We would like to thank Shengyi Guo for excellent research assistance. We would also like to thank without implicating Joe Haslag for his comments on an earlier draft of the paper. Any errors and omissions as well as any opinion, propositions, or conclusions are exclusively our own. The contents reflect the authors' own views and should not be associated with the Federal Reserve Bank of Dallas nor with the Federal Reserve System.

#### Abstract

The failure of the "heterodox" inflation stabilization attempts of the 1980s in Argentina, Brazil and Peru along with the apparent success of the more orthodox Bolivian and Mexican stabilizations have left researchers again looking at the dynamics of inflation. This paper seeks to add to recent findings by testing whether the recent seemingly different inflation experiences in Argentina, Bolivia, Brazil, Mexico and Peru are consistent with the new classical model-of-inflation. - Monetary models of inflation with rational expectations carry a number of testable implications. First, money growth and inflation should be cointegrated while the short term dynamics display temporary and stochastic dislocations from this equilibrium relationship. Second, the equilibrium error anticipates future monetary policy due the fact that agents have superior information to that of the econometrician. Third, cointegration between money growth and inflation implies, as Campbell and Shiller (1987 and 1988) show, that cross equation restrictions can be readily generated from the error correction form. Our results show that the new classical model of inflation is generally consistent with the inflation experiences of Argentina, Bolivia, Brazil, Mexico, and Peru in spite of their supposed heterogeneity.

## Introduction

The inflationary process in Latin America has received a large amount of attention over the last decade especially after the onset of the debt crisis in 1982. In the aftermath of the initial orthodox adjustment and acceleration of inflation, a strong revisionist version of the old monetarist-structuralist debate emerged. ${ }^{1}$ The older monetarist inflation theories have been supplanted by rational expectations models of inflation while structuralist theories grew into new-structuralist or "inertial" inflation theories. The failure of the "heterodox" inflation stabilization attempts of the 1980s in Argentina, Brazil, and Peru along with the apparent success of the more orthodox Bolivian and Mexican stabilizations have left researchers again looking at the dynamics of inflation. This paper seeks to add to recent findings by testing whether the recent inflation experiences in Argentina, Bolivia, Brazil, Mexico and Peru are consistent with the new classical model of inflation.

The inflation experiences of these countries differed in the 1980s (Figures 1-5). ${ }^{2}$ Four of the countries attempted "heterodox" stabilization policies combining incomes policies with monetary and fiscal austerity: Argentina in 1985-1987, 1988, and 1989, Brazil in 1986, 1987, 1989, and 1990, Mexico in the period 1988 to the present, and Peru in 1986-1987. Only

[^0]the Mexican program proved a long term success. Four of the countries's inflation rates reached hyperinflationary levels: Argentina in June and July 1989 and December 1989, Bolivia in early 1985, Brazil in 1990, and Peru in 1990-1991. Only two of these countries had brought their inflation rates back to moderate levels by 1990, Bolivia and Mexico. The sample of countries used in this study offers a rich diversity of high inflation experiences in 1980s. The aim of this paper is to see if the classical model successfully describes the inflationary process across these experiences.

Monetary models of inflation with rational expectations carry a number of testable implications. First, the main tenet of monetary models is that inflation is (ultimately) a monetary phenomenon. This precludes the existence of speculative sources of inflation. In the context of rational expectations, speculative bubbles can theoretically emerge due the inconsistency inherent in models where the present price level is a function of future expected price levels [Diba and Grossman 1988a and 1988b]. Theoretically, inflation can accelerate infinitely even though money grow remains stationary. Such bubbles, however, would have the growth rates of prices and money continuously diverging which precludes cointegration between inflation and money growth. Hence, one can empirically rule out inflationary bubbles if money growth and inflation are cointegrated. We will interpret the non-existence of rational inflation bubbles to mean that the inflationary process is consistent with monetary models in general.

Second, forward looking or rational expectations imply structural restrictions on the monetary model which can be interpreted best in the context of cointegrated models. The solution for the inflation rate in these models resembles the general form for the present
value models of Campbell and Shiller (1987 and 1988). Specifically, the models imply that money growth and inflation are cointegrated in the long run while the short term dynamics display temporary and stochastic dislocations from this equilibrium relationship. These "disequilibria", however, in turn do not imply that the present value model is not valid. On the contrary, the equilibrium error can be seen to anticipate future monetary policy due the fact that agents have superior information than does the econometrician. Causality running from the equilibrium error to money growth and inflation does not imply that the error causes changes in the variables of the model but instead anticipates them [Campbell and Shiller 1988: 506-507].

Cointegration between money growth and inflation, given the above interpretation, suggests that the appropriate framework should be an error correction representation for the two joint processes. As Campbell and Shiller (1987 and 1988) show, the cross equation restrictions can be readily generated from the error correction form. Unfortunately, rejection of these cross equation restrictions, however, does not lead to any clear interpretation of the underlying inflation-money growth dynamic. The ultimate goal of the analysis is to gauge the ability of the model to describe the inflationary process in each of these countries.

The paper is organized as follows. Section I presents a model of inflation in line the with classical theory and discusses the stationarity properties of money growth and inflation. Cross equation restrictions are developed in section II. The empirical results of the model are shown in section III while section IV summarizes and concludes the paper.

## I. A Classical Model of Inflation

The model starts with the money demand specification of Cagan (1956).

$$
\begin{equation*}
m_{t}-p_{t}=y_{t}-\alpha i_{t}+\epsilon_{t} \tag{1}
\end{equation*}
$$

where $m_{1}$ is the natural logarithm of the money stock, $p_{t}$ is the natural logarithm of the price level, $y_{t}$ is the natural logarithm of real output, $i_{t}$ is the nominal interest rate, and $\epsilon_{t}$ is a zero mean random error term all evaluated at time t. ${ }^{3}$ The standard assumption describes $\epsilon_{\mathrm{t}}$ as a random walk of the form

$$
\begin{equation*}
\epsilon_{t}=\epsilon_{t-1}+\eta_{t} \tag{2}
\end{equation*}
$$

where $\eta_{\mathrm{t}}$ is white noise.
The classical model assumes a Fisher relationship for the nominal interest rate.

$$
\begin{equation*}
i_{t}=r_{t}+E\left[\pi_{t+1} \mid \Phi_{t-k+1}\right] \tag{3}
\end{equation*}
$$

where $r_{t}$ is the real interest rate, $E[]$ is the expectations operator, $\pi_{t+1}=p_{t+1}-p_{t}$ is the logarithmic inflation rate, and $\Phi_{1}$ is the information set at time t . The model subsumes rational expectations, i.e. individuals use all information available to them to form expectations about future inflation rates.

[^1]Real output and real interest rates are assumed to follow random walks (real output also has a drift).

$$
\begin{gather*}
y_{t}-y_{t-1}=\tilde{y}+\omega_{1 t}  \tag{4}\\
r_{t}-r_{t-1}=\omega_{2 t} \tag{5}
\end{gather*}
$$

where $\omega_{1 t}$ and $\omega_{\mathrm{x}}$ are white noise.
Taking first differences on equation (1) and combined with equations (2) to (5) yields the following expression.

$$
\begin{equation*}
\mu_{t}-\pi_{t}=\tilde{y}-\alpha\left(E\left[\pi_{t+1} \mid \Phi_{t-k+1}\right]-E\left[\pi_{t} \mid \Phi_{t-k}\right]\right)+\xi_{t} \tag{6}
\end{equation*}
$$

where $\mu_{t}$ is the logarithmic growth of money and

$$
\begin{equation*}
\xi_{t}=\eta_{t}+\omega_{1 t}-\alpha \omega_{2 t} \tag{7}
\end{equation*}
$$

is white noise.
Rearranging equation (6) yields

$$
\begin{equation*}
\pi_{t}=\mu-\tilde{y}+\alpha\left(E\left[\pi_{t+1} \mid \Phi_{t-k+1}\right]-E\left[\pi_{t} \mid \Phi_{t-k}\right]\right)-\xi_{t} \tag{8}
\end{equation*}
$$

Taking expectations on equation (8) conditional on $\Phi_{r-k}$ and solving forward n periods into the future into equation (9) yields

$$
\begin{align*}
E\left[\pi_{t} \mid \Phi_{t-k}\right]=\frac{1}{1+\alpha}[ & \left.-\sum_{i=0}^{n-1}\left(\frac{\alpha}{1+\alpha)}\right)^{i} \tilde{y}+\sum_{i=0}^{n-1}\left(\frac{\alpha}{1+\alpha}\right)^{i}\left(E\left[\mu_{t+i} \mid \Phi_{t-k}\right]\right)\right]  \tag{9}\\
& +\left(\frac{\alpha}{1+\alpha}\right)^{n} E\left[\pi_{t+n} \mid \Phi_{t-k}\right]
\end{align*}
$$

For the evolution of inflation expectations (and thus inflation) to be stable (no bubbles), they must satisfy the following transversality condition

$$
\begin{equation*}
\lim _{n \rightarrow \infty}\left(\frac{\alpha}{1+\alpha}\right)^{n} E\left[\pi_{t+n} \mid \Phi_{t-k}\right]=0 \tag{10}
\end{equation*}
$$

If equation (10) is satisfied, the no bubbles solution to the inflation rate is

$$
\begin{equation*}
\pi_{t}=\mu_{t}-\tilde{y}+\frac{\alpha}{1+\alpha} \sum_{i=0}^{\infty}\left(\frac{\alpha}{1+\alpha}\right)^{i}\left(E\left[\mu_{t+i+1} \mid \Phi_{t-k+1}\right]-E\left[\mu_{t+i} \mid \Phi_{t-k}\right]\right)-\xi_{t} \tag{11}
\end{equation*}
$$

On the other hand, if the transversality condition is violated, a rational bubble can exist. For the bubble to be consistent with expectations, it must evolve in the following way

$$
\begin{equation*}
E\left[B_{t+1} \mid \Phi_{t-k}\right]-\left(\frac{1+\alpha}{\alpha}\right) B_{t}=0 \tag{12}
\end{equation*}
$$

Solutions to (14) satisfy the stochastic difference equation

$$
\begin{equation*}
B_{t+1}-\left(\frac{1+\alpha}{\alpha}\right) B_{t}=\zeta_{t+1} \tag{13}
\end{equation*}
$$

where the random variable $\zeta_{\text {t }}$ satisfies

$$
\begin{equation*}
E\left[\zeta_{t} \mid \Phi_{t-k}\right]=0 \quad \forall k \geq 0 \tag{14}
\end{equation*}
$$

The solution of inflation rate with a bubble is ${ }^{4}$

$$
\begin{equation*}
\pi_{t}=\mu_{t}-\bar{y}+\frac{\alpha}{1+\alpha} \sum_{i=0}^{\infty}\left(\frac{\alpha}{1+\alpha}\right)^{i}\left(E\left[\mu_{t+i+1} \mid \Phi_{t-k+1}\right]-E\left[\mu_{t+i} \mid \Phi_{t-k}\right]\right)+B_{t}-\xi_{t} \tag{15}
\end{equation*}
$$

The presence of bubbles carries a number of implications [Diba and Grossman 1988a: 522-523]. The first is that the presence of bubbles precludes the stationarity of any degree of differencing of the inflation series. Taking first differences of the bubble in equation (16) using the lag operator L yields ${ }^{5}$

$$
\begin{equation*}
\left[1-\left(\frac{1+\alpha}{\alpha}\right) L\right](1-L) B_{t}=(1-L) \zeta_{t} \tag{16}
\end{equation*}
$$

One could continue differencing this representation of the bubble. The ARMA representation of equation (20), however, will never be stationary (as the root of [1$((1+\alpha) / \alpha) z]=0$ lies inside the unit circle) nor invertible. The bubble introduces a non-
${ }^{\text {a }}$ To see this note that

$$
E\left[B_{t+1} \mid \Phi_{t-k}\right]-B_{t}=\frac{1}{\alpha} B_{t}
$$

Substituting this value into equation (8) yields the additive term $\mathrm{B}_{1}$.
${ }^{5}$ The following discussion follows Diba and Grossman's (1988a and 1988b).
stationarity which cannot be differenced away.
The presence of bubbles would also rule out cointegration between inflation and money growth. Reconsider equation (19) which / $\alpha$ ates

$$
\begin{equation*}
\pi_{t}=\mu_{t}-\bar{y}+\frac{\alpha}{1+\alpha} \sum_{i=0}^{\infty}\left(\frac{\alpha}{1+\alpha}\right)^{i}\left(E\left[\mu_{t+i+1} \mid \Phi_{t-k+1}\right]-E\left[\mu_{t+i} \mid \Phi_{t-k}\right]\right)+B_{t}-\xi_{t} \tag{17}
\end{equation*}
$$

Suppose both inflation and money growth are stationary after first differencing (i.e. integrated of order 1 or $\mathbf{I}(1)$ ) and recall that the growth rate of real output is assumed to be constant. In this classical representation, the left hand side of equation (21) is an equilibrium relationship of inflation and money growth with cointegrating vector $\alpha^{\prime}=[1$, $-1]$ and an intercept while the right hand represents the residuals $\mathrm{Z}_{\mathrm{r}}$. If there are no bubbles, the residuals are stationary and inflation and money growth are cointegrated of order ( 1,1 ). In the presence of bubbles, however, the residuals of the cointegrating regression are not stationary. Hence, if inflation and money growth are cointegrated, no bubbles exist. Further, cointegration of money growth and inflation rules out any nonstationarity of the unobserved variables [Diba and Grossman 1988a: 525-526]. Hamilton and Whiteman (1985) come to similar conclusions by showing that if money growth is stationary after $d$ differences and inflation is stationary after differencing $d$ times, then speculative inflationary bubbles cannot exist.

## II Cross Equation Restrictions

The new classical view of inflation posits that inflation rates are functions of current
and expected future money growth rates. The form of these relationships generate a set of easily testable restrictions on the inflationary process. The inflation generation process of the classical model without bubbles followed

$$
\begin{equation*}
\pi_{t}=\mu_{t}-\tilde{y}+\frac{\alpha}{1+\alpha} \sum_{i=0}^{\infty}\left(\frac{\alpha}{1+\alpha}\right)^{i}\left(E\left[\mu_{t+i+1} \mid \Phi_{t-k+1}\right]-E\left[\mu_{t+i} \mid \Phi_{t-k}\right]\right)-\xi_{t} \tag{18}
\end{equation*}
$$

The task now is to derive an error correction form of the monetary growth process in order to generate forecasts of $\mu_{t+i}$ and then test the restrictions implied by equation (1).

Suppose inflation and money growth are both $\mathrm{I}(1)$ and cointegrated $\mathrm{CI}(1,1)$. The trick now is to generate an error correction representation of the inflationary process. Let the time series vector $X_{t}=\left[\pi_{t}, \mu_{t}\right]$. By the Wold decomposition theorem, $X_{t}$ can be represented

$$
\begin{equation*}
(1-L) X_{t}=C(L) v_{t} \tag{19}
\end{equation*}
$$

where $C(L)$ is a $2 \times 2$ matrix in the lag operator and $v_{t}$ is a vector white noise process with $\boldsymbol{v}_{\mathbf{t}}=\left[\begin{array}{ll}\mathbf{v}_{1, t}, & \mathbf{v}_{2, t}\end{array}\right]$.

Engle and Granger (1987) show that the corresponding ARMA representation of the MA process of equation (2) will not be invertible and that an error correction form would be the appropriate model choice. To see this, multiply both sides of equation (2) by the cointegrating vector $[1,-1]$ to get

$$
\begin{equation*}
(1-L) Z_{t}=\alpha^{\prime}(1-L) X_{t}=\alpha^{\prime} C(L) v_{t} \tag{20}
\end{equation*}
$$

For $\mathrm{Z}_{\mathrm{t}}$ to be stationary, i.e. $\mathrm{I}(0)$,

$$
\begin{equation*}
\alpha^{\prime} C(1)=\overrightarrow{0} \tag{2}
\end{equation*}
$$

where 0 is a $1 \times 2$ vector of zeros. Hence, $C(L)=C(1)+(1-L) C^{\prime}(L)$ cannot be simply inverted to form an AR representation of $\mathrm{X}_{\text {. }}$. Granger and Engle (1987) show that the $\mathrm{CI}(1,1)$ process of equation (2) will have an error correction representation ${ }^{6}$

$$
\begin{equation*}
(1-L) X_{t}=A^{*}(L)(1-L) X_{t}-\lambda Z_{t-1}+b(L) v_{t} \tag{22}
\end{equation*}
$$

where $A^{\prime}(0)=0, \lambda$ is a vector of constants, $\lambda$ is a $(2 \times 1)$ vector of constants, $\operatorname{det}[C(L)]=$ $(1-\mathrm{L}) \mathrm{b}(\mathrm{L})]$, and $\mathrm{b}(\mathrm{L})$ is a scaler lag polynomial. As $\mathrm{b}(\mathrm{L})$ is invertible, premultiplying equation (5) by $b^{-1}(\mathrm{~L})$ yields

$$
\begin{equation*}
D(L)(1-L) X_{t}=-g(L) \lambda Z_{t-1}+v_{t} \tag{23}
\end{equation*}
$$

where $D(L)=b^{-1}(L)\left[I-A^{-}(L)\right]=b^{-1}(L) A(L)$ and $g(L)=b^{-1}(L)$. Define the matrix $M$ as
${ }^{6}$ The Granger Representation Theorem [Engle and Granger 1987: 255-256]. These results follow from factoring the adjoint matrix of $\mathrm{C}(\mathrm{L})$.

$$
M=\left[\begin{array}{cc}
0 & 1  \tag{24}\\
1 & -1
\end{array}\right]
$$

Now

$$
M X_{t}=\left[\begin{array}{cc}
0 & 1  \tag{25}\\
1 & -1
\end{array}\right]\left[\begin{array}{l}
\pi_{t} \\
\mu_{t}
\end{array}\right]=\left[\begin{array}{c}
\mu_{t} \\
Z_{t}
\end{array}\right]
$$

and

$$
X_{t}=M^{-1}\left[\begin{array}{l}
\mu_{t}  \tag{26}\\
Z_{t}
\end{array}\right]=\left[\begin{array} { l l } 
{ 1 } & { 1 }
\end{array} \left[\begin{array}{c}
\mu_{t} \\
1
\end{array} 00\left[\begin{array}{l}
Z_{t}
\end{array}\right]\right.\right.
$$

Substituting equation (30) into equation (27) yields

$$
D(L)(1-L) M^{-1}\left[\begin{array}{l}
\mu_{t}  \tag{27}\\
Z_{t}
\end{array}\right]=-g(L) \lambda Z_{t-1}+v_{t}
$$

Since (1-L) is a scaler in L, equation (10) can be rearranged in the following way ${ }^{7}$
${ }^{7}$ See Campbell and Shiller (1988), p. 510-511. The intuition behind this reformulation lies in the fact that $Z_{\mathrm{t}}$ is stationary.

$$
H(L)\left[\begin{array}{c}
(1-L) \mu_{t}  \tag{28}\\
Z_{t}
\end{array}\right]=\omega_{t}
$$

In order-to-generate optimal forecasts of money growth, we rewrite the VAR representation of equation (11) in the following way

$$
\begin{equation*}
Y_{t}=\Theta Y_{t-1}+e_{t} \tag{29}
\end{equation*}
$$

where

$$
Y_{t}=\left[\begin{array}{c}
(1-L) \mu_{t}  \tag{30}\\
(1-L) u_{t-1} \\
\cdot \\
\cdot \\
\cdot \\
\cdot \\
(1-L) \mu_{t-p-1} \\
(1-L) \mu_{t-p} \\
Z_{t} \\
Z_{t-1} \\
\cdot \\
\cdot \\
\cdot \\
Z_{t-p-1} \\
Z_{t-p}
\end{array}\right] \quad e_{t}=\left[\begin{array}{c}
\omega_{1 t} \\
0 \\
\cdot \\
\cdot \\
\cdot \\
0 \\
\omega_{2 t} \\
0 \\
\cdot \\
\cdot \\
\cdot \\
0
\end{array}\right]
$$

and $\theta$ is the companion matrix of the VAR of the form

$$
\Theta=\left[\begin{array}{cccccccccc}
\theta_{111} & \theta_{112} & \ldots & \theta_{11 p-2} & \theta_{11 p} & \theta_{121} & \theta_{122} & \ldots & \theta_{12 p-1} & \theta_{12 p}  \tag{31}\\
1 & 0 & \ldots & 0 & 0 & 0 & 0 & \ldots & 0 & 0 \\
0 & 1 & \ldots & 0 & 0 & 0 & 0 & \ldots & 0 & 0 \\
. & . & \ldots & . & . & . & . & \ldots & . & . \\
. & . & \ldots & . & . & . & . & \ldots & . & . \\
. & . & \ldots & . & . & . & . & \ldots & . & . \\
0 & 0 & \ldots & 1 & 0 & 0 & 0 & \ldots & 0 & 0 \\
\theta_{211} & \theta_{212} & \ldots & \theta_{21 p-1} & \theta_{21 p} & \theta_{221} & \theta_{222} & \ldots & \theta_{22 p-1} & \theta_{22 p} \\
0 & 0 & \ldots & 0 & 0 & 1 & 0 & \ldots & 0 & 0 \\
0 & 0 & \ldots & 0 & 0 & 0 & 1 & \ldots & 0 & 0 \\
. & . & \ldots & . & . & . & . & \ldots & . & . \\
. & . & \ldots & . & . & . & . & \ldots & . & . \\
. & . & \ldots & . & . & . & . & \ldots & . & . \\
0 & 0 & \ldots & 0 & 0 & 0 & 0 & \ldots & 1 & 0
\end{array}\right]
$$

Optimal forecasts of the Y , will thus be generated by

$$
\begin{equation*}
E\left[Y_{t+i} \mid \Phi_{t-k}\right]=\theta^{k+1+i} Y_{t-k} \tag{32}
\end{equation*}
$$

One important aspect of the VAR of equation (36) is that if the cointegrated present value model holds, $\mathrm{Z}_{\mathrm{t}}$ will "Granger-cause" changes in money growth and changes in inflation [Campbell and Shiller 1988: 513]. If economic agents have superior information to that of the econometrician, one would find that the equilibrium error anticipates the changes in inflation and money growth. Hence, below we test for such a causal relationship.

Equation (1) implies a set of restrictions on the optimal forecast equation (15).

Recall the money demand function

$$
\begin{equation*}
\pi_{t}=\mu-\tilde{y}+\alpha\left(E\left[\pi_{t+1} \mid \Phi_{t-k+1}\right]-E\left[\pi_{t} \mid \Phi_{t-k}\right]\right)-\xi_{t} \tag{33}
\end{equation*}
$$

Rewriting-equation (37) in the new notation yields

$$
\begin{equation*}
Z_{t}=-\bar{y}+\alpha\left(E\left[Z_{t+1} \mid \Phi_{t-k+1}\right]+E\left[\mu_{t+1} \mid \Phi_{t-k+1}\right]-E\left[Z_{t} \mid \Phi_{t-k}\right]-E\left[\mu_{t} \mid \Phi_{t-k}\right]\right)-\xi_{t} \tag{34}
\end{equation*}
$$

Taking expectations conditional on $\Phi_{t \cdot k}$ of equation (38) and rearranging yields

$$
\begin{equation*}
E\left[\left.Z_{t}-\frac{\alpha}{1+\alpha} Z_{t+1}-\frac{\alpha}{1+\alpha} \Delta \mu_{t+1}-\frac{1}{1+\alpha} \tilde{y} \right\rvert\, \Phi_{t-k}\right]=0 \tag{35}
\end{equation*}
$$

Let $R_{1}=[0,0, \ldots, 0,1,0,0, \ldots, 0,0]$ and $R_{2}=[1,0, \ldots, 0,0,0,0, \ldots, 0,0]$. The classical restrictions in equation (18) can be expressed as

$$
\begin{equation*}
H_{1}^{o}=R_{1} \Theta^{k}-\frac{\alpha}{1+\alpha} R_{1} \Theta^{k+1}-\frac{\alpha}{1+\alpha} R_{2} \Theta^{k+1}=0 \tag{36}
\end{equation*}
$$

which are non-linear in the parameter matrix $\theta$. The Wald statistic for this test is

$$
\begin{equation*}
T H_{1}^{o}\left[\left(\frac{\partial H_{1}^{o}}{\partial \Theta}\right)^{\prime} \hat{\Sigma}_{\hat{E}}\left(\frac{\partial H_{1}^{o}}{\partial \Theta}\right)\right]^{-1} H_{1}^{o} \sim \chi_{p}^{2} \tag{37}
\end{equation*}
$$

where T is the number of observations and $\Sigma_{\theta}$ is the estimated covariance matrix of the
estimated $\theta$ matrix.

## III Empirical Results

## a. Cointegration Tests

Before moving to the tests for cointegration, tests on the order of integration are in order. ${ }^{8}$ Tables 1 through 10 show the Dickey-Fuller (1979) and Phillips-Perron (1988) tests for stationarity for money and prices in Argentina, Bolivia, Brazil, Mexico, and Peru. The Phillips and Perron (1988) tests correct for non-normality of variables (tested for using the Jarque and Bera (1980) tests). In Argentina, Bolivia, Brazil, Mexico, and Peru, $\mathbf{M}_{2}$ money growth and inflation are strongly stationary after differencing. In all countries, inflation is not unambiguously $\mathrm{I}(1)$ as opposed to $\mathrm{I}(0)$. The cointegration tests below, however, indicate that it is $\mathbf{I}(1)$ as is money growth. ${ }^{9}$

Generally, cointegration means that (non-stationary) time series variables tend to move together such that a linear combination of them is stationary. As in the analysis above, some have interpreted cointegration as representing a long run equilibrium

[^2]relationship. Differencing $X_{1} d$ times to generate a stationary time series and then estimating a VAR based upon the differenced series is inappropriate in the presence of cointegration. Recall that if a ( $\mathrm{p} \times 1$ ) vector time series $\mathrm{X}_{1}$ ( $\mathrm{p}=2$ in this case) is first difference stationary, i.e. $\mathrm{I}(1)$, and cointegrated, i.e. $\mathrm{b}=1$, there exists an error correction form
\[

$$
\begin{equation*}
\Delta X_{t}=A_{1} \Delta X_{t-1}+\ldots+A_{k-1} \Delta X_{t-k+1}+\Pi X_{t-1}+\varepsilon_{t} \tag{38}
\end{equation*}
$$

\]

where $I I=\alpha \beta^{\prime}, \beta^{\prime}=\left[\beta_{\pi}, \beta_{\mu}\right]$ is the cointegrating vector, $\alpha^{\prime}=\left[\alpha_{\pi}, \alpha_{\mu}\right]$ is the error correction. coefficient (or speed of adjustment). An important aspect of this theorem is that the VAR should incorporate the long run equilibrium relationship between the levels. A VAR based purely upon differences would exclude this relevant information in addition to displaying infinite variance.

In general, there can exist ( $\mathrm{p}-1$ ) independent cointegrating vectors. A weakness in the Engle and Granger (1987) approach is that it offers no clear criterion for choosing the number of cointegrating vectors. Johansen and Juselius (1990) take a general maximum likelihood approach to choosing the number of independent cointegrating vectors, estimating II, $\alpha, \beta^{\prime}$, and testing restrictions on $\alpha$ and $\beta$. Their technique is based upon the following general version of equation (1). ${ }^{10}$
${ }^{10}$ The $I$ matrix is the same in equation (42) and equation (43). It can be shown that the level variable can take on any lag from 1 to k without affecting II. The coefficients on the lagged differenced variables, of course, change.

$$
\begin{equation*}
\Delta X_{t}=\Gamma_{1} \Delta X_{t-1}+\ldots+\Gamma_{k-1} \Delta X_{t-k+1}+\Pi I X_{t-k}+\mu+\Phi D_{t}+\varepsilon_{t} \tag{39}
\end{equation*}
$$

where $D_{t}$ is a set of seasonal dummies which sum to zero.
The analysis- of the negative of the growth in real money balances looks at the behavior of $\mathcal{B}^{\prime}=[1,-1]$ of the vector time series $\mathrm{X}_{\mathrm{t}}=\left[\pi_{\mathrm{t}}, \mu_{\mathrm{t}}\right]$. The maximum likelihood estimates for the cointegrating vector $\mathbb{B}^{\prime}$ can be obtained from the following eigenvalue problem. ${ }^{11}$

$$
\begin{equation*}
\left|\lambda S_{k k}-S_{k o} S_{o o}^{-1} S_{o k}\right|=0 \tag{40}
\end{equation*}
$$

where $\mathrm{S}_{\mathrm{ij}}$ are the residual moment matrices from the OLS regressions of $\Delta \mathrm{X}_{\mathrm{t}}$ and $\mathrm{X}_{\mathrm{t} j}, \Delta \mathrm{X}_{\mathrm{t} j}$, $\mathrm{j}=1, \ldots, \mathrm{k}-1$. The estimates of $B^{\prime}$ are just the corresponding eigenvectors while the (maximum) eigenvalues along with the trace (computed from the eigenvalues) are used as test statistics for the rank of $\Pi$. Notice that if $\operatorname{Rank}(I I)=r=p$, any vector is a cointegrating vector and hence the original vector times series $\mathrm{X}_{\mathrm{t}}$ is stationary. Hence, if inflation and money growth are $\mathrm{I}(0)$, then we should find two cointegrating vectors. If $\operatorname{Rank}(\mathrm{I})=\mathrm{r}<\mathrm{p}$, then the data are $I(1)$ and we have $r$ cointegrating vectors. If $\operatorname{Rank}(I I)=r=0$, then we find no cointegrating vectors and a VAR based purely on the first difference of $X_{1}$ is appropriate. The critical values and sizes of the test statistics appear in the appendix of Johansen and Juselius (1990).

[^3]The estimated $\beta^{\prime}$ can then be substituted into equation (43) to derive estimates of $\alpha$. One can also impose restrictions on $\Pi$ in the form of individual vectors $\mathbb{B}^{\prime}$ and $\alpha$. In this case, we are interested in testing whether $B^{\prime}=[1,-1]$. The likelihood ratio test is distributed as a $\chi_{(1)}^{2}$.

The results of the rank tests appear for Argentina in tables 11a, for Bolivia in 12a, for Brazil in tables 13a, for Mexico in 14a, and for Peru in 15a. In all cases, the trace and maximum eigenvalue tests indicate that the $\Pi$ matrix is $r a n k=1$, i.e. $r=1$, at the $5 \%$ significance level. In other words, there is only one cointegrating vector for inflation and money growth. This also indicates that the original time series are not stationary as the II is not full rank, i.e. equal to 2 . The significant cointegrating relationships rule out rational inflationary bubbles in each case.

Tests on the cointegrating vector appear for Argentina in table 11b, for Bolivia in 12b, for Brazil in 13b, for Mexico in 14b, and for Peru in 15b. Specifically, we test for long run money neutrality which takes the form of testing whether $\mathcal{B}^{\prime}=[1,-1]$. In all countries but Mexico, one cannot reject the neutrality of money. This anomoly probably results from non-normalities in the series. To confirm this, a Phillips-Perron stationarity test on the growth in real balances appears in tables 11 b through 15 b . In all cases, real balances strongly reject the null hypothesis of non-stationarity.

Tables 16 through 21 present the remaining tests of the present value model. As mentioned above, ${ }^{12}$ if the present value model holds, equilibrium errors, $Z_{t}$, should

[^4]anticipate changes in money growth. In all countries, $Z_{\mathrm{t}}$ significantly Granger-causes $\Delta \mu_{\mathrm{t}}$ while significant causality in the other direction occurs only in Bolivia, Mexico, and Peru.

The cross equation restrictions, on the other hand, do not conform as readily to the present value model. For all reasonable values of the semi-elasticity of money with respect to the interest rate, $\alpha$, in Argentina, Mexico and Peru, one does not reject the present value model for an information lag of $(k-1=1) 1$ quarter. In the Bolivian and Brazilian cases, the model is rejected for all reasonable values of $\alpha$ for information lags of ( $\mathrm{k}-1=$ ) 1 month at less than the $1 \%$ significance level while rejected $(k-1)=2$ months at the $5 \%$ level for Bolivia and at the $10 \%$ level for Brazil.

## IV Conclusions

The inflation processes in Argentina, Bolivia, Brazil, Mexico, and Peru generally conform to the implications of the new classical model in spite of its simple form. Inflation and money growth are cointegrated in all countries ruling out speculative inflationary bubbles. Agents apparently anticipate future changes in money growth (and, by cointegration, inflation) in line with the rational expectations monetary model. Further, the cross equation restrictions implied by the model are not rejected in Argentina when the information lag is one quarter and Mexico and Peru when the information lag is one month. These restrictions, however, are rejected in Bolivia and Brazil with a one month information lag.

The results show that forward looking expectations do play a part in the inflation process of all countries. Further, "speculative" sources play an insignificant role at least in
the medium to long term. Certainly, the model is too simple to explain many other important aspects of inflation in these Latin American countries especially in the Brazilian case. A more detailed structural specification incorporating forward looking variables may improve the performance of the model.

## Appendix: Tests of Stability

This appendix shows the results of CUSUM calculations for the inflation model in Argentina, Bolivia, Brazil, Mexico, and Peru. ${ }^{1}$ The CUSUMs are calculated based upon the recursive residuals from the first equation of the VAR in equation (28) in the text of the following form

$$
\begin{equation*}
\Delta \mu_{t}=\theta_{11}(L) \Delta \mu_{t-1}+\theta_{12}(L) Z_{t-1} \tag{A1}
\end{equation*}
$$

The CUSUM series are presented in Figures A1 through A5 along with 5\% and $10 \%$ confidence bands. None of the series cross the significance bounds indicating no significant structural change. Sharp movements in the series, however, might indicate structural break. Argentina, (1980-81, 1983), Bolivia (1985), Mexico (1982-83, and Peru (1988 and 1990) show some moderate movements in the CUSUM series. Still, permanent regime changes and structural instability do not seem to be indicated by the data.

## Mexico: CUSUM 1971:7 to 1989:9

Figure A5
Peru: CUSUM 1983:1-1990:6

[^0]:    ${ }^{1}$ See the articles in Baer and Welch (1987) for discussions of the initial adjustment which ignited the revised monetarist-structuralist debate. Sargent (1986) succinctly lays out the new classical view of inflation. The works contained in Baer and Kerstenetzky (1964) present a good summary of the old debate.
    ${ }^{2}$ Good reviews on the recent inflation experiences in each of these countries include Bruno, et al, (1991), Pastor (1989), Sachs and Morales (1988), Paredes and Sachs (1991), and Dornbusch and Edwards (1991).

[^1]:    ${ }^{3}$ This error term can be viewed as one which is either viewed by market participants or constructed by them. $\epsilon_{\mathfrak{i}}$, however, is not observed by the researcher. See Diba and Grossman (1988a) and Campbell and Shiller (1987 and 1988).

[^2]:    ${ }^{8}$ Inflation in both countries is measured by the wholesale price index and $\mathrm{M}_{2}$ was picked as the monetary aggregate based upon cointegration tests on the money demand equation (1). The conclusions of the tests, however, do not depend on the choice of money aggregate. The Argentine data are quarterly observations from 1970 to 1984 and come from INDEC. The Bolivian data are monthly observations from June 1980 to September 1990 from the Banco Central de Bolivia. The Brazilian data are monthly observations from 1974 to 1985 and come from the Fundação Getúlio Vargas. The Mexican data are monthly observations from January 1972 to September 1989 from the Banco de Mexico Indicadores Economicos and from the data bank of Sie-Mexico. Finally, Peru's data are monthly observations from January 1983 to June 1990 from the Banco Central de Peru.
    ${ }^{9} \mathrm{M}_{2}$ was used.as. the money aggregate.in all countries except Mexico. We used $\mathrm{M}_{1}$ for Mexico but the results hold for $\mathrm{M}_{2}$ as well.

[^3]:    ${ }^{11}$ The Johansen and Juselius (1990) procedure assumes normality. The equations are estimated using RATS 3.10 software.

[^4]:    ${ }^{12}$ CUSUM tests for structural stability appear in appendix A. Even though structural breaks were not found, dividing the periods studied for each country did not significantly alter the results of the paper. These tests are available upon request.

[^5]:    ${ }^{1}$ For a good discussion of recursive residuals and CUSUM, see Harvey (1990).
