Abstract:

We measure cost efficiency of 202 Czech municipalities of extended scope in period 2003-2008. The study is the first application of overall efficiency measurement of the local governments in the new EU member states, and the second in postcommunist countries. We measure government efficiency through established quantitative and qualitative indicators of the provision of education, cultural facilities, infrastructure and other local services. First, we employ non-parametric approach of the data envelopment analysis and adjust the efficiency scores by bootstrapping. Second, we employ the stochastic frontier analysis and control for effects of various demographic, economic, and political variables. We compare scores under our preferred specification, i.e. pseudo-translog time-variant stochastic-frontier analysis with determinants, with alternative scores. The determinants that robustly increase inefficiency are population size, distance to the regional center, share of university-educated citizens, capital expenditures, subsidies per capita, and the share of self-generated revenues. Concerning political variables, increase in party concentration and the voters' involvement increases efficiency, and local council with a lower share of left-wing representatives also tend to be more efficient. We interpret determinants both as indicators of slack, non-discretionary inputs, and unobservable outputs. The analysis is conducted also for the period 1994-1996, where political variables appear to influence inefficiency in a structurally different way. From comparison of the two periods, we obtain that small municipalities improve efficiency significantly more that large municipalities.

Keywords: Public spending efficiency, Data Envelopment Analysis, Stochastic Frontier Analysis, local governments

1 Introduction

Efficiency of local public spending is a topic of recent interest in public and urban economics. For practitioners, robust efficiency measures serve as performance benchmarks that help to discipline and improve local public management; for academic economists, the production function approach embedded in the efficiency measures allows to measure and explain the government's bias to the production of publicly irrelevant outputs, and separate between competing explanations why the local governments increase public spending.

In the last two decades, measuring efficiency in local governments became widespread particularly within individual European countries. Recent evidence is available from Belgium (Vanden Eeckaut et al. 1993; De Borger, Kerstens 1996; De Borger et al. 1994; for Flanders, see Geys, Moesen 2009a, 2009b), Finland (Loikkanen, Susiluoto 2005), Germany (Geys et al. 2010; Kalb 2010), Italy (Boetti et al. 2010), Norway (Borge et al. 2008), Portugal (Afonso, Fernandes 2006, 2008), and Spain (Arcelus et al. 2007, Balaguer-Coll et al. 2007; Gimenez, Prior 2007). Out of Europe, recent studies cover, inter alia, the large U.S. cities (Grossman et al. 1999; Moore et al. 2005), Canadian municipalities (Pollanen 2005) as well as Australian municipalities (Worthington, Dollery 2002).

There are three reasons to measure efficiency of local governments rather than central governments: (i) Unlike cross-country comparisons of public sector efficiency, single-country studies feature relatively consistent statistics and suffer less from unobserved heterogeneity, hence more likely comply with the restrictive assumption of a homogenous production function. (ii) Municipalities implement many "state-delegated" powers assigned by the central government, where the only room for manoeuvre is on the cost side. (iii) At the local level, policies are more means-focused than ends-focused also because of the absence of many instruments that address the main socio-economic (distributive) conflicts, such as income taxation, and therefore are more related to the provision of (local) public goods.

We empirically asses cost efficiency of 202 municipalities of extended scope in the Czech Republic over the period 2003–2008. This period features institutional and territorial stability, unlike the reform years 2000–2002. By measuring efficiency comprehensively instead by sector-specific scores, we avoid an issue of fungibility of spending and misclassification into spending categories that is quite frequent at the local level. To our knowledge, our study is a first comprehensive local government efficiency exercise in the new EU members states, and the second in the post-communist region (cf. Hauner 2008). The analysis of determinants allows us to assess whether patterns of efficiency in municipalities of a post-communist country differ from those in the culturally and institutionally not so distant Western European countries (e.g., Belgium, Finland, or Germany); it also permits to briefly observe the evolution in performance and efficiency from 1990s to 2000s.

We apply both parametric and non-parametric efficiency measurement methods, and also explain why the most refined parametric method (stochastic frontier analysis with a timevariant Pseudo-Translog specification and determinants) is, at least in our setting, preferred to the best non-parametric method (data envelopment analysis with variable returns to scale and bias corrected by bootstrapping). We end up with efficiency scores and compare with alternative methodologies. For each individual municipality, our procedure allows to isolate away separately (i) the effect of including determinants and (ii) the effect of assuming stochastic parametric versus deterministic non-parametric methodology, which is crucial for the interpretation of individual scores and benchmarking.

This analysis of the slack is conditional on the proper definition of the relevant set of outputs; we focus on basic services and maintenance of infrastructure, including also selected quality indicators. As is typical in the literature, the efficiency scores thus have to be interpreted as the provision of observable core services. In the parametric approach, we employ and control for effects of various demographic, economic, and political variables. Important ones are population size, distance to the regional center, education, fiscal capacity, and local political competition. We interpret determinants both as effects upon the slack and the presence of non-discretionary inputs and unobservable outputs.

With a preferred method, we replicate the analysis also for the period 1994–1996, with a few changes. The effect of determinants is quite similar, with exception of political variables that appear to influence inefficiency in a structurally different way. From comparison of the two periods, we also obtain that small municipalities improve efficiency significantly more that large municipalities. As a result, initially low differences between efficiency scores, especially between medium-size and large municipalities, have magnified over time.

The paper proceeds as follows. Section 2 briefly outlines the methodology on estimation of efficiency scores, and Section 3 presents the dataset. Section 4 gives the non-parametric results with year-specific scores and their averages. The key Section 5 delivers the parametric results for panel data with determinants, evaluates the role of determinants, and compares the available methods. Section 6 analyzes efficiency in 1990s. Section 7 concludes.

2 Methodology

Although discretion exists in many variables in the researcher's menu of choices, a key decision in an efficiency estimation is always whether cost efficiency of decision-making units will be measured in the class of non-parametric or parametric methods. A non-parametric approach generates the best practice frontier by tightly enveloping the data, where this envelopment is achieved by solving a sequence of linear programs. The main advantage of the non-parametric approach is the absence of the apriori specification of the functional form of the frontier. Two main techniques stand out within the non-parametric approach, Data Envelopment Analysis (DEA) and Free Disposal Hull Analysis (FDH). DEA, initiated by Farrel (1957) and made widespread by Charnes et al. (1978), assumes that the production frontier is convex, while FDH, suggested by Deprins et al. (1984), drops the convexity assumption. These methods are fully deterministic, and the entire deviation from the frontier is interpreted as inefficiency.

The parametric approaches establish the best practice frontier on the basis of a specific functional form applied in an econometric estimation. Moreover, the deviations from the best practice frontier derived from parametric methods can be interpreted in two different ways. While deterministic approaches interpret the whole deviation from the best practice frontier as inefficiency (corrected OLS method), stochastic frontier models proposed by Aigner et al. (1977) and Meeusen and van den Broeck (1977) decompose the deviation from the frontier

into an inefficiency part and a stochastic term. In addition, environmental variables can be easily treated with a stochastic frontier, whereas commonly used two-stage DEA models (e.g., OLS and Tobit censored regression) ignore serial correlation of efficiency scores (Simar, Wilson 2007).¹

We can examine efficiency from an input or an output perspective. Input-oriented efficiency measures how inputs can be contracted given output levels, while output-oriented efficiency keeps input fixed and explores a possible output expansion. The choice of the orientation is not entirely arbitrary; the orientation is better put on the side that is more subject to a discretionary choice. In the case of Czech municipalities, the policy-makers more likely influence spending levels (inputs) than the size of infrastructure, number of public facilities and amount of population (outputs), hence input-oriented efficiency is more appropriate.

2.1 Data Envelopment Analysis

Data Envelopment Analysis (DEA) determines the most efficient municipalities in the sample. These form the "best practice frontier" in a multi-dimensional space defined by inputs and outputs. The relative efficiency of municipalities lying under this best practice frontier is computed by their deviations from the frontier. The exact procedure is described in Section A.1 in Appendix. We estimate technical efficiency with respect to a production frontier with costs as input.

Either of three restrictions on the returns to scales applies: Constant returns to scale (CRS) are reasonable if a proportional increase in inputs is expected to result in a proportional increase in outputs. With sufficiently high fixed costs of operation, smaller municipalities will tend to have higher average costs for outputs and larger municipalities exploiting scale economies will tend to have lower average costs. Hence, it can be more appropriate in our case to select variable returns to scale (VRS) or non-increasing returns to scale (NIRS). We compute efficiency estimates under all three returns-to-scale assumptions to illustrate differences and potential drawbacks of each particular assumption (see also Banker et al. 1996; Simar, Wilson 2002).

Given that DEA is by definition a deterministic method, the efficiency estimates are subject to uncertainty due to sampling variation. To allow for statistical inference, we apply homogenous bootstrap by Simar and Wilson (2000). The technique is described in Section A.3 in Appendix.

2.2 Stochastic Frontier Analysis

Stochastic frontier analysis (SFA) estimates the frontier parametrically, allowing for the error term, and possibly introducing also environmental variables in the estimation. As it represents our preferred method, we introduce the analysis in more details (see also Aigner et al. 1977). We consider input-oriented efficiency where the dependent variable is the level of spending, and independent variables are output levels. The method assumes a given functional form

¹Recent contributions of Daraio and Simar (2005, 2007) propose conditional DEA estimators offering a one-stage approach for treating environmental variables.

for the relationship between costs y and outputs \mathbf{x} , usually Cobb-Douglas or Translog. For a municipality i, a stochastic frontier production function model is given as

$$y_i = f(\mathbf{x}_i) + \epsilon_i, \quad \epsilon_i = v_i + u_i. \tag{1}$$

In contrast to DEA, a deviation from the frontier is not interpreted entirely as an inefficiency. The statistical error ϵ_i is rather decomposed into noise v_i which is assumed to be i.i.d., $v_i \sim N(0, \sigma_v^2)$, and a non-negative inefficiency term u_i having usually half-normal or truncated normal distribution.² It is also assumed that $cov(u_i, v_i) = 0$ and u_i and v_i are independent of the regressors.

The Cobb-Douglas functional form for the costs writes

$$\ln y = \beta_0 + \sum_{p=1}^P \beta_p \ln x_p,\tag{2}$$

while Translog generalizes Cobb-Douglas form by adding cross-products,

$$\ln y = \beta_0 + \sum_{p=1}^{P} \beta_p \ln x_p + \frac{1}{2} \sum_{p=1}^{P} \sum_{q=1}^{P} \beta_{pq} \ln x_p \ln x_q.$$
(3)

Battese and Coeli (1992) extend the original cross-sectional version of SFA in Eq. (1) to panel data. The model is expressed as

$$y_{i,t} = f(\mathbf{x}_{i,t}) + \epsilon_{i,t} \quad \epsilon_{i,t} = v_{i,t} + u_{i,t}, \tag{4}$$

where $y_{i,t}$ denotes costs of municipality *i* in time t = T, T + 1, ... and $\mathbf{x}_{i,t}$ is vector of outputs of municipality *i* in time *t*. Statistical noise is assumed to be i.i.d., $v_{i,t} \sim N(0, \sigma_v^2)$, and independent of $u_{i,t}$. Technical efficiency $u_{i,t}$ may vary over time

$$u_{i,t} = u_i \exp[\eta(t-T)],\tag{5}$$

where η is parameter to be estimated, and $u_{i,t}$ is assumed to be i.i.d. as truncations of zero of $N(\mu, \sigma_u^2)$. The model is estimated by maximum likelihood.³ Like Battese and Corra (1977), we introduce parameter $\gamma := \sigma_u^2/(\sigma_u^2 + \sigma_v^2)$ that conveniently represents the magnitude of

$$E[u_i|\epsilon_i] = \frac{\sigma\lambda}{1+\lambda^2} \Big[\frac{\phi(\epsilon_i\lambda/\sigma)}{\Phi(-\epsilon_i\lambda/\sigma)} - \frac{\epsilon_i\lambda}{\sigma} \Big],$$

 $^{^{2}}$ Exponential or gamma distributions are chosen less commonly, and the resulting ranking is moreover argued to be quite robust to the choice of the distribution (Coelli et al. 2005).

³SFA estimation relies on decomposing observable $\epsilon_{i,t}$ into its two components which is based on considering the expected value of $u_{i,t}$ conditional upon $\epsilon_{i,t}$. Jondrow et al. (1992) derive the conditional distribution (halfnormal) and under this formulation, the expected mean value of inefficiency is:

where $\lambda = \sigma_u/\sigma_v$, $\phi(\cdot)$ and $\Phi(\cdot)$ are, respectively, the probability density function and cumulative distribution function of the standard normal distribution, $f(u|\epsilon)$ is distributed as $N^+(-\epsilon\gamma,\gamma\sigma_v^2)$. If $\lambda \to +\infty$, the deterministic frontier results (i.e., one-sided error component dominates the symmetric error component in the determination of ϵ). If $\lambda \to 0$, there is no inefficiency in the disturbance, and the model can be efficiently estimated by OLS.

technical efficiency in the error term; if $\gamma = 0$, then all deviations from the frontier are due to noise, while $\gamma = 1$ represents the opposite case when all deviations are attributed to technical inefficiency.

In Stochastic Frontier Analysis, environmental or background variables may be included by computing the efficiency scores in the first step and then regressing them on environmental variables in the second step. The second-stage efficiency model is expressed as

$$u_{i,t} = \delta \mathbf{z}_{i,t} + w_{i,t},\tag{6}$$

where $\mathbf{z}_{i,t}$ is a vector of environmental variables of municipality *i* in time *t*, δ is a vector of parameters to be estimated, and $w_{i,t}$ is random noise. A shortcoming is inconsistency of assumptions in the two stages that leads to biased results: In the first stage, inefficiencies are assumed to be identically distributed, while in the second-stage, the predicted efficiencies to have a functional relationship with the environmental variables. Therefore, we estimate efficiency and its determinants in a single-stage (Kumbhakar et al. 1991; Reifschneider, Stevenson 1991; Huang, Liu 1994; Battese, Coelli 1995). We follow simultaneous estimation technique by Battese and Coelli (1995) who expand Huang and Liu's (1994) model for panel data context. Eqs. (4) and (6) are estimated simultaneously, and additionally, it is assumed that $v_{i,t} \sim N(0, \sigma_v^2), v_{i,t}$ is i.i.d. and independently distributed of $u_{i,t}, u_{i,t}$ is obtained by truncation at zero of $N(\delta \mathbf{z}_{i,t}, \sigma_u^2), u_{i,t} \geq 0$. Hence, environmental variables influence the mean of the truncated normal distribution of $u_{i,t}$.

3 Data

3.1 Municipalities

This section covers the institutional context for the municipalities analyzed, describes inputs and outputs, and provides descriptive statistics. To begin with, notice that time span in our sample, 2003–2008, corresponds to an exceptionally stable period, both from the economic and institutional point of view. In contrast, the preceding years 2000–2002 marked a major reform of the territorial public administration. The tax-allocation formula affecting the sources of municipalities was virtually unchanged in the period analyzed, with a minor parametric reform implemented as late as in the year 2008.

By international comparison, the Czech Republic is characterized by extreme territorial fragmentation (Hemmings 2006). Each municipality exercises both independent competencies and specific delegated powers, and the scale of operation is increased for delegated powers. The reason is that the extent of delegated powers differs with municipality administrative type. Out of 6243 municipalities, 1226 run population registration, 617 provide building permits, 388 are municipalities of the "second type", and 205 are municipalities of extended scope or "third type".

Our subject of analysis are municipalities of extended scope. These third-type municipalities constitute a specific administrative tier in the Czech government. Their origin goes back to a reform initiated in 2000 whose primary aim was to delegate a wide range of responsibilities to 14 new regional governments (NUTS 3 level) from the national level. In the second stage of the reform, 76 territorial districts were dissolved, and major part (approx. 80%) of their agenda passed to the 205 municipalities of extended scope; the minor part of former district services rests now with the 14 regions.⁴

Each municipality of extended scope administers a district comprising, on average, 30 other municipalities. Nevertheless, the third-type municipality always consists of the central town in the district,⁵ so population of municipality of extended scope constitutes a relatively large share of total population in the district; mean size of population in the municipality of extended scope is 19,497 and mean population size of the district is 40,712.

Independent competencies of a municipality include provision of primary schools and kindergartens, primary health care, local police, fire brigade, public utilities, territorial planning, maintenance of local roads, and garbage collection. Delegated responsibilities of the municipalities of extended scope encompass mainly administration of population register, issuance of identity cards, travel documents, driving licenses, water and waste management, environmental protection, management of forestry, local transportation provision, roads maintenance, social benefits payments, and social care services. The large extent of delegated responsibilities is one of the motives for input-oriented analysis. However, in some fields, the room for discretion is negligible not only on the output side, but also on the input side. Especially for mandatory social transfers, the municipality is only an administrative intermediary disbursing funds allocated by the central government to beneficiaries. In the subsequent subsection, we attempt to isolate away non-discretionary inputs and outputs.

The revenues of municipalities consist of tax revenues (in 2008, 44% on average), non-tax revenues (11%), capital incomes (7%) and subsidies/grants (38%). Most of the tax revenue is via a formula-based allocation of personal income tax, corporate income tax and value-added tax. The allocation is a per-capita payment based on population size with 17 brackets (until 2008). In municipalities, a small share of the total tax allocation is based on local incomes of the self employed and the employed. In addition, there is some leeway for local revenue through real-estate taxes (though within statutory limits) and fees. Grants are generally earmarked, and a non-earmarked grant is also provided to cover the cost of providing central-government services. There is regulation on debt, and revenues are also raised through sales of assets and flows from off-budget accounts (Hemmings 2006).

Homogeneity is definitely key in efficiency estimation. In some within-country studies (Afonso, Fernandez 2008), concern for homogeneity motivated even clustering district into subsamples. Even though we can identify and isolate away outliers and also control for determinants, a sufficiently homogeneous sample of municipalities is still necessary to eliminate the risk of omitted variable bias and the resulting misspecification. Therefore, we opt for municipalities with the extended powers: the range of responsibilities is similar, the districts administered are of a similar size, the municipalities constitute regional centers, and the sample is large enough even for single-year cross-sectional analysis. In addition, the municipalities of extended scope have much more discretion over spending than regions. Untied municipal

⁴The transfer of agenda from the former districts also explains why some statistics are still being collected and provided only at the level of the non-existent administrative districts.

⁵Figure A1 in Appendix shows geographical division of the Czech Republic into the districts administered by the municipalities of extended scope.

revenue in the form of tax and capital revenue accounts for over 70% of revenue, with earmarked grants accounting for the remainder. In contrast, a little under 40% of revenues of the regional governments are untied (Hemmings 2006).

For the purpose of homogeneity, we exclude the capital city of Prague, which is not only extremely large (with 1.2 milion inhabitants, four times the second largest city), but also constitutes one of the 14 regions of the Czech Republic, hence exercises an idiosyncratic mix of public services. From the sample, we eliminate also three other largest cities in the Czech Republic, i.e., Brno (371,000), Ostrava (308,000) and Plzen (170,000). They substantially exceed levels of population in the rest of the sample, where median is 12,212, mean is 19,497, and maximal size is 101,268. The analysis is thus employed for 202 municipalities of extended scope with population ranging from around 3,000 up to 101,000. The full list of municipalities is provided in Table A2 in the Appendix.

3.2 Inputs

The crucial task in the computation of efficiency is to properly define outputs and inputs. Following the majority of the literature (see six of out eight recent studies in Table A3), we approximate inputs by *Total current spending*. This is even more appropriate given that capital spending is highly volatile and subject to co-financing with EU Structural Funds. Our source is the complete database of municipality budgets ARIS provided by the Ministry of Finance.⁶ In the year 2008, the current expenditures represented 78% of total expenditures (if mandatory expenditures were included) and 72% of total in the absence of mandatory expenditures.⁷

To provide a look into the budget composition, we aggregated data on current expenditures into 10 groups: Administration; Agriculture; Culture and sports; Education; Environment protection; Health; Housing and regional development; Industry and infrastructure; Public safety; Social and labor market policy. Table 1 provides summary statistics of individual expenditure groups. We excluded two groups of large mandatory payments: social transfers payments and subsidies on education. The former are purely non-discretionary formula-allocated grants that are earmarked and monitored in use, and the latter are temporary transfers to municipalities in years 2003 and 2004 associated with financing of the primary schools.⁸ The last column in Table 1 shows the share of each expenditure group in the average budget after the exclusion. Prices are adjusted by CPI inflation and expressed in base year 2003.

⁶ Available at: http://www.mfcr.cz/cps/rde/xchg/mfcr/hs.xsl/aris.html

⁷ The raw ARIS data on total current spending include also huge financial operations, such as transfers to own funds, which cannot be taken into account, hence we subtracted this item (item no. 63 in functional classification of budget composition).

⁸Since the year 2005, the state subsidies to primary schools are directly transferred to schools without involvement of the municipality budgets.

	Mean	Min	Max	Share $(\%)$
Administration	73,782	18,608	413,069	32.06
Agriculture	1,604	0	$34,\!134$	0.7
Culture and sports	$29,\!433$	0	282,169	12.79
Education: discretionary	24,410	2,802	$156,\!127$	10.61
Environmental protection	20,246	0	175,700	8.80
Health	2,663	0	$62,\!300$	1.16
Housing and regional development	31,320	722	219,797	13.61
Industry and infrastructure	$27,\!177$	0	$385,\!696$	11.81
Public safety	9,719	0	$122,\!909$	4.22
Social care: discretionary	9,860	0	$107,\!973$	4.29
Total after exclusion	$230,\!163$	$36,\!451$	$1,\!498,\!326$	100.00

 Table 1. Expenditures: summary statistics

Source: ARIS database, Ministry of Finance; own calculations.

Note: Thousands (Czech koruna), N=1212.

To account for diverse cost conditions in municipalities, we alternatively work with the *wage-adjusted inputs* obtained by dividing costs by real wage. Thereby, we assume that the labor cost difference across regions may serve as a good proxy for the overall cost difference. Wage adjustment input is particularly useful in DEA where alternative ways to include wage in the production process are less convenient. The wage variable nevertheless contains sizeable imperfections: since data on gross wages are unavailable on the municipal level, we first collect wages for the 76 territorial districts for the period 2003–2005, and in 2006–2008 use wage growth in 14 regions to approximate for the district wages.

Total current spending however hides one accounting problem, which cannot be technically overcome. Generally, a municipality can provide a service by itself, or it can hire a firm to provide it. If such service requires some capital investment, then this investment translates to capital expenditures of a municipality providing the service by itself. However, a municipality hiring the firm pays invoice including depreciation of the investment and this is reflected in its current expenditures. Hence, municipalities using services of firms extensively are disadvantaged as their current expenditures are biased upwards. We believe that relative size of the depreciation in the total current spending is small and can be neglected in the baseline analysis. Still, Section B in Appendix provides a robustness check, where results with input of total expenditures (sum of current and capital) are presented and compared to the original results.

3.3 Outputs

Our preference for a comprehensive approach to efficiency is motivated by issues of fungibility of spending and misclassifications into expenditure categories. Moreover, we can swiftly disregard that some expenditure items may relate to various classes of outputs. At the same time, a single output variable may be relevant for different classes of outputs. Our variable selection is driven primarily by literature in the field (see Table A3 in the Appendix), by the country specifics of the local public sector in the Czech Republic, data availability, and by the attempt to match each specific expenditure group with a group-specific set of output variables. As agriculture and health spending is negligible in municipalities budgets, we do not seek outputs specific to these expenditure groups. In the end, we select the following 19 output variables, listed also in Table 2.

Administration Administration expenditures are related to size of *Population of the district* administered by the municipality. This reflects that a municipality with extended powers carries out many administrative services for the district as the whole. Social care expenditures reflect support for retirements homes and homes for disabled, hence we include *Old population* (population above 65 years of age) and the number of *Homes for disabled* among outputs.

Cultural facilities Expenditures on culture and sports comprise subsidies for theaters, municipal museums and galleries, libraries, sport clubs, sport events and costs on monuments preservation. The numbers of theaters, cinemas, children's centers and libraries are all summed into a variable of *Cultural facilities*; the facilities may be both private and public. Additionally, we include the number of *Municipal museums and galleries* (hence, in public ownership only), the number of *Objects in municipal monuments reserve* and the size of *Sporting and recreational area*.

Education Municipalities finance mostly primary schools and kindergartens, while grammar schools are financed mostly by the regional government. As a quantitative output, we include the number of *Pupils in primary schools and kindergartens* in a municipality. To evaluate the quality of education, we include the percentage of *Pupils who enter the upper secondary schools* at the age of 11 or 13. Thereby, we exploit the fact that children with higher skills and better education have an option to enrol for a six-year or eight-year program in the upper secondary schools with more demanding classwork.

Environment Environmental protection primarily deals with waste collection, air, soil and ground water protection, and nature preservation. *Municipal waste* corresponds to expenditures on waste collection. *Pollution area* is a variable that includes environmentally harming areas such as built-up area and arable land, *Nature reserves* is linked to spending on nature preservations, and the size of *Urban green areas* reflects spending on parks maintenance.

Housing and industry For housing and regional development we selected *Built-up area* and the number of *New dwellings* completed. The built-up area corresponds to the extra provision of services of municipal utilities and the new dwellings represent the effect of municipal financial support for housing construction. Industry and infrastructure spending contains support of businesses, costs on municipal roads maintenance, support of public transportation and costs of water resources management. As corresponding outputs we use the number of *Businesses*, the size of *Municipal roads* (close to traditionally measured surface of roads) and the number of *Bus stations*.

Public safety Expenditures on public safety involve municipal police and fire brigade services which we proxy by *Built-up area* served and *Municipal police* dummy.

	Mean	Min	Max	Source
Pupils in primary schools and kindergartens	$2,\!154$	81.96	11,944	IIE
Pupils entering secondary schools (%)	11.31	0	33.70	IIE

Note: N = 1212.

As a very preliminary analysis, we carry out individual pre-analyses for each expenditure group, shown in Table 3. In simple pooled OLS, we regress the group-relevant outputs on group expenditures and realize that R^2 falls within the range 0.70–0.90 in all but two cases; for *Housing* and *Social care*, we cannot find better outputs to increase R^2 above 0.45. Although the variable of municipal museums and galleries has negative significant coefficient, we keep it among outputs. Small municipalities, i.e. those having lower spending, are more likely to have municipal museums than big municipalities, where many private museums and galleries operate and survive more easily. Similarly, we observe negative coefficient for new dwellings which may reflect some specific characteristic of a municipality where housing construction is more developed, hence we also keep it among outputs.

When selecting outputs, we also consider tradeoff between relevance and dimensionality. Irrelevant outputs can bias efficiency scores but a high number of (especially highly correlated)

Table 3. Outputs relevant for the individual expenditure groups (pooled OLS)

outputs artificially makes many municipalities fully efficient. In addition, efficiency analysis suffers from misspecification if the model omits relevant variables or if it includes irrelevant variables. Omission of relevant variables leads to underestimation of the mean efficiency, while the inclusion of irrelevant variables leads to overestimation, and the effect of omission of relevant inputs on efficiency is more adverse compared to the inclusion of irrelevant ones (Galagedera, Silvapulle 2003).

If we err on the side of caution and include a larger set of outputs, the problem of dimensionality emerges. As a given set of observations is projected in an increasing number of orthogonal directions, the Euclidean distance between the observations necessarily must increase. Moreover, for a given sample size, increasing the number of dimensions results in more observations lying on the boundaries of the estimated production set (Simar, Wilson 2008). When dimensionality is large, unless a very large quantity of data is available, the results will have a large bias, large variance and very wide confidence intervals.

Banker et al. (1989) argues that the total number of observations should be at least three times as much as the total number of inputs and outputs. Additional tests show that the ratio of observations and dimensionality should be even higher (Pedraja-Chaparro et al. 1999). On the basis of convergence rates for DEA estimators, Simar and Wilson (2008) also conclude that

a much larger sample size is needed. In our case, we would have 202 (or 1212) observations and 20 inputs and outputs in total, therefore some reduction is reasonable.

The recent literature offers several methods how to decrease dimensionality. Geys and Moesen (2009a) seek the most representative output per each expenditure group and construct the set of outputs from a few pre-selected variables. Borge et al. (2008) apply fixed national cost weights upon 20 indicators; Afonso and Fernandez (2008) normalize to averages. Most often, however, discrimination among outputs tends to diminish importance of outputs that are largely correlated with others. Two procedures stand out in the literature. Jenkins and Anderson (2003) propose a variable-reduction procedure that decides which of the original correlated variables can be entirely omitted with the least loss of information. In contrast, principal component analysis decreases dimensionality by producing uncorrelated linear combinations of the original outputs. Adler and Yazhemsky (2010) apply Monte Carlo simulation to generalize that principal components analysis provides a more powerful tool with consistently more accurate results. Adler and Yazhemsky (2010) also suggest that the most cautious approach would be to drop principal components (PC) one-by-one until a reasonable level of discrimination is achieved or until you have reached the rule-of-thumb of at least 80% (or 76% under VRS) of the variance of the original data.

If we included all output variables as outputs, the model would have 20 (19+1) dimensions. This dimensionality would not only bring wide confidence intervals, but is also unnecessary, as many variables contain largely identical information related to the municipality size. Table A5 shows the correlation matrix of output variables, where population of a municipality is very highly correlated with the number of pupils (0.993), the number of old people (0.988), the number of businesses (0.967), built-up area (0.935), the length of municipal roads (0.916), district population (0.898), municipal waste (0.846), cultural facilities (0.831), and urban green area (0.827).

Therefore, we follow principal components analysis and use the 80-percent rule. Table 4 shows weights of the output variables that are aggregated into the first six principal components. Six components suffice to explain 80.28% of the variance in the original outputs. The first component PC1 explains more than 51.6% of the variance and represents the size effect of a municipality, as it mainly contains information of variables which are highly correlated with population; note that correlation between population in the municipality and PC1 is 0.976. Interpretation of other PCs is no as straightforward, which is the main drawback of the principal components analysis.

For some observations, the values of components can be negative. To get positive output data, we apply an affine transformation which does not affect results for DEA (Ali, Seiford 1990; Pastor 1996). Specifically, for each municipality i, we transform the original value of a component k, $Y_{k,i}$, $\forall k \in \{1, \ldots, 6\}$. We obtain the transformed value $Y'_{k,i} = Y_{k,i} + B_k$, where $B_k = |\min\{Y_{k,i}\}_{i=1}^N| + 1$ which will ensure strictly positive output data.

In the next step, we try to identify atypical observations which can be outliers and therefore distort our efficiency estimates. Outliers play a relatively important role in determining efficiency scores of other observations in the sample. By distorting efficiency frontier, some virtually efficient observations may be regarded as inefficient. To obtain robust scores, it is

	PC1	PC2	PC3	PC4	PC5	PC6

 Table 4. Principal component analysis

thus necessary to identify and potentially remove the outliers. Out of several ways how to deal with outliers, we apply both Wilson's method (Wilson 1993) and order-m frontiers by Cazals et al. (2002). A full description of the methods follows in Section A.2 in Appendix.

Firstly, we estimate Wilson statistics (Wilson 1993) to observe maximally 10 potential outliers for each year. We construct log-ratio plot of the statistics and define from 5 to 10 potential outliers with only small variance across years. When closely scrutinized, we find out that all of them are bigger cities representing regional centers with atypically high outputs. We decide to keep these data in the sample, as there are no errors in the data and these observations are atypical only because of size. We also perform an additional test for outlier detection based on order-m frontiers (Czasals et al. 2002) that scrutinizes super-efficient observations. We construct order-m efficiency scores for m = 25, 50, 100, 150, and find no super-efficient observation with a low DEA score, hence our super-efficient values do not distort efficiency rankings.

3.4 Determinants

The idea is to test for effects of various demographic, economic and political variables upon inefficiency. The determinants may represent either (i) a direct effect of operational environment on pure inefficiency (either technical or allocative), or the presence of (ii) non-discretionary inputs and (iii) unobservable outputs. Non-discretionary inputs represent production in a more or less favorable environment, e.g., stocks of human capital and other competitiveness indicators. Unobservable outputs are typically associated with service quality; given that we focus on core services with largely quantitative characteristics, extra value added of services may be produced based on the characteristics of the municipalities, such as the municipality size and the level of income. We cannot neglect the hidden inputs or outputs; once the selection of inputs and outputs is imperfect, missing inputs and extra outputs may be misinterpreted as budgetary slack in terms of low effort, over-employment and large private rents.

Unfortunately, a single determinant may theoretically bring in several effects, and extra analysis is required to discriminate between the effects. Moreover, there is vague boundary between the very definition of the effects. For instance, explaining inefficiency by slack stemming from less effort can be alternatively interpreted as lower amount of human capital, which is not slack, but lacking input. Sometimes, like in the case of education variable, we can suspect the presence of hidden inputs and hidden outputs at the same time, where each predicts the opposite sign of the education variable. Thus, our interest is restricted mainly to finding if the overall effect is robust across specifications, and based on the sign we may conclude which of the effects dominates.

In line with the literature, and based on the data available, we control for the following determinants:

Population Economies of scale and agglomeration externalities typically make the larger municipalities more efficient; moreover, small governments are less efficient than the central government due to fiscal vulnerability, or the absence of sufficient experience among local staff (Prud'homme 1995). Small governments may also be captured by local interest groups

(Bardhan, Mookherjee 2000), or prone to moral hazard if dependent on transfers from the central government (Rodden 2003). On the contrary, higher electoral control typical at the local level reduces incentives for incumbents for rent-seeking (Seabright 1996) and yardstick competition disciplines local representatives not to waste resources. In addition, the scale economies and agglomeration externalities may be larger in the private than public sector, hence the relative cost of public sector (e.g., reservation wage) increases in a large municipality. We introduce dummies for population sizes of the municipalities around three thresholds: 10,000; 20,000 and 50,000. This construction reflects that population variable as such is highly correlated with the first component. Another point is that the three thresholds are also used in tax-revenue sharing schemes, consisting of 17 population thresholds in total.

Geography The smaller is geographical distance between the municipality and the regional center, the higher is (yardstick) competition between municipalities, and also more direct access to local public goods provided by the region. Both yardstick competition and the level of consumption spillovers suggest that distance increases costs hence reduces input-oriented efficiency; evidence for the effect is, inter alia, in Loikkanen and Susiluoto (2005). We measure distance in time to reach the regional center. The spatial interdependence between efficiency scores can also be analyzed in the direct way, but based on the preliminary spatial analysis of groups of expenditures (Stastna 2009), we leave this topic to future research.

Education Municipalities with a higher share of University graduates may be more efficient either by disposing with more qualified labor, or through voters' higher and more competent control (De Borger, Kerstens 1996). Yet, university graduates may also raise productivity in the private sector, and raise reservation wage for the public sector. In addition, wealth or income effect cannot be identified directly, and education thus may involve also the income effect that leads to demand for (unobservable) high-quality services. The effect of education is thus ambiguous. We are also aware of reverse causality; the characteristics that make a municipality cost-efficient may also attract the mobile (high-skilled) citizens. A good message is at least that correlation of the variable with the output variable *Pupils entering secondary* schools is only 0.027, hence the effect of graduate education is not captured in the output variable. This point is particularly relevant in the Czech context where the parent's education is the strongest determinant of a pupil's achievement.

Fiscal capacity Low fiscal capacity may serve as a hard-budget constraint that reduces public sector wages, lowers operating surpluses and induces fiscal stress, in which case efficiency goes up. This finding is in line with earlier analyses of overall efficiency in Belgium (De Borger et al. 1994; De Borger and Kerstens 1996), and Spain (Balaguer-Coll et al. 2007).

We introduce three dimensions of fiscal capacity. The extent how municipality is dependent on *Self-generated revenues* is the direct measure of hard-budget constraint. Balaguer-Coll et al. (2007) speak in this case of "patrimonial revenues" and relate them to lower willingness to save. Next, we study whether the past *Government debt* implying larger interest and amortization payments serve as fiscal hardship that improves efficiency. Geys and Moesen (2009a) find that high debt repayments rather impinges on municipal efficiency; the idea is that past fiscal mismanagement persists over time. The last fiscal variable is *Capital spending*. A hypothesis is that fiscal vulnerability, in this case high capital investment in a given year, pushes for cost savings on the current expenditures (Athanassopoulos, Triantis 1998).

By including *Subsidies from the upper levels of government* among determinants, we answer the question whether the grants fully translate into a larger provision of public goods or if municipalities receiving higher grants tend to be less efficient (Hines, Thaler 1995). Empirical evidence supports that the option of sharing expenditures in a broader constituency induces slack, hence the "flypaper effect" is rather significant (e.g. Kalb 2010; De Borger et al. 1994; De Borger, Kerstens 1996; Loikkanen, Susiluoto 2005).

Politics Political characteristics of a municipality may largely influence its efficiency. By weak-government hypothesis, high *Political concentration* reflecting low party fragmentation should decrease narrowly focused spending, hence should improve efficiency. Some evidence nevertheless suggests that single-party municipal governments in particular are inefficient (Geys et al. 2010; Borge et al. 2008). In Czech municipalities, concentration could be measured either in the council or in the executive board led by the mayor. The members of the executive board, including the mayor and the deputy mayor, are elected from the members of the local council and represent the majority coalition. We dispose only with data on seats in the municipality council, hence our concentration index (i.e., Laakso-Taagepera or Hirschmann-Herfindahl index) exhibits downward bias relative to concentration of the executive power in the coalition.

Electoral year may be related to larger spending into additional (unobservable) outputs, hence to inefficiency. At the same time, local elections take place in the same year like national election, hence effects are confounded with the national political business cycle. Wage growth in the electoral year is nevertheless average, namely third largest in the sample out of six years.

Additionally, we consider political ideology, albeit it is not easy to identify ideology on the local level. We prefer to measure the share of municipal-council representatives from *Left-wing* parliamentary parties (Social Democrats and Communists) out of representatives from all parliamentary parties. Geys et al. (2010) find that the high share of left-wing parties is associated with higher efficiency. We expect the opposite; the left-wing parties in the Czech Republic have an older and less educated electorate, and this should represent less monitoring and higher level of the social services, which are in our dataset unobservable output variables. Moreover, ideological variable may also represent (un)willingness to introduce high-powered incentives in the public sector.

Finally, we include two variables that are related to the interest in monitoring and shaping local politics. The first is the share of seats of *Parliamentary parties* in the municipality council. The second is voters' involvement measured by *Turnout* in municipal elections (see Geys et al. 2010; Borge et al. 2008). While the former is expected to increase costs, the latter should improve efficiency. Table 5 presents statistics of potential determinants; more information about the data follows in Table A6 in the Appendix. Correlation matrix of the determinants in Table A7 features generally very low degrees of correlation. Only two patterns stand out. In small municipalities (below 10,000 inhabitants), we find less university-educated people (-0.378), less votes for parliamentary hence more votes for local parties (-0.331) and bigger voters' turnout (0.661). In contrast, large municipalities (above 50,000 inhabitants) attract better educated citizens (0.385), lead to more concentrated political competition (0.233) of parliamentary rather then local parties (0.197), and local elections have lower turnout (-0.395).

4 Non-parametric efficiency

4.1 General results

This section presents cross-sectional results computed by Data Envelopment Analysis in the years 2003–2008. We allow for constant (CRS), variable (VRS) and non-increasing returns to scale (NIRS). Figure 1 presents the distributions of efficiency scores where we average year-specific municipality scores over the 2003–2008 period. As outputs do not vary too much over time, averaging scores computed for each year can smooth errors on the input side. Unlike the upper three panels, the bottom three panels in Figure 1 adjust for wage differences.

The distribution of CRS scores substantially differs from that of VRS and NIRS. The distributions of VRS and NIRS scores are very similar, hence municipalities very rarely operate on the part of production function with increasing returns to scale. Wage adjustment does not introduce major differences in either case; the distributions with adjustment are only a bit smoother suggesting that some extreme efficiency scores can be attributed to relatively (un)favorable wage conditions in the municipality.

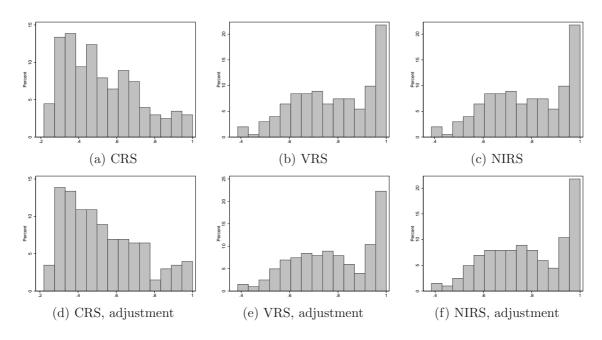

Figure 1. Distributions of DEA efficiency scores: 2003–2008 averages

Concerning the case without adjustment, the mean value of CRS score is 0.52 and minimum is 0.22. There is only single observation which is fully efficient under CRS for the whole period. For VRS, both mean value (0.79 > 0.52) and minimum (0.39 > 0.22) increase, as by construction of the VRS frontier, the observations are closer to the VRS frontier. The amount of fully efficient municipalities under VRS varies from 52 in 2005 to 61 in 2007 and there are 30 municipalities which stay fully efficient over the whole period. The Appendix offers descriptive statistics for individual years (Table A8), individual CRS and VRS averaged scores in the case without adjustment (Table A9) and with adjustment for wage differences (Table A10).

4.2 Population subgroups

To obtain a further insight into the differences of efficiency scores under different scale assumptions, it may be useful to explore how these differences vary across subgroups of municipalities defined by population size. Table 6 presents summary statistics and correlations for scores of municipalities if divided into four groups. We use again 2003–2008 averages and the results presented are without wage adjustment. The pattern of correlations is similar for the case with wage adjustment.

CRS scores are highly correlated with the size of population levels if measured in the full sample (-0.869). This only confirms the finding of VRS that large municipalities operate on the part of production function with decreasing returns to scale. However, size is not very indicative of efficiency if we look at within-group differences. For the two groups of above-average-sized municipalities, the correlations are -0.244 and -0.220. In other words, these municipalities form a cloud of observations far from the CRS frontier where the position

				Correlation

Table 6. Correlations of DEA efficiency scores in subgroups of municipalities

of each municipality within this cloud is almost unaffected by its population. These results suggest to use variable returns to scale assumption. However, in the presence of variable returns, a municipality is assessed only to peers that have comparable mix of outputs. If an output mix is unique to the municipality, there are no comparable peers, and the municipality is automatically assigned full efficiency. In particular for a small group of large municipalities, their efficiency is driven up by the lack of appropriate benchmark. Indeed, within the group of large municipalities, the correlation between size and VRS score is 0.527.

When correlations between VRS (or NIRS) scores and population are further scrutinized, we can see that in the full sample and within the groups of below-average-sized municipalities, the correlation is low or even absent, as VRS scores manage to correct for the size effects. Thus, the lack of appropriate benchmark presents a problem only for the large municipalities.

Finally, to discriminate between CRS and VRS, we analyze correlations of the efficiency scores. In groups of municipalities with population below 50,000, the two methods produce similar results, but differ significantly for large municipalities. In other words, the scale assumption really matters for large municipalities which are biased downward by the CRS but potentially biased upward by VRS. The next subsection however shows that the lack of comparable peers may be to some extent addressed in VRS by bootstrapping.

4.3 Bias-corrected scores

Our next step is to bootstrap VRS efficiency scores to allow for statistical inference. The original DEA scores are biased by construction (see Section A.3) and bootstrapping helps us to correct for the bias and construct confidence intervals for each efficiency score. To apply homogenous bootstrap as developed by Simar and Wilson (1998), the independence assumption has to hold. For this purpose, we employ graphical test of independence developed by Fisher and Switzer (1985) and described in Wilson (2003). The χ -plot for the VRS efficiency scores in 2008 reveals that all observations are inside the required interval, hence the independence assumption holds.⁹

We apply homogeneous bootstrap by an algorithm described in Simar and Wilson (1998) with 2,000 bootstrap replications. Figure 2 shows the distribution of bias-corrected efficiency scores averaged over the period 2003–2008 compared to the original VRS estimates and Table 7 offers summary statistics.¹⁰ The distribution of bias-corrected scores is denser but otherwise has a very similar pattern as the original distribution. An expected change is that the originally fully efficient municipalities are shifted to lower percentiles. Generally, municipalities with the lack of comparable observations, i.e. large municipalities in our context, have larger bias and wider confidence intervals. Hence, correction for bias does not help us to deal effectively with the large municipalities. The decrease in efficiency scores of large municipalities also explains why bias-corrected VRS scores correlate with CRS scores more than the original VRS scores (cf. Table 8).

		Mean	Min	Max
(a)	VRS	0.786	0.387	1
(b)	VRS, adjustment	0.784	0.385	1
(c)	VRS, bias-corrected	0.694	0.364	0.879
(d)	VRS, adjustment, bias-corrected	0.692	0.362	0.892

Table 7. VRS and bias-corrected VRS efficiency scores (2003–2008 averages): summary statistics

Figure 3 illustrates the size of confidence intervals of the bias-corrected VRS efficiency scores averaged over 2003–2008 in the case without adjustment. (These correspond to Panel (c) in Fig. 2.) The municipalities are ordered by their original VRS efficiency scores. Apparently, the originally fully efficient observations have large confidence intervals. Yet, the ranking of municipalities does not change substantially, as is expressed by the Spearman's correlation coefficients of 0.954 (no adjustment) and 0.949 (wage adjustment). Figure 3 also helps to identify municipalities with atypical values of input-output combinations which have wide intervals even for relatively small scores.

Table 8 summarizes the correlations between six alternative specifications for non-parametric efficiency. We prefer the bias-corrected VRS specification with wage adjustment (denoted

⁹Results of the test are available per request.

¹⁰The analysis runs in R software with FEAR package (Wilson 2008). The detailed data on bias-corrected efficiency scores are available in Table A11 in Appendix, and individual data on confidence intervals can be provided upon request.

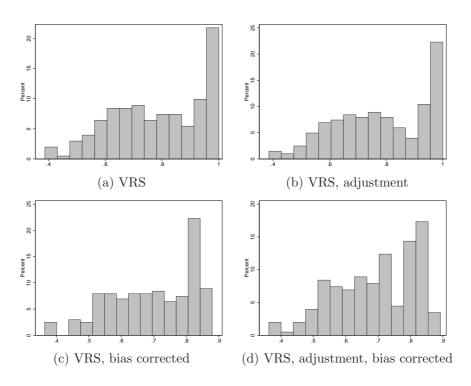

Figure 2. Distributions of the original VRS and the bias-corrected VRS efficiency scores: 2003–2008 averages

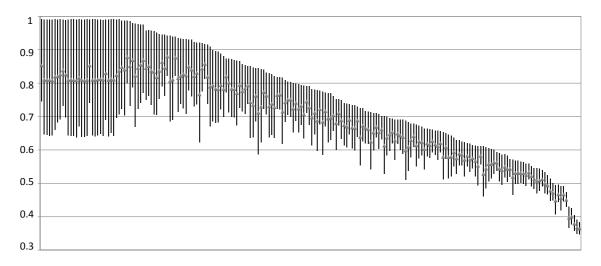

Figure 3. Bias-corrected scores and their confidence intervals: 2003–2008 averages

VRS BC). For robustness check, it is nevertheless illustrative to observe two facts. First, the presence or absence of wage adjustment does not change rankings substantially (correlations 0.98, 0.964, 0.93). Second, correlations between methods differing only in returns to scale

assumption are larger in the case with wage adjustment (0.345, 0.408, 0.95) than without adjustment (0.296, 0.359, 0.949). This is another reason for incorporating relative wages in the analysis.

 Table 8. Spearman rank correlations of DEA efficiency scores

5 Parametric efficiency

5.1 Results without determinants

This section computes efficiency scores using Stochastic Frontier Analysis.¹¹ Unlike DEA, where year-specific scores are obtained only as cross-sectional estimates, SFA estimates the time-profile of the scores endogenously in a single panel. In addition, determinants can be conveniently included. We consider various specifications: Cobb-Douglas or a more flexible Translog production function, time-variant or time-invariant efficiency, and efficiency with determinants and without determinants. Furthermore, we treat wage differentials in three ways: (i) no adjustment, (ii) spending adjusted by wage differences exactly as in DEA and estimation of production function, and (iii) estimation of cost function where wages are included directly among outputs. Since wage differentials influence costs directly, we disregard the option when the wage is a part of the vector of determinants. In total, we cope with four dimensions of modeling. We first assess time variance, the inclusion of wage differences, and then discuss the appropriate functional form. Finally, we examine the effect of determinants.

Our baseline estimates for Cobb-Douglas production are in Table 9. First and foremost, coefficients of principal components suggest that the components may be irrelevant explanatory variables. Albeit PC1 is always significant and positively affects total costs, most of the other components have insignificant positive or even negative effect on costs. Our reading is that either we have constructed irrelevant outputs or another functional specification (Translog) is required. As expected, the wage positively affects costs. Concerning other parameters, the variance of the inefficiency in total error variance is relatively large, and statistical noise accounts only for $1 - \gamma \approx 15\%$ of the total variance. Significance of parameter μ confirms that assumption of truncated-normal distribution is more appropriate than half-normal distribution.

 $^{^{11}\}mathrm{We}$ use software Frontier 4.1 developed by Coelli (1996) for parametric estimation.

Importantly, the parameter η is significant, so efficiency does change over time. In the case without any wage variable, the parameter is negative and significant, which suggests that efficiency decreases over time. Once we control for wages, the sign is exactly opposite, i.e. the efficiency increases over time. Inclusion of wages in the panel data estimation is thus crucial as the real wages increase over time and this effect translates into an increase in spending. As a result, we abandon all time-invariant models that abstract away from wage differences.

Note: TV(TI) denotes time-(in)variant efficiency. ***, **, * denote statistical significance at 1%, 5% and 10% level, respectively. † denotes statistical significance at 10% level on one-tail.

In the next step, we estimate efficiency by means of Translog production with timevariant efficiency and wage differences included. Table 10 reports the results. The first and the third column include all cross-product terms of principal components, i.e. the number of explanatory variables increases from 6(7) to 27(28). Some of the basic principal components are still negative and their significance does not change much in comparison with the baseline case. Most of the cross-product terms (16 out of 21) are not significant either. Hence, we drop explanatory variables with high p-value and after a few iterations end up with a new production function encompassing only four significant components and seven significant cross-product terms. This Pseudo-Translog function is captured in the second and fourth column of Table 10. Log-likelihood decreases only slightly when insignificant variables are dropped out. Interestingly, all principal components are part of the new production function, although some of them enter the production only in an interaction with another component. Thus, we may conclude that components computed from our output variables are indeed relevant for this analysis. Finally, the estimated parameters γ , μ and η are similar to those obtained in baseline Cobb-Douglas specification with time-variance and wage differences. Table A12 in the Appendix offers individual scores for the Pseudo-Translog, both when costs are adjusted by wage differences and estimated using cost function.

Figure 4 shows distributions of the efficiency scores obtained from different specifications. Again, scores are averaged over the entire period, but now the year-specific scores are achieved simultaneously, and satisfy time profile in Eq. (5). The three upper panels are for wage-adjusted inputs, and the bottom three panels are for estimation of cost function when

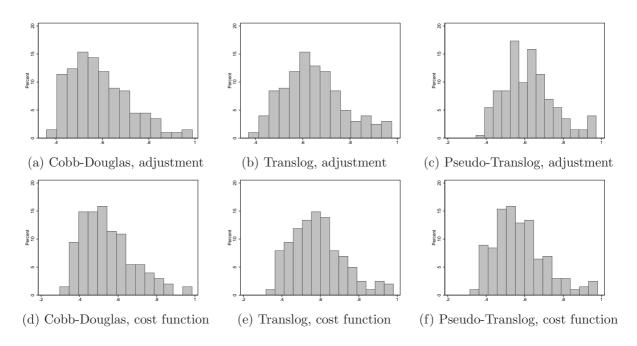

Figure 4. Distributions of the SFA efficiency scores: 2003–2008 averages

wage is directly included among outputs. Efficiency scores are on average lower with Cobb-Douglas production function, and density is higher for lower scores. Nevertheless, we tend to prefer Pseudo-Translog specification. A more flexible production function (Translog or Pseudo-Translog) improves scores of some municipalities which suggests that neglecting some outputs in a narrower specification incorrectly shifts a municipality among those with lower efficiency. Comparing densities of Pseudo-Translog case relative to Translog case, we can see that municipalities with extremely below-average scores and extremely above-average scores move closer to the average. That is, removing insignificant outputs increases density around the mean. Table 11 further reveals that correlation among scores is large and significant across different specification and also across different cases of wage inclusion.

5.2 Results with determinants

This section aims to explore whether extra characteristics significantly affect the efficiency score, which may be attributed either to effect on technical or allocation efficiency, the existence of non-discretionary inputs, or production of additional (directly unobservable) output. Note that estimates illustrate effects upon inefficiency as in Eq. ??. We consider both production function specifications, Cobb-Douglas and Pseudo-Translog, and adjust costs for wages or estimate cost function. This yields four specifications in Table 12. To construct each specification, we run several regressions and based on the log-likelihood ratio test we delete (one by one) insignificant determinants to improve the fit of the model. The four different specifications allow us to see how robust are the effects of determinants upon inefficiency. Note that the inclusion of determinants in a single stage not only explains the inefficiency term, but also affects its level, unlike two-stage estimation.

Table 12 reports the results. By comparing the results with baseline estimates in Table 9 and modified estimates in Table 10, we realize that inclusion of determinants improves the explanatory power of principal components. Most of the components become positive and significant, and for Translog specification, additional cross-product terms are significant. What is also specific for Translog is that we can reject null hypothesis $\gamma = 0$ irrespective how wages are treated. For Cobb-Douglas, in contrast, if cost function is estimated, the hypothesis that inefficiencies are entirely given by determinants cannot be rejected, and the original cost function model simplifies to $y_{i,t} = f(\mathbf{x}_{i,t}) + \delta \mathbf{z}_{i,t} + v_{i,t}$ that can be estimated by OLS.

The effects of determinants are as follows:

Population size The negative effect of small population dummies upon costs, as well as the positive effect of large population dummy, are robust across all specifications. In absolute terms, coefficients are lower for Pseudo-Translog specification than for Cobb-Douglas specification, especially for big municipalities. The explanation is that output PC11 (the square of PC1) is highly correlated to population. In this way, Pseudo-Translog specification may reflects that population-related outputs increase exponentially with municipality size. Loikkanen and Susiluoto (2005) found the similar relation for Finnish municipalities, whereas Geys and Moesen (2009a) and De Borger et al. (1994) discovered that the marginal diseconomy for Flemish municipalities is positive, but tends to decrease in size. We attribute the effect of size mostly to legacy of the 2002 reform which put enormous fiscal stress especially upon the emerging small municipalities (c.f. Hemmings 2006). The small municipalities had to arrange the agenda for the very first time; in contrast, larger municipalities transferred districts' powers relatively easily, given that the location of the agenda within the town or city remained unchanged. An alternative explanation is through unobservable quality outputs such as the quality of pathways, parks maintenance etc.¹²

¹² Relationship between efficiency scores and population in 2007 can be seen in Figure A2. To see that differences in efficiency scores cannot be solely assigned to differences in tax revenues we also plot different brackets for allocation of tax revenues. In group of municipalities with population between 20,000-50,000, scores do not vary too much despite three different brackets. For comparison we plot total tax revenues per capita and population in 2007 (see Figure A3), where discontinuity is a little bit more visible for this group of

Geography The distance from the regional center has a predictable sign, conforming to the literature (Loikkanen, Susiluoto 2005). Citizens in peripheral municipalities have worse access to goods and services provided in the regional center, and their municipalities accordingly produce extra unobservable outputs. Alternatively, the municipalities on the periphery are less subject to yardstick competition.

Education Concerning university-educated population, we find robustly positive effect upon inefficiency, contrary to Afonso and Fernandes (2008), and De Borger and Kerstens (1996). This makes our country-specific study an exception to the literature covering mainly the Western European countries. The effects of higher reservation wage plus extra demand for high-quality (non-core) services are likely behind. What must be absent or offset must be the hypothetically increased monitoring resulting in improved accountability. A topic for future research is if this difference is specific for post-communist countries or not, and also to what extent public sector services drive mobility of the university graduates at the local level.

Fiscal capacity First, we confirm the predicted sign of the share of self-generated revenues; the higher fiscal capacity, the softer budget constraint and the higher is inefficiency (c.f. Balaguer-Coll et al. 2007). In contrast, capital expenditures per capita have positive effect upon inefficiency in all but one case where it is insignificant. Increase in capital expenditures in our context does not introduce fiscal strain that must be compensated but rather need motivates (perhaps complementary) current expenditures.

Then, we have two results which call for a cautious interpretation. The level of debt is significant in only one case; there seems to be only weak, if any, persistence from past overspending decisions. We cannot argue that debt motivates savings. The effect of subsidies per capita is conditional on how wages are incorporated. The positive effect validating the fly-paper hypothesis, as observed elsewhere (Kalb 2010; De Borger et al. 1994; De Borger, Kerstens 1996; Loikkanen, Susiluoto 2005), is only for wage included among outputs. We keep the other specification mainly because it allows for better comparison with DEA scores.

Politics Out of political variables, voters' involvement in terms of turnout in local elections is the best predictor of low costs and high efficiency, quite as, inter alia, Geys et al. (2010) found in German municipalities. The share of left-wing municipal-council representatives (Communists and Social Democrats) among representatives from all parliamentary parties makes the municipality less efficient. Thus, local politics is not entirely devoid of value choices. The result may be driven either by lower competence of Left-wing representatives, or by the production of extra unobservable outputs, typically extra social services. The negative effect of left-wing parties upon efficiency was obtained also in German municipalities (Kalb 2010).

municipalities (however not too much as total tax revenues include not only revenues based on tax allocation formula).

With two remaining political variables, the results are weaker. Political concentration index confirms the well established weak-government hypothesis (low concentration increases costs), but is significant only for wage-adjusted spending. Electoral year dummy is effectively a dummy for single year 2006; costs increase, exactly as predicted, but also if wage is included among outputs.

Table 12. Final SFA results: time-variant efficiency, determinants

Note: ***, **, * denote statistical significance at 1%, 5% and 10% level, respectively. † denotes statistical significance at 10% level on one-tail.

Table 13 presents descriptive statistics and correlations for efficiency scores obtained in the three specifications where stochastic inefficiency cannot be rejected. Figure 5 plots the distributions. By comparing with Figure 4, the scores under determinants are denser for the bottom part of the distribution. The scores obtained from the Cobb-Douglas specification are again substantially lower. Correlation of all pairs of these three efficiency rankings is nevertheless very high, even higher than in case when determinants are not considered (see Table 11). Although we obtained three very similar efficiency rankings, we prefer the one estimated from the last specification, i.e. Pseudo-Translog and wage among outputs. Including only relevant outputs and their cross-product terms improve the flexibility of the production function in comparison to Cobb-Douglas. Therefore, Table A13 in the Appendix presents only individual scores of the Pseudo-Translog models with wage adjustment and when cost function is estimated. In addition, adjustment of expenditures for wage is arguably very strict, when wage differentials do not fully translate to differences in costs, so estimating cost function with wage as an output seems to be more appropriate.

				Wage adjustment		$Cost\ function$
	Mean	Min	Max	Cobb-Douglas	Pseudo-Translog	Pseudo-Translog
Wage adjustment						
Cobb-Douglas	0.305	0.087	0.863	1		
Pseudo-Translog	0.508	0.221	0.914	0.974	1	
Cost function						
Pseudo-Translog	0.438	0.163	0.790	0.950	0.982	1

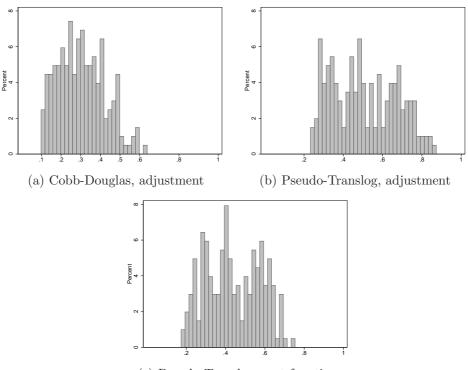

Table 13. Spearman correlations of SFA efficiency scores with determinants: 2003–2008 averages

5.3 Overall assessment of multiple rankings

In the final step, we look into similarities and dissimilarities of efficiency scores computed by different approaches, i.e. DEA and SFA. The efficiency ranks from various approaches have been compared both in global efficiency and for specific outputs (Balcombe et al., 2006; De Borger, Kerstens, 1996; Geys, Moesen (2009b); von Hirschhausen et al., 2006). In our perspective, one way to deal with multiple rankings is to correctly identify the causes for differences in the individual efficiency scores. Therefore, although we offer one preferred specification (Pseudo-Translog SFA with determinants), we also present how modifying assumptions shapes the other outcomes.

In specific, by eliminating determinants from Pseudo-Translog SFA specification, and looking at the individual score differences, we can isolate the pure effect of including determinants. Their influence upon a score of an individual municipality is further decomposed by looking into a difference between an individual vector of the determinants and the vector of average values. As a result, policy makers in each municipality can understand which dimension affects their particular score the most.

Similarly, by comparing bias-corrected VRS scores with Pseudo-Translog specification without determinants, the pure effect of a deterministic non-parametric frontier is isolated;

(c) Pseudo-Translog, cost function

Figure 5. Distribution of SFA efficiency scores: 2003–2008 average, determinants

the municipality may infer especially if the shift of the score is more due to size (channeled through the scales assumption in VRS) or due to the error expressed by the size of the confidence interval (generated by bootstrapping).

For the purpose of comparability, we select only methods with inputs adjusted by wage. From non-parametric methods, we have CRS, VRS and bias-corrected VRS. From parametric methods, we present both Cobb-Douglas and Pseudo-Translog specifications, both with and without determinants. Table 14 reports the rank correlations.

	CRS	VRS	VRS BC
No determinants			
Cobb-Douglas	0.791	0.362	0.431
Pseudo-Translog	0.711	0.500	0.560
Determinants			
Cobb-Douglas	0.944	0.230	0.304
Pseudo-Translog	0.928	0.212	0.278

Table 14. Spearman correlations of DEA and SFA efficiency scores: wage adjustment

The first interesting observation is two methodologically largely inconsistent methods, DEA CRS and Pseudo-Translog SFA *with* determinants, are in fact highly correlated. Unlike that, bias-corrected VRS that represents the best out of non-parametric methods is only

weakly related to the best out of parametric methods, namely Pseudo-Translog with determinants. Finally, by introducing Cobb-Douglas instead of Pseudo-Translog or by estimating without determinants, SFA results tend to be more correlated with the bias-corrected VRS.

Next, we identify robustly strong and robustly weak performers. Table 15 examines if different methods identify the same subsets of municipalities in the top and the bottom deciles. For each pair, the table presents the share of common observations in the respective decile out of total observations in the decile. We confirm the previous observations: Pseudo-Translog SFA with determinants behaves completely differently than bias-corrected DEA VRS, with shares of common observations only 10% and 25%; and again, DEA CRS is surprisingly close to Pseudo-Translog SFA with determinants.

	CRS	VRS BC	P-T det.	C-D	P-T
DEA, CRS	•				
DEA, bias-corrected VRS	30/30				
Pseudo-Translog, determinants	45/75	10/25			
Cobb-Douglas, no determinants	50/40	35/40	10/10

Table 15. The shares of common observations in top/bottom deciles (in %)

We proceed by identifying those observations which remain highly efficient or highly inefficient across different methods. Table 16 presents observations that occur consistently either at the top or at the bottom. The selection criterion is to appear in the top (or bottom) decile at least for three methods out the five pre-selected. We group the municipalities into population subgroups to demonstrate that size indeed matters.

6 Efficiency in 1990s

The last step of our analysis is to conduct a comparative exercise of efficiency scores in 1990s and 2000s. We compare two distant periods, 1994–1996 and 2004–2006. Scores of municipalities in 2004–2006 are taken from the analysis above. In 1990s, we have to exclude 3 more cities for which some data are missing (Rokycany, Turnov and Havířov), and work with 199 observations per year, i.e. 597 observations in total.

6.1 Data

As inputs, we keep using *Total current spending*, but are aware of possible errors stemming from misclassifications of spending into capital and current expenditures. In terms of outputs, we are fairly limited by data availability. For the purpose of comparability, we replicate as many output variables from the previous analysis as possible. This seems reasonable even if the municipalities in 1990s did not dispose with extended powers delegated by the state, hence were only indirectly responsible for some of the selected outputs. Note that the levels of some outputs are constant for the entire period.

Since pupils in primary schools are available only for small sample of municipalities, we use Pupils in kindergartens only. Nevertheless, the correlation 0.99 in the subsample where both variables are present indicates that the distortion is a minor one. The statistics of students entering upper secondary schools, and municipal museums and galleries are not available, hence we introduce just the number of *Museums*. *Cultural facilities* (libraries, cinemas, theaters, galleries, other cultural facilities and children's centers) are summed after Lora normalization. We use *Sport facilities* (swimming pools, playgrounds, stadiums) instead of the recreational area which is unavailable, and again sum after Lora normalization. Instead of waste collected, we introduce dummy for *Landfills*. We do not have *Dwellings completed* or any substitute; for administration, we include *Population of municipality* instead of population of districts, as the municipalities were not vested with administrative powers serving the entire district population. Table 17 gives descriptive statistics of the outputs in 1994–1996. As in previous analysis, we aggregate output variables into six principal components that together explain 80.95 % of the variance in the data and transform them to obtain strictly positive output data (see Table A14).

	Mean	Min	Max
Pupils in kindergartens	667.0	83	3,485
Museums	1.050	0	6
Cultural facilities	12.37	1	73

Note: N = 597.

While the construction of demographic and geographic determinants applied in the main analysis of 2003–2008 remains unchanged, we have to reshape fiscal and political variables. First, we split grants into those stemming from 76 administrative districts (to be dissolved in 2002) and those from the central government. The new variables are now denoted *District* subsidies and *State subsidies*, and we expect the same sign, but theoretically a different level. *Self-generated revenues* are inflation-adjusted non-tax revenues plus other revenues (mainly fees), defined as a share of non-tax revenues, tax revenues, other revenues and total subsidies. Interestingly, the size of subsidies and capital expenditures per capita relative to the average budget per capita was higher in 1990s than in 2000s (43.9% versus 30.8% for subsidies, 62.6% versus 43.7% for capital expenditures). The share of self-generated revenues was also on average higher by 10 percentage points.

Political landscape in the early 1990s was markedly different from that in the posttransition period 2000s. Turnout was at historically high levels, scoring extra 20 percentage points in 1994 elections than in 2006 elections. The main national parties constituted in 1991, and there was still a legacy of a large civic movement called Civic Forum. The left-wing parties represented mainly unreformed Communist Party and a group of relatively small left-wing "reform communists" (Levý Blok, Strana Demokratické Levice, including at that time relatively small Social Democrats). The parties typically built pre-electoral coalitions in 1990s, which turned out to be exceptional after the year 2000. One consequence is that we have to redefine the share of *Parliamentary parties* into the share of those coalitions which involve some parliamentary parties, including independent candidates. For the *Left-wing parties*, we also have to think broadly of coalitions involving left-wing parties (Communist and Social Democrats) and independent candidates, instead of single parties. Summary statistics of the determinants are presented in Table 18, and can be compared to statistics from 2003–2008 available in Table 5.

6.2 Results

To attain maximal comparability, we directly use Pseudo-Translog SFA specification with time-variant scores, determinants, and estimate cost function. The model estimated is presented in Table 19. We present several specifications. The principal components constructed out of output variables are significant, but some only in the interactions. The first specification includes also electoral year dummy, distance from the regional center and university graduates that however appear to be insignificant. The first two specifications include dummy for the large municipalities, which also proves to be insignificant, hence we exclude it in the last specification. Moreover, in the third specification, instead of total subsidies we use state and district subsidies. Although inclusion of these two variables increase log-likelihood, significance of some other variables improved, hence we prefer the last third specification.

Table 19. Results for 1994–1996: SFA, Pseudo-Translog, time-variant efficiency, determinants

Note: ***, **, * denote statistical significance at 1%, 5% and 10% level, respectively. † denotes statistical significance at 10% level on one-tail.

The effects of determinants are of our main interest. *Population size* increases inefficiency, but the effect is present only for small municipalities. The dummy for the largest municipalities is insignificant. In other words, the scope for improvements in the operation in largest municipalities appeared to not to be significantly different from the medium size municipal-

ities. *Distance* to the regional center is insignificant as well; insignificance of both largest population dummy and distance may be attributed to a very low intensity of interregional competition in the early transition period.

Fiscal capacity in the form of *Self-generated revenues* relaxes the budget constraint, and increases inefficiency, exactly as predicted and seen also in the 2000s. *Subsidies* show an expected positive effect on inefficiency, where the magnitude of the effect of *District subsidies* exceeds the magnitude of *State subsidies*. We may hypothesize that district subsidies, albeit lower in absolute size, less likely bring in additional output that could shift the municipality closer to the best-practice frontier. These local-type subsidies more likely crowd-out other type of productive spending which consequently increases slack. Alternatively, direction of these subsidies is to marginal improvements that are not captured by our rough measure of outputs.

Political variables in 1990s are the least consistent with observations in the next decade. The effect of *Voters' turnout* is unchanged, in a sense that larger participation decreases inefficiency. In contrast, the *Electoral year* is insignificant. Note that in both subsamples, we have just a single electoral year (1994 and 2006), hence implications based on the electoral year have to be stated with utmost care. Interestingly, the share of *Parliamentary parties* decreases costs. We may think of close alignment of political and social elites at that time; managerial expertise in the public sector that was just being developed, and political parties attracted those who looked for a career in the public service. The reason that coalitions with *Left-wing* parties spent significantly less is difficult to identify without extra evidence. We suggest that the effect may go through unobservable outputs; the anti-regime or opposition status of the left-wing parties led these coalitions to focus more on protecting the status quo rather than developing the municipalities. Also, the scope for redistributive policies at the local level was even more limited in 1990s than in the subsequent decade.

As a final step, we compare the individual scores in the two periods. Average individual scores in 1994–1996 period are presented in Table A15. Figure 6 shows the changes for subsamples differentiated by size. Clearly, the large municipalities suffered from a dramatic drop (located in the SE corner) and mainly small and medium municipalities improved significantly (located in the SE corner). Nevertheless, we interpret the individual results with caution: With unobserved differences in sectoral efficiencies, a sufficiently large change in the output mix may affect the comprehensive score even without any change in sectoral efficiencies or any change of the relevant environmental variable. Thus, the scores must be carefully applied in the comparison of two periods that involve substantial difference of the structures of outputs.

The relative improvement is mainly conditional on size. Table 20 reports the average rank improvements for subgroups defined by population level thresholds, and Spearman rank correlations between efficiency scores in periods 1994–1996 and 2004–2006. Apparently, small municipalities tend to outperform large municipalities over time. The relative position within a subgroup is the most stable for medium-size municipalities; in contrast, both small and large municipalities are subject to substantial changes in their relative standing.

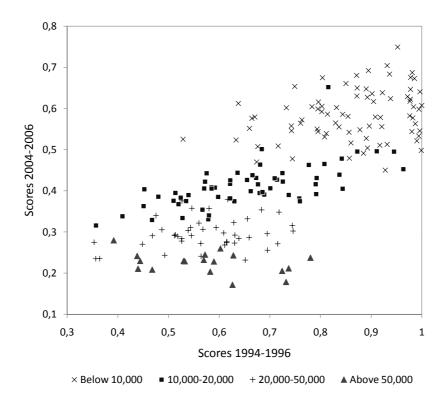

Figure 6. The evolution of the efficiency scores from 1994–1996 to 2003–2008

Municipalities	Average	Max	Min	Correlation
Below 10 000	8.26	103	-74	0.232
10,000-20,000	11.7	76	-68	0.687
20,000-50,000	-15.6	29	-77	0.317
Above $50,000$	-45.9	28	-108	-0.203
Full sample	0	103	-74	0.765

Table 20. Rank improvement from 1994–96 to 2003–2008 and rank correlation between the scores in1994–96 and 2003–2008

7 Conclusion

This article examines the extent of cost inefficiency of local governments in a sample of 202 municipalities of extended scope in the Czech Republic in the period 2003–2008. The input side is defined by current spending of the municipalities, and the outputs are core services provided. We apply both parametric and non-parametric efficiency measurement methods. Given the possibility to treat time variance endogenously and include determinants, we prefer stochastic frontier analysis with a time-variant Pseudo-Translog specification and determinants, estimated in a single stage.

Interestingly, our preferred specification is dissimilar to the best non-parametric method of data envelopment analysis with variable returns to scale and bias corrected by bootstrapping. We discuss how to attribute the differences to the (i) the effect of excluding determinants and (ii) the effect of assuming deterministic non-parametric versus stochastic parametric methodology.

The exogenous variables that robustly increase inefficiency are population size, distance to the regional center, share of university-educated citizens, capital expenditures, subsidies per capita, and the share of self-generated revenues. These are attributed to well-known effects of decreasing yardstick competition, flypaper effect, and softer budget constraint. Concerning political variables, increase in party concentration and the voters' involvement increases efficiency, and local council with a lower share of left-wing representatives also tend to be more efficient. We interpret determinants not only as indicators of slack, but also as indicators of non-discretionary inputs, and unobservable outputs, especially if increased cost (inefficiency) is present in municipalities with a high share of mobile (educated) citizens.

A comparative analysis is conducted also for the period 1994–1996, where a few determinants lose significance, and political variables appear to influence inefficiency in a structurally different way. From comparison of the two periods, we also obtain that small municipalities improve efficiency significantly more than large municipalities. As a result, initially low differences between efficiency scores, especially between medium-size and large municipalities, have magnified over time.

A Methodology

A.1 Data Envelopment Analysis

Let **X** denote the input matrix of dimension $N \times p$, where p denotes the total number of inputs, and **Y** denotes the output-matrix of dimension $N \times q$, where q is the number of outputs. Municipality $i \in \{1, \ldots, N\}$ uses inputs \mathbf{x}_i to produce outputs \mathbf{y}_i . The objective is to find $\theta_i \in [0, 1]$, representing the maximal possible proportion by which original inputs used by municipality i can be contracted such that given level of outputs remains feasible. Efficiency score of municipality i, θ_i , is obtained by solving the following problem:

$$\min_{\theta_i,\lambda_i} \quad \theta_i \quad \text{s.t.} \quad -\mathbf{y}_i + \mathbf{Y}\lambda_i \ge 0 \\
\quad \theta_i \mathbf{x}_i - \mathbf{X}\lambda_i \ge 0 \\
\quad \lambda \ge 0$$
(7)

Here θ_i is scalar and λ_i is vector of N constants. Inputs \mathbf{x}_i can be radially contracted to $\theta_i \mathbf{x}_i$ such that \mathbf{y}_i is feasible under given technology. This radial contraction of the input vector produces a projected point $(\mathbf{X}\lambda_i, \mathbf{Y}\lambda_i)$, which is a linear combination of the observed data weighted by vector λ_i and lies on the surface of the technology.

This optimization problem is solved separately for each of the N municipalities, therefore each municipality *i* is assigned its specific set of weights λ_i . The vector λ_i reflects which municipalities form the efficient benchmark for the municipality *i*. Municipality *j* affects θ_i if $\lambda_{ij} > 0$. We call these influential observations as peers.

Efficiency computed from the model in (7) is based on underlying assumption of constant returns to scale (CRS) technology, as in the original paper by Charnes et al. (1978). Banker et al. (1984) extend the analysis to account for variable returns to scale (VRS) technology by adding additional convexity constraint

$$\sum_{j=1}^{N} \lambda_{ij} = 1. \tag{8}$$

This constraint ensures that an inefficient municipality is only benchmarked against peers of a similar size. We can easily adjust the model to non-increasing returns to scale (NIRS) (Färe et al. 1985). Under this restriction, the municipality i is not benchmarked against substantially larger municipalities, but may be compared with smaller municipalities. NIRS technology is generated by substituting the restriction (8) by

$$\sum_{j=1}^{N} \lambda_{ij} \le 1. \tag{9}$$

A.2 Outliers

Wilson (1993) provides a diagnostic statistics which may help to identify outliers, but this approach is computationally infeasible for large data sets. Nevertheless, for our case the statistic is computable. The statistic represents the proportion of the geometric volume in input \times output space spanned by a subset of the data obtained by deleting given number of observations relative to the volume spanned by the entire data set. Those sets of observations deleted from the sample that produce small values of the statistic are considered to be outliers. As noticed in Wilson (1993), the statistics may fail to identify outliers if the effect of one outlier is masked by one or more other outliers. Therefore, it is reasonable to combine this detection method with alternative methods.

Cazals et al. (2002) have introduced the concept of partial frontiers (order-m frontiers) with a nonparametric estimator which does not envelop all the data points. Order-m efficiency score can be viewed as the expectation of the minimal input efficiency score of the unit i, when compared to m units randomly drawn from the population of units producing at least the output level produced by i, therefore the score is not bounded at unity. An alternative to order-m partial frontiers are quantile based partial frontiers proposed by Aragon et al. (2005), extended to multivariate setting by Daouia and Simar (2007). The idea is to replace this concept of "discrete" order-m partial frontier by a "continuous" order- α partial frontier, where $\alpha \in [0, 1]$. Simar (2007) proposed an outlier detection strategy based on order-m frontiers. If an observation remains outside the order-m frontier as m increases, then this observation may be an outlier.

In our case, we construct order-m efficiency scores for m = 25, 50, 100, 150. The number of super-efficient observations decreases in m. For m = 100 we have 3–6 (depending on the year) observations with $\theta^m > 1$ and 1–3 observations with $\theta^m > 1.01$. To find if these outliers influence efficiency of other observations, i.e. if they constitute peers, we compute basic DEA efficiency scores and explore super-efficient observations serving as peers. In the next step, we scrutinize observations having our potential outliers as peers. We compare their efficiency scores θ^{DEA} and θ^m . If an observation is super-efficient ($\theta^m > 1$ for relatively large m) and if it has low θ^{DEA} score, then it may be distorted by the presence of the outliers. We find no super-efficient observation with a low DEA score, hence our super-efficient values do not distort efficiency rankings.

A.3 Bootstrap in DEA

DEA efficiency estimates are subject to uncertainty due to sampling variation. To allow for statistical inference, we need to know statistical properties of the nonparametric estimators, therefore to define a statistical model that describes the data generating process (Simar 1996), i.e. the process yielding the data observed in the sample (\mathbf{X}, \mathbf{Y}) .

Once we define a statistical model (see for example Kneip et al. 1998), we can apply bootstrap technique to provide approximations of the sampling distributions of $\hat{\theta}(\mathbf{X}, \mathbf{Y}) - \theta(\mathbf{X}, \mathbf{Y})$, where $\hat{\theta}(\mathbf{X}, \mathbf{Y})$ is the DEA estimator and $\theta(X, Y)$ is the true value of efficiency. Knowledge of the sampling distribution allows us to evaluate the bias, the standard deviation of $\hat{\theta}(\mathbf{X}, \mathbf{Y})$, and to derive bounds of confidence intervals for $\theta(\mathbf{X}, \mathbf{Y})$. Simar and Wilson (2000) describe the methodology for bootstrapping in non-parametric models.

The bootstrap bias estimate $\hat{\delta}$ can be obtained from:

$$\hat{\delta}(\hat{\theta}(\mathbf{X}, \mathbf{Y})) \approx \frac{1}{B} \sum_{b=1}^{B} \hat{\theta}_{b}^{*}(\mathbf{X}, \mathbf{Y}) - \hat{\theta}(\mathbf{X}, \mathbf{Y}), \qquad (10)$$

where the bias estimate $\hat{\delta}$ is the difference between mean of the Monte-Carlo realizations of $\{\hat{\theta}_b^*(\mathbf{X}, \mathbf{Y})\}_{b=1}^B$ and DEA efficiency estimator. Hence, the original DEA efficiency estimator may be corrected for the bias.

$$\tilde{\theta}(\mathbf{X}, \mathbf{Y}) = \hat{\theta}(\mathbf{X}, \mathbf{Y}) - \hat{\delta}(\hat{\theta}(\mathbf{X}, \mathbf{Y}))$$
(11)

However, Efron and Tibshirani (1993), recommend not to correct for the bias unless $|\hat{\delta}(\hat{\theta}(\mathbf{X}, \mathbf{Y}))| > \hat{\sigma}(\hat{\theta}(\mathbf{X}, \mathbf{Y}))/4$, where $\hat{\sigma}(\hat{\theta}(\mathbf{X}, \mathbf{Y}))$ is a standard deviation, i.e. a square-root of the variance of the bootstrap distribution:

$$\hat{\sigma}^2(\hat{\theta}(\mathbf{X}, \mathbf{Y})) \approx \frac{1}{B} \sum_{b=1}^B \hat{\theta}_b^*(\mathbf{X}, \mathbf{Y}) - \left(\frac{1}{B} \sum_{b=1}^B \hat{\theta}_b^*(\mathbf{X}, \mathbf{Y})\right)^2 \tag{12}$$

The bootstrap is consistent if the available bootstrap distribution mimics the original unknown sampling distribution. The *naive* bootstrap procedure, however, does not satisfy this condition because of the boundary estimation framework (Efron and Tibshirani 1993). Simar and Wilson (1998) propose the homogenous smooth bootstrap which can be applied to overcome this problem. This procedure can be used only if independence assumption holds, i.e. under independence between technical inefficiency and output levels as well as the mix of inputs. Wilson (2003) provides a survey of tests for independence. We employ the graphical method developed by Fisher and Switzer (1985).

B Robustness check

As mentioned above, the input of total current spending may include depreciation of investment for municipalities which hire a firm to provide a certain service requiring capital investment. These municipalities are disadvantaged in the efficiency analysis as their input is biased upwards. Unfortunately, these expenditures are not distinguishable and cannot be separated. Despite the fact that relative size of this item in the total current spending is the most probably small and controlling for this additional spending would lead to only minor change in rank of a municipality, we decide to carry out robustness analysis.

Instead of total current spending, we include total spending covering not only current, but also capital expenditures. Here, municipalities disadvantaged in the original analysis are now advantaged (they have lower capital spending as they pay only for depreciation of capital goods and do not purchase it). We aim to show that previous results are robust to such reclassification of the input, i.e. effects of determinants upon inefficiency are similar and ranking of municipalities does not change dramatically with most of top and bottom performers being the same. For this purpose, we employ the most preferred method—stochastic frontier analysis with a time-variant Pseudo-Translog specification and determinants, estimated in a single stage.¹³

Table A1 presents results from the robustness analysis. We can see that effects of determinants are very similar. Inefficiency increases with the municipality size, the share of university graduates, subsidies per capita, the share of self-generated revenues and the distance from the regional center. Concerning political variables, we observe opposite effect of left-wing parties. Negative effect upon inefficiency stems from the fact that left-wing parties are less likely to support investments, hence decrease capital expenditures. Other political variables have the same effect as in the original analysis. Magnitude of the coefficients changes significantly for subsidies per capita and electoral year, which now have much larger positive effect upon inefficiency. Higher subsidies per capita are more likely to translate to higher capital spending than to current spending and local councils increase more capital spending than current spending in the year of local elections.

In addition, we compare scores and rankings computed in the original and robustness analysis. Spearman correlation coefficient for efficiency scores is 0.938, hence rankings of municipalities do not differ too much. Comparing rankings of average efficiency scores over 2003–2008, we observe that a municipality on average changes its rank only by 10 places, maximal positive jump is 62 places and negative 51 places, hence top (bottom) performing municipality never becomes bottom (top) performing. If we look at the overlap of municipalities in the top and the bottom deciles, we can see that 17 (12) out of 20 bottom (top) municipalities in robustness analysis are among bottom (top) 20 also in the original analysis. Hence, overlap is high for the bottom decile and little bit lower for the top decile, i.e. the worst performing municipalities mostly remain the same. The best performing municipalities

¹³ This analysis is carried out only for the purpose of robustness check, we are aware that efficiency scores computed here are not appropriate because output is not adjusted for capital goods.

in the original analysis may be those carrying out more investments, hence moving in this robustness efficiency ranking down.

To conclude, the results from the robustness analysis are very similar to those in the original analysis, as well as rankings computed. The problem of upward biased input for some municipalities in the original analysis is not severe and does not affect the rank of the municipality in a large extent.

IES Working Paper Series

2010

- 1. Petra Benešová, Petr Teplý : *Main Flaws of The Collateralized Debt Obligation's Valuation Before And During The 2008/2009 Global Turmoil*
- 2. Jiří Witzany, Michal Rychnovský, Pavel Charamza : Survival Analysis in LGD Modeling
- 3. Ladislav Kristoufek : *Long-range dependence in returns and volatility of Central European Stock Indices*
- 4. Jozef Barunik, Lukas Vacha, Miloslav Vosvrda : *Tail Behavior of the Central European Stock Markets during the Financial Crisis*
- 5. Onřej Lopušník : *Různá pojetí endogenity peněz v postkeynesovské ekonomii: Reinterpretace do obecnější teorie*
- 6. Jozef Barunik, Lukas Vacha : Monte Carlo-Based Tail Exponent Estimator
- 7. Karel Báťa : Equity Home Bias in the Czech Republic
- 8. Petra Kolouchová : Cost of Equity Estimation Techniques Used by Valuation Experts
- 9. Michael Princ : *Relationship between Czech and European developed stock markets: DCC MVGARCH analysis*
- 10. Juraj Kopecsni : Improving Service Performance in Banking using Quality Adjusted Data Envelopment Analysis
- 11. Jana Chvalkovská, Jiří Skuhrovec : *Measuring transparency in public spending: Case of Czech Public e-Procurement Information System*
- 12. Adam Geršl, Jakub Seidler : Conservative Stress Testing: The Role of Regular Verification
- 13. Zuzana Iršová : *Bank Efficiency in Transitional Countries: Sensitivity to Stochastic Frontier Design*
- 14. Adam Geršl, Petr Jakubík : Adverse Feedback Loop in the Bank-Based Financial Systems
- 15. Adam Geršl, Jan Zápal : *Economic Volatility and Institutional Reforms in Macroeconomic Policymaking: The Case of Fiscal Policy*
- 16. Tomáš Havránek, Zuzana Iršová : *Which Foreigners Are Worth Wooing? A Meta-Analysis* of Vertical Spillovers from FDI
- 17. Jakub Seidler, Boril Šopov : Yield Curve Dynamics: Regional Common Factor Model
- 18. Pavel Vacek : Productivity Gains From Exporting: Do Export Destinations Matter?
- 19. Pavel Vacek : Panel Data Evidence on Productivity Spillovers from Foreign Direct Investment: Firm-Level Measures of Backward and Forward Linkages
- 20. Štefan Lyócsa, Svatopluk Svoboda, Tomáš Výrost : *Industry Concentration Dynamics and Structural Changes: The Case of Aerospace & Defence*
- 21. Kristýna Ivanková : Isobars and the Efficient Market Hypothesis
- 22. Adam Geršl, Petr Jakubík : *Relationship Lending, Firms' Behaviour and Credit Risk: Evidence from the Czech Republic*
- 23. Petr Gapko, Martin Šmíd : Modeling a Distribution of Mortgage Credit Losses
- 24. Jesús Crespo Cuaresma, Adam Geršl, Tomáš Slačík : *Global Financial Crisis and the Puzzling Exchange Rate Path in CEE Countries*
- 25. Kateřian Pavloková : *Solidarita mezi generacemi v systémech veřejného zdravotnictví v Evropě*
- 26. Jaromír Baxa, Roman Horváth, Bořek Vašíček : *How Does Monetary Policy Change? Evidence on Inflation Targeting Countries*

- 27. Radovan Parrák, Jakub Seidler : *Mean-Variance & Mean-VaR Portfolio Selection: A Simulation Based Comparison in the Czech Crisis Environment*
- 28. Vladimír Benáček : *Aspekty efektivnosti při volbě profese a školy: Přizpůsobují se pražské střední školy potřebám podniků?*
- 29. Kamila Fialová : Labor Institutions and their Impact on Shadow Economies in Europe
- 30. Terezie Výprachtická : *Could the Stability and Growth Pact Be Substituted by the Financial Markets?*

2011

- 1. Roman Horváth, Jakub Matějů : How Are Inflation Targets Set?
- 2. Jana Procházková, Lenka Šťastná : Efficiency of Hospitals in the Czech Republic
- 3. Terezie Výprachtická : *The Golden Rule of Public Finance and the Productivity of Public Capital*
- 4. Martina Mysíková : Income Inequalities within Couples in the Czech Republic and European Countries
- 5. Veronika Holá, Petr Jakubík : Dopady změn parametrů pojištění vkladů v roce 2008
- 6. Vladimír Benáček, Eva Michalíková : *The Factors of Growth of Small Family Businesses: A Robust Estimation of the Behavioral Consistency in the Panel Data Models*
- 7. Aleš Maršál : The Term Structure of Interest Rates in Small Open Economy DSGE Model
- 8. Robert Flasza, Milan Rippel, Jan Šolc : *Modelling Long-Term Electricity Contracts at EEX*
- 9. Jan Hlaváč : *Financial performance of the Czech private pension scheme: Its current position and the comparison with other CEE countries*
- 10. Tomáš Havránek, Zuzana Iršová, Karel Janda : *Demand for Gasoline Is More Price-Inelastic than Commonly Thought*
- 11. Martina Mysíková : Personal Earnings Inequality in the Czech Republic
- 12. Ondřej Lopušník : Reflections on the reconciliation problem
- 13. Martin Gregor, Lenka Šťastná : *The Decentralization Tradeoff for Complementary Spillovers*
- 14. Lenka Šťastná, Martin Gregor : *Local Government Efficiency: Evidence from the Czech Municipalities*
