4 percent for Ireland and 9 percent for the S&P 500. The bulk of the portfolio remains invested in the (US) riskless asset (85 percent). Removing short-sale possibilities marginally increases the equity weights, to approximately 20 percent. Finally, a regime switching model implies larger equity weights. When short-sales are admitted, the investment in stocks is on average 40-50%. Although rich temporal dynamics can be detected and periods exist in which the net weight to all stocks ought to be negative (i.e. $w_t^{ISEQ} + w_t^{FTSE} + w_t^{S\&P} < 0$), in general there is a tendency towards a thorough diversification across the three national stock markets. Table 4 provides a more accurate description by reporting mean values of portfolio weights over our recursive exercise. The mean investment in stocks is 43 percent, with a prevalence of US and UK stocks (16 and 15 percent). However, standard deviations are high. There is some evidence that the larger variations in the predicted Sharpe ratio for US stocks may often command short position in this market, especially to finance the purchase of UK stocks.

Table 4 in fact reports summary statistics for recursive portfolio weights under regime switching also for other values of λ, i.e. 0.2, 1, and 2. However, it is clear that when short sales are permitted, the optimal weights are simply multiples of those previously obtained under $\lambda = 0.5$, since

$$\frac{\tilde{\boldsymbol{\omega}}_t(\lambda_1)}{\tilde{\boldsymbol{\omega}}_t(\lambda_2)} = \frac{\frac{1}{\lambda_1}\hat{\boldsymbol{\Sigma}}_t^{-1}\left(\hat{\boldsymbol{\mu}}_t + \hat{\mathbf{A}}_t\mathbf{x}_t + \mathbf{r}_t - r_t^{US}\boldsymbol{\iota}_3\right)}{\frac{1}{\lambda_2}\hat{\boldsymbol{\Sigma}}_t^{-1}\left(\hat{\boldsymbol{\mu}}_t + \hat{\mathbf{A}}_t\mathbf{x}_t + \mathbf{r}_t - r_t^{US}\boldsymbol{\iota}_3\right)} = \frac{\lambda_2}{\lambda_1}.$$

This is not the case when no-short sale constraints are imposed, although a rough proportionality across values of λ may be preserved. The table shows that for low λs, an investor obviously becomes very aggressive and would invest roughly 100 percent of her wealth in stocks. UK and US equities play equal roles (with weights around 35 percent), while Irish equities enter with a weight between 25 and 30 percent. Higher λ s (1 and 2) imply moderate demand for equity. In general, imposing no-short constraints has the effect of increasing the demand for the S&P 500 and to reduce the weight of the other two portfolios, an indication that the more extreme oscillations of the US Sharpe ratio may induce investors to go short in it, to finance positive demands of the two other portfolios.

Table 5 completes the analysis by showing the (pseudo) out-of-sample, one month portfolio performance under different levels of λ and for the three competing models. In particular, we report mean one-month net portfolio return, the lower and upper values of a standard 95% confidence interval (that reflects the volatility of portfolio returns over 1995:01 - 2004:11), and the implied Sharpe ratio that adjusts mean returns to account for risk. The final eight columns of Table 5 report performance measures also for portfolios that fail to include the US riskless asset, i.e. pure equity portfolios in which $w_t^{ISEQ} + w_t^{FTSE} + w_t^{S\&P} = 1$.[27] The table reports in bold the maximum values of mean portfolio returns and of the Sharpe ratio across models. Obviously, the boldface font abounds in the third panel, where performance results for the two-state regime switching VAR appear: mean performance is always superior for all

[27] The four columns concerning pure equity portfolios are identical across values of λ. The algebra of mean-variance optimization implies that when a riskless asset is available two-fund separation applies, and heterogeneous risk preferences only produce different demands for the riskless asset and a homogeneous risky portfolio.

portfolios including the riskless asset, independently of the assumed value for λ. For most values of λ and in this case quite independently of the fact that portfolios are allowed to include the riskless asset, the MMS framework also produces the best possible Sharpe ratios. For instance, when $\lambda = 0.5$ and a no short sale constraint is imposed, a regime switching asset allocation obtains a 1.26 percent per month average performance (higher than 1.20 for a VAR strategy and 0.86 for an IID one); however, some performance risk should be taken into account, as a 95 percent interval spans $[-0.7,\ 3.2]$, i.e. covers a negative region. Even adjusting for risk, the Sharpe ratio is 0.72, which is higher than those produced by competing models. In general and in a Sharpe ratio metric, the distance between the MMS model and the benchmarks tends to increase when higher values of λ s are considered: for instance, when $\lambda = 2$ the MMS ratio is 1.2, vs. 1 for both VAR and IID models. For pure equity allocations, the implied Sharpe ratios are systematically lower, but the regime switching framework still tends to systematically outperform other models.

In conclusion, not only we have found strong statistical evidence of regimes in the multivariate distribution of the three national stock index (excess) returns under investigation, but we have also evidence that such regimes are economically important insofar as they systematically improve the out-of-sample performance of a mean-variance portfolio optimization strategy. Importantly, Table 4 shows that—despite the good performance of the Irish stock market over the past 25 years—Irish stocks ought to enter the optimal portfolio, but never with dominant weights and more in virtue of the good linear hedging properties (low correlation) of the ISEQ vs. other stock indices than as a result of exceptional Sharpe ratios.

4.4. Joint Dynamics of Excess Stock Returns and Spot Exchange Rates

As a way of performing a robustness check, we extend our results to the case in which the monthly log-changes in the spot rates between the Irish punt vs. the US dollar and the British pound vs. the US dollar are added to the vector of excess returns to form a 5×1 vector $\mathbf{y}_t$ (i.e., $l = 2$, in the notation of Section 2). The result is a version of (3) in which spot exchange rates both linearly predict subsequent excess stock returns and at the same time contribute to the empirical characterization of the nonlinearities (regimes) required to characterize the data. Additionally, this exercise gives us an opportunity to compute Sharpe ratios and related optimal portfolio weights for a US investor who fails to hedge her exposure to foreign currency risk. In fact, in this case the law of motion of wealth in the mean-variance optimization problem becomes

$$W_{t+1} = \omega_t^{ISEQ}(1 + x_{t+1}^{ISEQ} + s_{t+1}^{punt/USD} + r_t^{IRL}) + \omega_t^{FTSE}(1 + x_{t+1}^{FTSE} + s_{t+1}^{pound/USD} + r_t^{UK}) + \\ + \omega_t^{S\&P}(1 + x_{t+1}^{S\&P} + r_t^{US}) + (1 - w_t^{ISEQ} - w_t^{FTSE} - w_t^{S\&P})(1 + r_t^{US}),$$

where $s_{t+1}^{(\cdot)/USD}$ denotes the log-change in the corresponding monthly spot rate.

For simplicity, we refrain here from conducting afresh the model specification search previously undertaken in Section 3.2 and proceed instead to simply estimate a two-state multivariate regime switching VAR(1) model generalized to include spot exchange rates. Parameter estimates are reported in Table 6. Once more, panel A presents a benchmark single-state VAR(1) model, while panel B is devoted to the regime switching estimates. Panel A gives already interesting indications: the linear (vector autoregressive) predictive power of exchange rates for one-month ahead excess stock returns appears to be rather weak, both in terms of statistical significance as well as in economic terms. For instance, a 1 percent depreciation of the British pound vs. the US dollar only implies a 0.10 percent decline in the FTSE index, even though the corresponding coefficient has a p-value below 0.01. US excess stock returns are hardly affected by the exchange rate of the dollar vis-a-vis the British pound and (quite obviously) the Irish punt. Finally, within a linear framework, stock returns have no power whatsoever to explain the subsequent dynamics of exchange rates. Similar to Table 3, Irish excess returns keep displaying a positive serial correlation coefficient, while the opposite applies to UK excess returns. All exchange rates are positively serially correlated.

Panel B presents regime switching estimates. Both states are persistent, with an average duration of 9 months. Their interpretation is made easy by computing within state unconditional (monthly) means:

$$E[\mathbf{y}_t|S_t = 1] = [0.14\ 0.22\ 0.13\ 0.28\ 0.36]'$$
$$E[\mathbf{y}_t|S_t = 2] = [0.66\ 0.62\ 0.54\ 0.38\ 0.05]'$$

(the first three elements are equity risk premia). It is natural to start the interpretation from the second state, when risk premia are high (between 6 and 8 percent in annualized terms). Unreported state probability plots clearly identify this state with the period 1978-1979, 1987-1988 (although the state is episodically overturned by a few short bear reversals, like October 1987), 1994-1999, and the recent 2003-2004 period. Interestingly, in this bull regime the British pound quickly depreciates while the punt is essentially stable. In this state, the depreciation of both the punt and the pounds predicts subsequently lower excess stock returns in Ireland, while UK excess returns remain sensitive to the British pound exchange rate only. Conversely, both spot exchange rates seem to be affected by past UK excess returns. However, all the estimate vector autoregressive coefficients remain small from an economic viewpoint.

The first state is a regime of moderate risk premia (between 1.6 and 2.5 percent on an annualized basis). State probability plots confirm that this regime picks up episodes of stable or even declining stock markets, like 1980-1981, 1984-1986, the early 1990s, and the bear period 2000-2002. In this state, exchange rates produce highly significant and economically non-negligible effects on subsequent excess stock returns. For instance a 1 percent depreciation of the British pound would (coeteris paribus) lead to an increase in ISEQ and FTSE excess returns equal to 1.2 and 0.8 percent, respectively. Importantly, all such coefficients turn out to have opposite (positive) sign when compared to the corresponding effects in the first state. In this case, the British pound also has a positive (but rather weak) effect on the US stock market. This shows that simple and misspecified linear VAR models end up hiding important linkages between exchange rates and stock prices: one regime (bear) exists in which past changes in spot exchange rates are rather important in shaping the direction in which equity valuations move; in general, depreciating currencies lead to higher stock prices. Since in the bull state the effect is weaker and shows a different partial derivative – i.e. depreciating currencies depress otherwise bullish markets – it is not surprising to find that the two opposing effects cancel out when a linear model – therefore unable to distinguish between regimes – is estimated.

We use this extended model to check whether our previous conclusions depend in any way on the specification of a model limited to stock returns, as well as on the viewpoint of a perfectly hedged US investor.[28] In particular, we compute optimal portfolio weights similarly to Section 4.4, when the investor fails to be perfectly immunized against exchange rate risk, and instead her choices fully reflect the forecast implications of (3). We find that our earlier results are robust. For the case $\lambda = 0.5$, Table 4 reports basic summary statistics for portfolio weights: obviously, extending our model to include spot exchange rates does not radically change portfolio implications, although we notice that accounting for the randomness in exchange rates would lead one un-hedged US investor to reduce her investment in foreign stocks. Table 5 shows instead realized, one-month ahead portfolio outcomes. Interestingly, explicitly accounting for exchange rate dynamics ends up enhancing realized mean portfolio returns (e.g. under a no-short sale constraint and assuming $\lambda = 0.5$ increases mean realized returns by 0.20 percent per month), although the same effect extends to the volatility of realized portfolio returns, with the result that Sharpe ratios are generally lower than those obtained under a simple two-state VAR model for excess stock returns only.

5. Conclusions and Extensions

In spite of the stellar (+15% a year), "Tiger-like" performance of the Irish stock market during the 1990s and moderate correlations between Irish, UK, and US equity returns, the potential benefits from international

[28] Notice there is already one sense in which the extended model has confirmed our previous conclusions: we keep finding two regimes with a roughly equivalent interpretation, while the dynamic linkages between the three stock markets are hardly influenced by the expansion of $\mathbf{y}_t$ to include changes in spot rates.

diversification into the stock markets of small open economies such as the Irish one, may be considerably smaller than what is commonly thought. In fact, the joint process of Irish, UK, and US excess equity returns is characterized by substantial nonlinearities—in the form of regimes—that make the long-run, overall 'association' among the ISEQ, the FTSE 100, and the S&P 500 higher than what one could measure in a simple (too simple) linear framework. In particular, we find that state co-movements involving the three markets depress the optimal mean-variance weight carried by ISEQ stocks to at most one-quarter of the overall equity portfolio. In this sense, it seems that international bull and bears shared by the more developed US and UK equity markets involve the Dublin's stock exchange so heavily to greatly reduce the mean-variance (utility) gains available through equity investments in Ireland. This is *what* tames, i.e. reduces its importance for diversification purposes, the Celtic Tiger in an asset allocation perspective.

Several extensions of our framework would be of interest. For instance, Kim *et al.* (2005) have reported that bi-variate ARMA-EGARCH methods would offer evidence of a regime shift in the integration of twelve national stock markets following the creation of the EMU. Aggarwal *et al.* (2004) report similar results for European stock markets and also highlight the importance of the EMU in the integration process. Yang *et al.* (2006) use bi-variate GARCH methods to conclude that correlations among national stock markets have been increasing and that correlations are positively related to conditional volatility. Although our focus was dominantly on the portfolio implications of a small open economy stock market displaying linear and nonlinear dynamic linkages with two major international markets, our analysis implies that correlations (and other forms of association) have been simply time-varying, not necessarily increasing over time (see e.g. Figure 6),[29] while our tests have shown that a two-state VAR hardly requires ARCH-type components. Although our paper has used models in the multivariate switching class to capture nonlinearities, other choices of nonlinear frameworks would have been possible. For instance, Bredin and Hyde (2007) use smooth transition regression models. Finally, while our paper has explored the possibility that exchange rates may have predictive power for stock returns, other popular predictor variables come to mind, such as short-term interest rates. Guidolin and Hyde (2007) explore a similar portfolio application when monetary policy carries time-varying effects on stock returns.

[29]This is consistent with recent findings in Goetzmann *et al.* (2005) by which international equity correlation have moved dramatically over the last century and half so that diversification benefits to global investing are simply not constant, but not necessarily declining. Adjaouté and Danthine (2005) report that low frequency movements in the time series of return dispersions for European stocks are suggestive of cycles and long swings in return correlations that fail to imply a declining importance of international diversification.

Table 3

Estimates of multivariate regime switching VAR(1) model for excess stock returns

The table reports the estimation output for the MMSIAH(*k*,*p*) model:

$$\mathbf{x}_t = \boldsymbol{\mu}_{s_t} + A_{s_t}\mathbf{x}_{t-j} + \Sigma_{s_t}\boldsymbol{\varepsilon}_t$$

where $\boldsymbol{\mu}_{s_t}$ is the intercept vector in state s_t, A_{s_t} is the matrix of autoregressive coefficients associated to lag $j \geq 1$ in state s_t and $\varepsilon_t = [\varepsilon_t^1\ \varepsilon_t^2\ \varepsilon_t^3]' \sim$ I.I.D. $N(0, I_3)$. s_t is governed by an unobservable, discrete, first-order Markov chain that can assume *k* distinct values (states). The data are monthly. The sample period is 1978:05 – 2004:12. The data reported on the diagonals of the correlation matrices are annualized volatilities. Asterisks attached to correlation coefficients refer to covariance estimates.

Table 4

Summary statistics for recursive mean-variance portfolio weights under a multivariate two-state VAR(1) model for excess stock returns

The table reports summary statistics for the weights solving the one-month forward mean-variance portfolio problem:

$$\max_{\mathbf{w}_t} E_t[W_{t+1}] - 1/2\,\lambda\, Var_t[W_{t+1}],$$

where W_{t+1} is end-of period wealth and λ is a coefficient of (absolute) risk aversion that trades-off mean and variance. The problem is solved recursively over the period 1995:01 – 2004:12 using in each month updated parameter estimates obtained over an expanding sample that starts in 1978:05. The table shows means and standard deviations for recursive portfolio weights. For the case of λ = 1/2, the table also reports summary statistics for portfolio weights obtained under two benchmark statistical models: the IID (myopic case) in which there is no predictability and means, variances, and covariances are simply updated over time; the single-state, the VAR(1) case in which only risk premia are predictable. Finally, the problem is solved from the point of view of a perfectly hedged US investor, i.e. the riskless interest rate is a short-term US yield.

	Statistic	Short Sales Admitted				No Short Sales

Table 5

Summary statistics for recursive mean-variance portfolio performances under a variety of models for excess stock returns

The table reports summary statistics for the 1-month portfolio return based on weights that solve the one-month forward mean-variance portfolio problem:

$$\max_{\mathbf{w}_t} E_t[W_{t+1}] - 1/2\,\lambda\, Var_t[W_{t+1}],$$

where W_{t+1} is end-of period wealth and λ is the coefficient of (absolute) risk aversion. The problem is solved recursively over the period 1995:01 – 2004:12 using in each month updated parameter estimates (and when appropriate, filtered state probabilities) obtained over an expanding sample that starts in 1978:05. The table shows means and standard deviations for recursive portfolio weights. The problem is solved from the point of view of a perfectly hedged US investor, i.e. the riskless interest rate is a short-term US yield. Boldfaced values for means and Sharpe ratios indicate the best performing model.
