## The Feldstein-Horioka Fact

**Domenico Giannone**, *European Central Bank and CEPR*

**Michele Lenza**, *European Central Bank*

### I. Introduction

The Feldstein-Horioka puzzle is one of the six major puzzles in international macroeconomics (Obstfeld and Rogoff 2000). Domestic saving and investment rates are highly correlated both within and between OECD countries: in countries where and in years when saving is high, so is investment. This fact seems incompatible with the intertemporal theory of the current account. Assuming perfect capital mobility, such a theory predicts that the determinants of saving and investment are not the same. Hence, countries should borrow and lend abroad whenever they need to invest or disinvest, without being constrained by domestic saving decisions. Feldstein and Horioka (1980) interpreted their finding as evidence of low capital mobility among OECD countries. Although the relation with capital mobility is not straightforward (see Frankel [1992] for a critical discussion), the saving-retention coefficient has been used as an indicator of capital mobility in the world capital market. However, in the decades following the publication of Feldstein and Horioka's results, capital mobility among OECD countries has kept on increasing whereas the correlation between saving and investment rates has only slightly decreased.<sup>1</sup>

On the other hand, the intertemporal theory of the current account fails to consider general equilibrium effects that, it has been argued, could provide an explanation for the puzzle (see Baxter and Crucini 1993; Ventura 2003). Since the world, as a whole, is a closed economy, world saving and investment have to be equal. Consequently, a common shock that, say, positively affects saving decisions of most countries tends to create imbalance in world capital markets and decreases the world interest rate. This, in turn, increases world investment and generates a positive correlation between saving and investment in all countries.

Partial equilibrium predictions of the theory are more likely to hold in response to idiosyncratic sources of fluctuations whose effect on world capital markets is likely to be negligible. Since global shocks are acknowledged to be an important force driving the world business cycle (see, e.g., Gregory and Head 1999; Kose, Otrok, and Whiteman 2003), general equilibrium effects should reconcile theory and evidence. However, general equilibrium explanations of the Feldstein-Horioka finding never found adequate empirical support since the saving-investment correlation does not decrease when controlling for global shocks (see, e.g., Glick and Rogoff 1995; Ventura 2003). Consequently, a belief has arisen that the high saving-investment correlation can be explained only by introducing frictions in international good or financial markets (Obstfeld and Rogoff [2000] and Ventura [2003] are two examples of this view).

This paper revisits the general equilibrium explanation and shows that, in contrast to what is claimed by existing empirical studies, it does help to rationalize the puzzle. Previous attempts to control for the effects of global shocks in saving and investment regressions assume homogeneity of their transmission mechanisms across countries. However, there are no theoretical reasons to focus only on global shocks that have homogeneous effects. In fact, also global shocks with heterogeneous effects can create imbalance on the world capital market, unless the nature of the heterogeneity is such that the effect in a group of countries is perfectly offset by the opposite effect in the rest of the world.

We propose a new methodology, factor-augmented panel regression, to isolate idiosyncratic sources of fluctuations. It improves on existing studies since countries are allowed to react with specific sign and magnitude to global shocks. We show that the homogeneity restriction is rejected by the data and biases the estimation of the saving-retention coefficient. Indeed, allowing for a heterogeneous propagation mechanism of global shocks, the saving-retention coefficient drops significantly from the 1980s on, consistently with the increase in capital mobility across OECD countries.

The paper is structured as follows. In Section II, we review commonly used methods to control for global sources of fluctuations and propose the novel factor-augmented panel regression. Section III presents the empirical results. Section IV presents conclusions.

## II. General Equilibrium and the Saving-Retention Coefficient

Many studies document the existence of strong cross-country linkages in macroeconomic fluctuations (for a survey, see Kose et al. [2003]). This suggests that international fluctuations are driven by few common

sources that can generate positive correlation between saving and investment through general equilibrium mechanisms. Such positive correlation is not in contradiction with the partial equilibrium intertemporal theory of the current account, whose predictions are conditional on idiosyncratic (country-specific or regional) shocks that, not affecting all the countries, are unlikely to generate imbalance in the world capital market.

Formally, consider the following representation for saving ( $S_{j,t}$ ) and investment ( $I_{j,t}$ ) rates<sup>2</sup> of country  $j$  at time  $t$ :

$$S_{j,t} = \lambda_{1,j}^S f_{1,t} + \cdots + \lambda_{r,j}^S f_{r,t} + S_{j,t}^{id}, \quad (1)$$

$$I_{j,t} = \lambda_{1,j}^I f_{1,t} + \cdots + \lambda_{r,j}^I f_{r,t} + I_{j,t}^{id}, \quad (2)$$

where  $f_{i,t}$ ,  $i = 1, \dots, r$ , are few global factors affecting saving and investment rates of all countries and  $S_{j,t}^{id}$  and  $I_{j,t}^{id}$  are the idiosyncratic components of saving and investment rates that are assumed to be driven by nonpervasive (idiosyncratic) shocks. The factor loadings  $\lambda_{i,j}^S$  and  $\lambda_{i,j}^I$  ( $j = 1, \dots, N$ ,  $i = 1, \dots, r$ ) are country specific and capture the heterogeneity in the transmission mechanisms of global shocks. In particular, each variable can react with a specific sign and intensity to the global factors  $f_{i,t}$  ( $i = 1, \dots, r$ ).<sup>3</sup>

For the reasons outlined above, the intertemporal theory of the current account refers to idiosyncratic components of saving and investment rates. We consider the following relationship:

$$I_{j,t}^{id} = \alpha_j + \beta S_{j,t}^{id} + \varepsilon_{j,t}, \quad (3)$$

where  $\beta$  is the saving-retention coefficient conditional on idiosyncratic shocks or, in terms of long-run fluctuations,

$$\frac{1}{T} \sum_{t=1}^T I_{j,t}^{id} = \bar{\alpha}_j + \beta_L \frac{1}{T} \sum_{t=1}^T S_{j,t}^{id} + \bar{\varepsilon}_j. \quad (4)$$

Equations (1) and (2) imply that (3) and (4) can be rewritten in terms of observable saving and investment rates as

$$I_{j,t} = \alpha_j + \beta S_{j,t} + \delta_{1,j} f_{1,t} + \cdots + \delta_{r,j} f_{r,t} + \varepsilon_{j,t} \quad (5)$$

and

$$\frac{1}{T} \sum_{t=1}^T I_{j,t} = \bar{\alpha}_j + \beta_L \frac{1}{T} \sum_{t=1}^T S_{j,t} + \delta_{1,j}^L \frac{1}{T} \sum_{t=1}^T f_{1,t} + \cdots + \delta_{r,j}^L \frac{1}{T} \sum_{t=1}^T f_{r,t} + \bar{\varepsilon}_j, \quad (6)$$

where  $\delta_{i,j} = \lambda_{i,j}^I - \beta \lambda_{i,j}^S$  and  $\delta_{i,j}^L = \lambda_{i,j}^I - \beta_L \lambda_{i,j}^S$ . Notice that the coefficients  $\delta_{i,j}$  and  $\delta_{i,j}^L$  can vary along the cross-sectional dimension since they are functions of factor loadings of domestic saving and investment rates in different countries. Assume, for example, that  $\beta = 0$  or  $\beta_L = 0$  in equations (3) and (4); in that case, the  $\delta_{i,j}$ 's or  $\delta_{i,j}^L$ 's would be equal across countries only if the  $\lambda_{i,j}^I$  were equal across countries or, in other words, if the response of the investment rates to common shocks was the same in all countries.

Let us investigate the consequences of equation (5) and (6) for the methodologies commonly used in the Feldstein-Horioka debate. We argue that, indeed, all of them are not robust to the introduction of heterogeneity in the transmission mechanisms of global shocks.

In their seminal paper, Feldstein and Horioka performed the following "long-run" regression:

$$\frac{1}{T} \sum_{t=1}^T I_{j,t} = \mu + \beta_L \frac{1}{T} \sum_{t=1}^T S_{j,t} + \bar{\eta}_j. \quad (7)$$

Temporal aggregation averages out from the data short- and medium-run fluctuations. Therefore, the long-run regression (7) is able to control for short- and medium-run effects of global shocks on saving and investment. On the other hand, time aggregation does not average out the long-run effects of global factors. Whenever these effects are significantly different across saving and investment rates in different countries, the country-specific long-run effect of global shocks,  $\delta_{1,j}^L(1/T) \sum_{t=1}^T f_{1,t} + \dots + \delta_{r,j}^L(1/T) \sum_{t=1}^T f_{r,t}$ , will not be captured by the constant term  $\mu$  and, hence, will be contained in the error  $\bar{\eta}_j$ . Since observed saving is also affected by global shocks, the estimation of  $\beta_L$  is not consistent.

Estimation methods alternative to the long-run regression of Feldstein and Horioka have been proposed in order to investigate the relation between saving and investment rates, and, invariably, they end up with results that point to a high correlation. Let us start considering the consequences of estimating  $\beta$  by a "baseline panel regression" or, more precisely,

$$I_{j,t} = \alpha_j + \beta S_{j,t} + \eta_{j,t} \quad (8)$$

when the data-generating process is given by (1) and (2). From (5) it can be easily seen that the error term  $\eta_{j,t}$  contains the common factors and is correlated with the regressors. Then, the estimates based on equation (8) are not consistent.

A method generally proposed to correct for this problem consists in adding time dummies to the baseline panel regression (8) by specifying the following regression equation:

$$I_{j,t} = \alpha_j + \gamma_t + \beta S_{j,t} + \zeta_{j,t}, \quad (9)$$

where  $\gamma_t$  is the so-called time effect.<sup>4</sup> However, this method is not always appropriate. In fact, comparing equation (9) with equation (5), one can see that time effects can properly capture comovement only if each global factor has the same effect across countries (i.e.,  $\delta_{i,j} = \delta_{i,h}$  for each  $j, h$ ). Otherwise, the estimate of  $\beta$  remains inconsistent. Again, this specification does not take into account the possibility of heterogeneous transmission mechanisms of global shocks.<sup>5</sup>

In conclusion, if global shocks propagate heterogeneously across countries, the relationship between idiosyncratic components of saving and investment rates cannot be consistently estimated by the regressions commonly used in the Feldstein-Horioka type of analysis. However, equation (5) suggests that we can relax the homogeneity assumption by plugging the common factors directly into the baseline panel regression, without imposing any restriction on the country-specific coefficients ( $\delta_{i,j}$ ,  $j = 1, \dots, N$ ,  $i = 1, \dots, r$ ). The idea is to control for the factors that affect all countries, for example, oil shocks or global productivity shocks, and that could create an imbalance on the world capital market.

This goal could be achieved by controlling for those variables that are mainly affected by global shocks and capture the closed economy constraint for the world economy, for example, world investment and world interest rate.

An alternative approach consists in extracting the global factors directly from saving and investment rates by cross-country aggregation. The latter capture the factors affecting saving and investment rates in all countries since the idiosyncratic components, driven by nonpervasive (country-specific or regional) shocks, are averaged out by worldwide aggregation. More precisely, as shown by Forni et al. (2000) and Stock and Watson (2002), the components of the factor model in (1) and (2) are identified and the unobserved global factors ( $f_{i,t}$ ,  $i = 1, \dots, r$ ) can be estimated, provided that the number of countries under analysis is large. Hence, we plug estimated factors in equation (5), obtaining the following *factor-augmented panel regression*:

$$I_{j,t} = \alpha_j + \beta S_{j,t} + \delta_{1,j} \hat{f}_{1,t} + \dots + \delta_{r,j} \hat{f}_{r,t} + \varepsilon_{j,t}. \quad (10)$$

In order to implement this methodology, we need to estimate  $r$ , the number of global factors, and the global factors  $f_{1,t}, \dots, f_{r,t}$  themselves.

Forni and Reichlin (1998) and Pesaran (2006) have proposed to estimate the common factors by means of cross-country aggregates. As pointed out above, data aggregates converge to the common factors as the cross-sectional dimension increases, because the idiosyncratic components are averaged out. However, this approach may be problematic if there is more than one common factor. Forni et al. (2000) and Stock and Watson (2002) have proposed to estimate the common factors,  $f_{1,t}, \dots, f_{r,t}$ , by means of the first  $r$  principal components. Consistency of this estimator is achieved as both the number of series and observations increase. These estimates are robust with respect to some form of nonstationarity in the data.<sup>6</sup> Moreover, the estimated factors can be considered as they were known provided that the number of countries is not too small relative to the sample size.<sup>7</sup>

The number of the common factors,  $r$ , should be set in order to fully capture the closed economy constraints on saving and investment. In other words, we need to isolate idiosyncratic sources of fluctuations in saving and investment, which are less likely to generate general equilibrium effects.

For what concerns specifically principal components, there have been different proposals essentially based on the ability to capture global comovement. A rule of thumb proposed by Forni and Reichlin (1998) suggests retaining only principal components that explain more than a certain threshold percentage of the panel variance. Bai and Ng (2002) formalize this idea by constructing a criterion based on a data-dependent threshold.

Finally, while studying in depth the heterogeneity in the transmission mechanisms of global shocks, we maintain throughout this and the next section the assumption of a fixed saving-retention coefficient ( $\beta$ ) across countries. Such a coefficient is meant to provide an overall assessment of the correlation between saving and investment left over after properly controlling for global shocks; that is all we need to evaluate the general equilibrium explanation of the Feldstein-Horioka puzzle.

### III. Empirics

#### A. *Global Fluctuations*

This section studies the features of the international business cycles focusing on their implications for the saving and investment debate. Our

database consists of annual data on saving and investment rates of 20 OECD countries for the period 1970–2007.<sup>8</sup> The extent of cross-country linkages can be measured by the correlation of domestic saving and investment with respect to their OECD-wide counterparts. By regressing domestic saving and investment rates onto the global OECD investment rates, we capture about half of the panel variance.<sup>9</sup> Another option is to look at OECD-wide aggregates that maximize the explainable variance. Principal components of the covariance matrix of the data have this property.

In table 1, we show that the first principal component explains about 50% and the second principal component slightly more than 15% of the variance of domestic saving and investment rates, on average. Then, at least two principal components explain significantly more than 10% of the panel variance and capture, overall, about two-thirds of the panel variance. Consequently, the rule of thumb proposed by Forni and Reichlin (1998) would suggest at least two common factors.<sup>10</sup> On the other hand, the Bai and Ng (2002) criterion proves inconclusive in our panel. These results show that cross-country linkages in saving and investment rates of OECD countries are strong. Following Forni et al. (2000) and Stock and Watson (2002), we can conclude that the factor model representations (1) and (2) describe our data well.

Moreover, the global factors also have a strong long-run effect on saving and investment rates of OECD countries: one aggregate accounts for more than 67% of the long-run panel variance.<sup>11</sup> In addition, by looking at the percentage of the variance of domestic saving and investment rates explained by global factors, it is evident how their impact varies considerably across countries (see figs. 1 and 2).

These findings are consistent with those of Kose et al. (2003), who highlight both strong persistence and heterogeneity in the transmission mechanisms of global shocks. This suggests that, in order to properly control for general equilibrium effects, it is important to take into account that countries react to global shocks with a specific sign, magnitude, and lag structure.

**Table 1**  
Share of the Overall Panel Variance Explained by Static Principal Components

	Principal Component				
	1st	2nd	3rd	4th	5th
Marginal	.4862	.1639	.1098	.0554	.0390
Cumulative	.4862	.6501	.7593	.8153	.8543

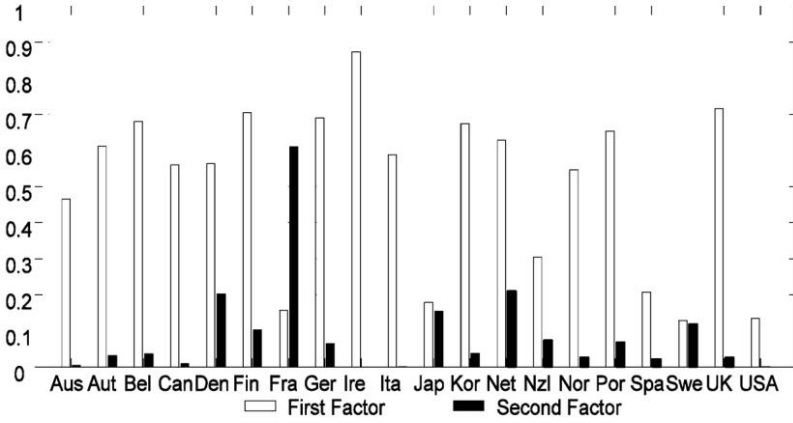

Fig. 1. Domestic saving: percentage of variance explained by the first two factors

As stressed in Section II, aggregates like those used above provide consistent estimates of the global factors for large sample size and cross-section dimension. Given the existence of two global factors, a single aggregate such as the OECD investment rate is not sufficient to fully capture the effect of global shocks. Hence, the first two principal components are appropriate estimators.

On the other hand, principal components have an important drawback with respect to aggregates such as, say, the global OECD saving or investment rate: they miss a clear intuition. While well suited to assess the strength of cross-country linkages and to estimate the factor space, in general they do not have an economic interpretation. In order to get an intuition on the nature of the principal components, we look at their

Fig. 2. Domestic investment: percentage of variance explained by the first two factors

relation with economic aggregates. In figure 3, we plot the first principal component and the global OECD investment rate.

These two aggregates are very similar, and their correlation coefficient is .93. A good candidate for the second principal component should be a variable mainly driven by common shocks and not collinear with the global investment rate. For example, the global OECD saving rate is not appropriate because it satisfies the first but not the second requirement. The world interest rate, on the other hand, is a good candidate because, given its role of clearing the world capital market, it is expected to react to shocks that tend to create imbalances between world investment and saving. Unfortunately, a measure of the world interest rate is not available, and its construction is problematic (see Barro 1991). For this reason we use two proxies, the long-run U.S. interest rate and the average long-run interest rate of the Group of 7 countries. The correlation between the second principal component and the U.S. long-run interest rate is .78, and for the average of the G7 long-run interest rates, it is .82. In figure 4, we plot these variables against the second principal component.

It is apparent how the two proxies of the world interest rate and the second principal component have a similar dynamic behavior, and, notably, they peak at the same time at the beginning of the 1980s. These results highlight the ability of our estimates of the common factors to capture the global forces driving prices and quantities in the world capital market.

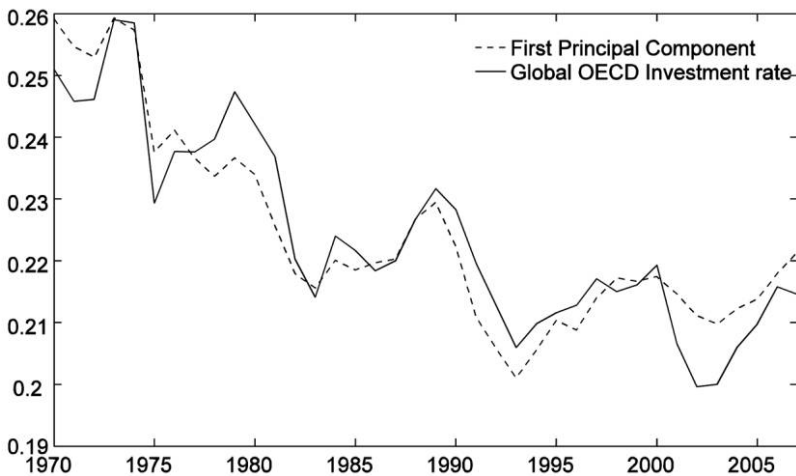

Fig. 3. First principal component

Fig. 4. Second principal component

### B. Saving-Investment Regressions

In this subsection, we estimate the saving-retention coefficient. Results are summarized in table 2.

As stressed above, the saving-retention coefficient should be estimated by appropriately taking into account general equilibrium effects

**Table 2**  
Regression Results

Type of Regression	Sample						
	1970–2007	1970–89	1990–2007	1970–79	1980–89	1990–98	1999–2007
Global investment + G7 interest rate (eq. [10a])	.38 [.03]	.48 [.05]	.09 [.06]	.56 [.08]	.29 [.12]	.11 [.09]	.06 [.06]
Two principal components (eq. [10b])	.32 [.04]	.26 [.06]	.14 [.05]	.36 [.10]	.03 [.09]	.15 [.14]	.07 [.07]
Baseline (eq. [8])	.47 [.03]	.53 [.04]	.35 [.04]	.51 [.06]	.28 [.08]	.51 [.08]	.26 [.07]
Global investment rate (eq. [10c])	.34 [.03]	.37 [.05]	.31 [.04]	.47 [.07]	.17 [.08]	.28 [.08]	.12 [.07]
Time effects (eq. [9])	.35 [.03]	.41 [.04]	.32 [.05]	.55 [.06]	.23 [.08]	.46 [.08]	.16 [.07]
Long-run regression (eq. [7])	.59 [.12]	.64 [.12]	.46 [.14]	.54 [.15]	.66 [.10]	.75 [.10]	.14 [.15]

due to the closed economy constraint. In fact, our empirical evidence highlights that global shocks are a relevant driving force for saving and investment and they propagate heterogeneously and with persistent effects across OECD countries. Results also indicate that in order to capture the effects of global shocks, we need both measures of equilibrium quantities and prices in international capital markets.

For these reasons, in the first row of table 2, we report results from the panel regression augmented with the global factors proxied by the OECD global investment ratio and the average G7 interest rate (eq. [10a]). In the second row, we report results obtained by augmenting the panel regression by principal component estimates of the global factors (eq. [10b]).

Results from subsamples allow us to study the evolution over time of the saving-retention coefficient in connection with the process of integration of international financial markets.

Outcomes from the estimation of the panel regressions augmented by the OECD investment rate and the G7 interest rate show that the saving-retention coefficient is highly significant in the 1970s and then steadily declines, becoming not significant in the last two decades. These results are confirmed when the factors are estimated by the first two principal components.<sup>12</sup> The temporal path in our estimates of the saving-retention coefficient is consistent with the widely documented evolution in the degree of international capital mobility that was low during the 1970s and has been steadily increasing since the 1980s.

In order to assess the effect of misspecification due to neglecting general equilibrium effects and the heterogeneity of the propagation mechanisms of global shocks, rows 3–6 of table 2 report the results for all the methods previously used in the Feldstein-Horioka debate and for the panel regression (eq. [10c]) augmented only by the global OECD investment rate.

The baseline regression (eq. [8]) further confirms the puzzle: the estimated saving-retention coefficient in the last two decades only slightly decreases relative to the previous two decades and remains high and significant. These results indicate that the general equilibrium effects provide an explanation for the Feldstein-Horioka puzzle. However, this fact remains hidden if the closed economy constraint on aggregate saving and investment is not fully captured as in the case with the panel regression augmented only with the global OECD investment ratio (eq. [10c], which does not capture the effects of global shocks on interest rates), with time effects (eq. [9], which does not take heterogeneity into account), or with the long-run regressions (eq. [7], which neglects persistent effects of global shocks).<sup>13</sup>

In summary, the empirical evidence suggests that, as originally claimed by Feldstein and Horioka in their seminal paper, the intertemporal theory of the current account failed to explain the relation between saving and investment rates before the 1980s. Instead, in the last decades the relation between saving and investment has become closer to what is predicted by the intertemporal theory of the current account. Given the partial equilibrium nature of this theory, if we do not isolate idiosyncratic sources of fluctuations taking heterogeneous responses of saving and investment rates to global shocks into account, this fact remains hidden.

#### **IV. Conclusions**

This paper shows that, in contrast to what is claimed by previous studies, general equilibrium effects can partly rationalize the high correlation between saving and investment rates observed in OECD countries. We develop a factor-augmented panel regression that enables us to isolate idiosyncratic sources of fluctuations. Contrary to existing studies, our approach allows for heterogeneous responses of saving and investment rates to global shocks. Empirical results show that the homogeneity restrictions bias upward the estimated correlation between saving and investment rates. By relaxing this assumption, we find that the correlation among saving and investment rates decreases over time, becoming very small in the last two decades. This finding is consistent with the empirical evidence that international capital mobility has increased in the last decades.

#### **Appendix A**

##### **Data**

Data frequency is annual, and the sample ranges from 1970 to 2007. The source of the data for saving, investment, and GDP is OECD, National Accounts, Annual Accounts, disposable income, and net lending–net borrowing.

Investment is gross capital formation. Saving is the sum of consumption of fixed capital and net saving. Saving and investment rates are calculated by the authors as the ratio of saving and investment to GDP.

Long-term interest rates of G7 countries are in OECD Economic Outlook Statistics and Projections/Financial Data.

Data refer to the following 20 countries: Australia, Austria, Belgium, Canada, Denmark, Finland, France, Germany, Ireland, Italy, Japan, Korea, Netherlands, New Zealand, Norway, Portugal, Spain, Sweden, United Kingdom, and United States.

## Endnotes

This paper was presented at the thirty-second ISOM in Cyprus (June 2009), and we wish to thank the editors Lucrezia Reichlin and Kenneth West, the discussants Richard Clarida and Philippe Lane, and the participants for comments and suggestions. We are particularly indebted to Lucrezia Reichlin, Oved Yosha, and Philippe Weil for inspiration and encouragement. We thank Michel Beine, Pierpaolo Benigno, Daniela Bragoli, Giacomo Carboni, Antonio Ciccone, Antonello D'Agostino, Andrea Lamorgese, Giordano Mion, Maurice Obstfeld, Giorgio Primiceri, Luca Sala, Chiara Scotti, Cristina Vespro, and Wolf

Wagner for many helpful suggestions and comments. All remaining errors are our own. Domenico Giannone gratefully acknowledges financial support from the Research Training Network on "Diversification versus Specialization" funded by the European Commission. The views expressed in this paper are exclusively those of the authors and do not necessarily reflect those of the European Central Bank and the Eurosystem.

1. This finding is relatively robust for OECD countries as a whole. However, some studies have found evidence of a reduction of the correlation between saving and investment limited to specific groups of countries and subperiods (for a survey, see Coakley, Kulasi, and Smith [1998]). Recently, Blanchard and Giavazzi (2002) found that the correlation between saving and investment rates decreased in the 1990s but only in Euro Area countries.

2. Saving and investment rates are computed, respectively, as the ratio of saving and investment to GDP.

3. Heterogeneous dynamic responses of saving and investment rates of each country are also allowed since some factors can be the lagged version of others. For example, a model with one global factor with contemporaneous and lagged effects is a particular case of (1) and (2) with  $r = 2$  and  $f_{2,t} = f_{1,t-1}$ .

4. For an application of this methodology to the Feldstein-Horioka debate, see, e.g., Ventura (2003).

5. Idiosyncratic components of saving and investment can also be estimated as the deviation of saving and investment from their OECD-wide counterparts as in Ostergaard, Sorensen, and Yosha (2002), which studies the excess sensitivity of consumption in U.S. states and provinces. However, it can be shown that this methodology is equivalent to estimate eq. (9) with time dummies as in Ventura (2003).

6. For time-varying factor loadings and structural breaks, see Stock and Watson (2002); for unit roots in the factors, see Bai (2004).

7. More formally, authors' calculations based on Bai (2003) and Bai and Ng (2006) show that factors can be treated as known if the number of countries is larger than the square root of the sample size since there is no generated regressor problem (Pagan 1984; Bernanke and Boivin 2003; Bai and Ng 2006).

8. More details on data sources can be found in app. A.

9. It is worth noticing that the difference between OECD-wide saving and investment is insignificant since the OECD countries as a whole can be seen as a closed economy.

10. Since the third principal component explains about 10% of the panel variance, we perform robustness checks of our empirical results in the next subsection assuming the existence of three common factors.

11. The aggregate we consider is the first principal component of the spectral density matrix at frequency zero. The latter represents the covariance matrix of the sample mean.

12. We performed two sets of robustness checks. First, results in table 2 refer to the full cross section of countries. However, Korea was not part of the OECD for a large span of our sample. Excluding Korea from our panel does not affect the results. Second, we performed regression (10b) considering also a specification with three common factors estimated by means of principal components. Except for a reduction of the correlation in the 1970s relative to the specification with two global factors, the results are not affected by the inclusion of the third factor.

13. In app. table B1, we show that (i) a high number of coefficients ( $\delta$ 's) on the second principal component in eq. (10b) are statistically significant, which provides further evidence that the OECD-wide investment rate is not able, alone, to account for the effects of global shocks on saving and investment rates in OECD countries, and that (ii) we cannot reject the hypothesis of heterogeneity in the coefficients on the two factors.
