Does Arrest Deter Violence?

Comparing Experimental and Non-Experimental Evidence on MandatoryArrest Laws

Radha Iyengar

Updated: April 2009

1. INTRODUCTION

For two decades there has been considerable debate in economics about the use and validity of experimental approaches in the development and design of public policy.[1] In criminology, there has been a marked increase in the use of randomized experiments signaling a widespread acceptance of experiments as an effective means of determining policy relevant parameters. Recently, a new set of papers in economics by Deaton (2009), and Imbens (2009), in addition to ongoing work by Heckman and coauthors (e.g. Heckman and Urzua, 2009; Heckman, Urzua, and Vytlacil, 2006), have revived the debate on the usefulness of experiments in estimating parameters of economic and policy importance in both first world and developing world contexts. The debate partitions empirical research into two broad categories: design-based studies (DBS) which focus on the empirical evaluation design and theory-based studies (TBS) which focus on the underlying theory and fit new or existing estimates explicitly within that framework. Included in DBS are both experimental evaluations, such as randomized controlled trials (RCT) and field experiments, and non-experimental evaluations focused on establishing causal relationships, such as difference-in-difference estimators, matching methods, and instrumental variables. Much of the TBS literature uses "structural estimation" in which the parameters of an explicit theoretical model are identified by imposing restrictions across various parameters in a generalized method of moments or maximum likelihood framework. This set of studies can also include models of sample selections and usually require explicit assumptions on optimality, rational expectations/behavior, and parametric or functional form. In the context of crime research, most empirical research has fallen into the DBS category; the emphasis on experimental evidence combined with the importance of establishing causation makes this methodological debate critical in directing future of crime policy research. This study considers the conflict between DBS and TBS in the context of an important social experiment: arrest laws for spousal abuse.

The most prominent and arguably influential theory among crime scholarship is that of deterrence, which predicts that an increase in the cost of a crime will reduce participation in that crime. While there existed some simple theoretical models (e.g. Becker, 1968; Ehrlich, 1972) and some limited calibrated models (Flinn, 1986), there was limited evidence on the efficacy

---

[1] Meyers (1992) provides useful overview on this debate. For additional details see for example Ashenfelter and Card (1985), Lalonde (1995), Heckman and Robb (1985), Friedlander and Robins (1995).

deterrence. To determine if any such significant deterrence effect existed, a prominent set of experiments funded by the National Institute of Justice tested the effect of increasing the probability of arrest on future incidences of spousal abuse (thus called the Spousal Assault Replication Program or SARP). The initial experiment, run in 1981 in Minneapolis, Minnesota, suggested that arrests were effective at deterring future violence, reducing future violence by more than 50 percent.[2] These results were used to justify laws requiring the warrantless arrests of individuals police believe to be responsible for misdemeanor assault of an intimate partner. Recent quasi-experimental evidence using FBI homicide data (Iyengar, 2009) finds that laws aimed at increasing arrests for spousal abuse appear to have increased intimate partner homicides. The apparent contradiction between the experimental and the non-experimental results can be understood by placing the experimental results in the broader context of a behavioral model of spousal abuse. The distinction this simple model highlights is that the deterrence effect is a product of both the probability of arrest conditional on reporting and the probability of reporting conditional on assault. By measuring only one of these parameters, the experiment could not accurately extrapolate to the unconditional effect of increased penalty (i.e. increased probability of arrest) on future violent incidents.

These experiments and the subsequent non-experimental evidence provide a stark example of a common situation where experimental evidence was necessary but not sufficient. It naturally begs the question: why do experiments occupy such an important place in policy debates when they are likely to be insufficient to answer the policy question? While there are a range of detailed and nuanced arguments on the relative efficacy of either experimental/DBS and TBS, the crux of the issue lies in the trade-off between internal and external validity.[3] The benefit of DBS is that they focus on identifying a parameter with great internal validity. This means that in experimental, quasi-experimental, or instrumental variable settings, we may obtain an unbiased estimate of the local average treatment effect (LATE) with minimal assumptions that are easier to test and to believe. The cost of this approach is that the parameter we estimate may not be parameter of interest. This is because we obtain the LATE rather than the average

---

[2] Subsequent replication produced what appeared to be a range of results from deterrence to escalation. However, a recent reanalysis of the six experiments suggests at in all cases, arrest reduced the probability of future violence. This will be discussed in detail in section 2.

[3] Following the definition in Burtless (1995), I define an "internally valid" estimate as an unbiased measure of a given treatment effect in the chosen sample. An "externally valid" estimate is a treatment-effect estimate that can be validly extended beyond the chosen sample to some other external group. .

treatment effect (ATE). As its name suggests the LATE is locally unbiased (or in the case of instrumental variables, consistent) for the group over whom the estimate is constructed.[4] Instrumental variables (IV) typically obtain the LATE because the estimation uses variation from only portion of the sample—in the language of IV the compliant subpopulation (Angrist and Imbens, 1995). Experimental studies will only obtain ATE if the sample under investigation is representative of the general population (or at least the population for whom the experimental results will be generalized).[5] Since most social experiments also rely on a voluntary subject population, by the same logic as IV, experiments with selected samples will tend to identify only the LATE, in this case local to the voluntary sample, rather than the average treatment effect (as in the case of a randomly selected sample).[6]

TBS on the other hand offer a detailed underlying framework for both analyzing and interpreting results. This allows studies to take observational and even experimentally obtained parameters and formally extrapolate the results to a wide range of settings. These studies also make explicit both the underlying behavioral mechanism which the policy or program effects and the assumptions necessary to apply the estimates to other settings. In this sense, the TBS design is built on the importance of external validity. The cost of such a method, however, is lack of transparency and credibility due to the often complex and detailed assumptions required for estimation. As such, these methods may lack the internal validity necessary to make policy makers and even other non-specialists confident in the estimates obtained.

Thus the tradeoff, agreed upon by all sides, is as follows: When done properly, randomized experiments can precisely isolate the effect of a specific intervention—that is experiments can estimate and statistically bound a targeted behavioral parameter.

---

[4] As Deaton (p. 10) suggests "this goes beyond…looking [at] an object where the light is strong enough to see; rather we have control over the light but choose to let it fall where it may". Of course, this is a bit extreme because the experimental parameters are not entirely separate from the desired parameter. As Imbens (p. 6) notes "even if simple average effects of these interventions are not directly answering questions about plausible economic policies, they are often closely related to the effects of such policies and therefore viewed as quantities of interest."

[5] This point ignores non-compliance among the subject population after the start of the experiment. In the case of experimental non-compliance, two approaches are used. One uses the original assignment and compares the assigned treatment and assigned control groups, regardless of actual treatment status. This estimate is the intent-to-treat (ITT) estimate and may also be obtained in some quasi-experimental settings. The second approach is to use the assigned treatment as an instrument for actual treatment status. In this case, the experiment reverts to the IV case.

[6] This is related to the point made by Heckman (1992) regarding experiments under the Job Training Partnership Act (JTPA). Experiments may not obtain the average treatment effect, even when properly administered, due to sample contamination—that is the sample chose is not the general population which would experience the treatment in the absence of the program.

Unfortunately, there is no guarantee that the parameter estimated is of particular interest or relevant for a related policy. On the other hand, while structural estimates (and generally TBS) provide a framework for extrapolating results, the estimates obtained from these methods often lack internal validity and credibility.

Thus, the use of the spousal abuse arrest experimental results to justify policies which had perverse effects illustrates both the danger of treating the LATE as the ATE and the importance of having clear, credible information available to policy makers during the policy design. It is for this reason that this paper rejects the dichotomy between internally-valid DBS and externally valid TBS as a false one. At the heart of the issue is a serious information problem regarding most behavioral outcomes related to desired policies. Thus we require several components: a credible measure the average effect of each behavioral parameter of interest;[7] an estimate of the relative magnitude of these multiple parameters; and the relationship between the distribution of treatment effects and relevant population characteristics. When considering the policy decision problem as a whole, we can see the issue is not the hierarchy of evidence based on methodological selection (although surely the quality of any particular study is important) but rather how to aggregate information from multiple sources.[8] Based on this insight, this study offers two contributions to the literature on the relative value of experimental, quasi-experimental, and structural estimates.

First, this article wishes to diverge with the general tendency on both sides to dismiss quasi-experimental methods as both atheoretical (relative to structural estimates) and potentially biased (relative to experimental estimates). Indeed all sides in the methodological debate seem to agree that "quasi-experimental" approaches are "second-best" alternatives to either extreme of structural estimation or experimental evaluations (e.g. Imbens, 2009, p.15; Deaton, 2009, p. 23). Actually, quasi-experimental studies play a critical role in bridging the gap between experimental and structural models; they provide the best possible means of measuring the relative magnitude of competing behavioral parameters conditional on a set of both observable and unobservable characteristics typically based on an underlying theory of economic or

---

[7] Note that in general an experimental "treatment effect" need not be the composite response parameter anticipated in a policy (we shall return to this point later)

[8] A procedure suggested to aggregate experimental, quasi-experimental and structural evidence is presented in section 6 of Imbens (2009). Imbens suggests that one may use experimental evidence to "pin down some combination of the structural parameters." It is this spirit that this article suggests combining experimental and quasi-experimental evidence

individual behavior. As always, there is a tradeoff and in particular, such evaluations require additional assumptions (as noted in Imbens, p. 15). However, one might argue that these evaluations provide the only feasible means to test the full effects of a policy and thus, provide greater, rather than less, external validity than randomized experiments. At the same time, the more simple, intuitive assumptions made by quasi-experimental methods provide a more transparent and credible estimates. Thus quasi-experimental findings can more useful for informing policy decisions than comparable structural model based estimates. This point is especially salient when applied to crime policy research where state-level variation in laws and procedures facilitates a wide range of DBS approaches. Crime researchers especially should ignore the value of quasi-experimental studies even in the presence of a wide range of potential experimental approaches.

Second, this article attempts to reconcile the two apparently oppositional methodological positions: DBS and TBS. If the goal is gathering sufficient and accurate information to inform policy decisions then there is a great deal of room for agreement between the two camps. As Imbens notes (p. 3) "conditional on the question of interest being one for which randomized experiment is feasible, randomized experiments are superior to all other designs in terms of statistical reliability." This statement is almost indisputable but that is largely because of the initial conditioning statement. At issue is that in many cases the policy option cannot be perfectly replicated in an experiment. Rather the experiment must be used to isolate some relevant behavioral parameter which we must than use to extrapolate. It is in this sense that as Deaton notes (p. 4) a "randomized controlled trial has no special priority." Indeed, one may agree that RCT is the "gold standard" for obtaining internally valid estimate of some behavioral parameters, while noting that in general the experimental results themselves will be insufficient to answer the question of interest. As such no matter how internally valid the estimate may be it is of little value to the policy question under debate. RCT specifically and DBS more generally must be subject to the same external validity scrutiny as their TBS counterparts. This study illustrates that it is not always the case that "better LATE than nothing" if the LATE estimate provide misleading information to policy makers. In the end, these estimates are not useful and may even be counterproductive if assumptions regarding the applicability of the results are not made *explicit* and appropriate caution is not taken in interpreting and presenting these results.

In order to more precisely discuss these points, this article will present and discuss both the experimental and the non-experimental evidence on spousal arrests. Section 2 discusses the experimental evaluations of arrest policy as an illustration for both the uses and limitations of experimental methods. Section 3 discusses the theoretical complexity in translating the spousal assault arrest experiment to an arrest policy. Section 4 discusses the use of quasi-experimental methods to resolve theoretical ambiguities and to contextualize evidence obtained experimentally. Section 5 returns to the broader debate, discusses issues the results from previous sections, and concludes.

2. EXPERIMENTAL EVALUATIONS OF ARRESTS FOR SPOUSAL ABUSE

The use of arrests for spousal abuse, and in particular the laws which mandated arrests, were premised on the results of a series of randomized experiments conducted by National Institute of Justice (NIJ). The experiments were carried out over a ten-year period, from 1981-1991, in six different cities with different police departments. The initial and most influential of these studies was the Minnesota Domestic Violence Experiment (MDVE).[9] The experiment was motivated by basic deterrence theory (suggesting that the increased penalty for a crime reduces the incidence of that crime), which was tested using an innovative design. This experiment, funded by the Minnesota Police Department, the Police Foundation, and the Department of Justice, was run by randomly assigning a police response to domestic violence calls (Sherman, 1980). The objective was to determine if arrests were more effective at reducing future violence. Police applied one of three possible treatments: (1) advising and counseling the couple, (2) separating the individuals, or (3) arresting the suspect. Researchers then interviewed the victims shortly after police involvement and then followed up every two weeks for six months. The original results found that arresting the suspect resulted in substantially less future violence than did either advising or counseling (Sherman, 1992). Indeed the initially estimated effect sizes suggested that future violence was reduced by nearly 50 percent.[10]

The experiment, while excellently designed and extremely well done, it suffered from a standard experimental problem: compliance. As noted in Angrist (2006), officers deviated from

---

[9] Evidence that MDVE was discussed when passing these laws can be found in Wanless (1992).

[10] An in depth evaluation of the results by Tauchen and Witte (1995) found that arrest resulted in significantly more deterrence than either advising or separating the couple, consistent with the original findings of the experiment. However, unlike the original findings, Tauchen and Witte use a dynamic setting which found that most of the deterrent effect of arrest occurs within two weeks of the initial arrest. .

their randomly assigned responses for largely one of three reasons: first, officers may have determined that it was inappropriate to advise or separate the couple because doing so may put the victim at risk. This was most often the case when the suspect attempted to assault the officer and when both parties were injured. Second, victims sometimes persistently demanded an arrest. Third, officers occasionally forgot to bring their report forms. When police were randomly assigned to arrest a suspect, they did so 98.9 percent of the time, when they were assigned to separate, they did so 77.8 percent of the time, and when they were assigned to counsel, they did so 72.8 percent of the time (Sherman and Berk, 1984). When estimating using treatment assigned as an instrument (rather than estimating the intent-to-treat effect), the effect size appears even larger. Put differently, among complier, the effect of arrest is nearly 80 percent reduction in recidivism. The direction of the bias gives us a great deal of information about non-compliers. Those who were arrested when assigned to a less severe police response were likely also subject to the "treatment" and may have reduce their violence dramatically. This dilutes the effect of the treatment group in the intent-to-treat measure resulting in larger IV estimates.

[TABLE 1 ABOUT HERE]

The MDVE was replicated by 5 other experiments over the next decade in Charlotte, NC, Colorado Spring, CO, Metro-Dade County, FL, Milwaukee, MN, and Omaha, NE. These replications were not exactly the same as the original experiment in two dimensions. First the precise treatments differed, though all assigned at least one "arrest" and one "non-arrest" police response. Table 1 reports the results from the randomized experiments. The most commonly held view is that the replications failed to show that arrest deterred and indeed provided some evidence of escalation. This does not appear to be the case in a simple comparison of means in which the only significant effects (Miami Dade survey, Omaha Police Reports and the original MDVE results) indicate that the arrest disposition reduced recidivism relative to any other alternative disposition.[11] An analysis of the pooled data from all 6 sites by Maxwell, Garner and Fagan (2001) finds that "arresting batterers was consistently related to reduced subsequent aggression against female intimate partners." While not all the effect sizes were statistically

---

[11] For an detailed and thoughtful review of how why these differences cannot well be interpreted given the data available, see Garner, Fagan, and Maxwell (1995)

significant, there did not appear to be any association between arresting the offender and escalation of violence against the victim.

Before turning to the limitations of these experiments, it is worth explicitly considering the value such estimates provide. First, prior to the results from the MDVE, there was a tendency for police to offer non-punitive and "therapeutic" responses to spousal abuse. The MDVE provided clear and convincing evidence that such approaches were substantially less effective at reducing violence than if the abuser had been subjected to an arrest. The authors of the initial MDVE report were even able to separate the deterrence effect from a simple incapacitation effect. Since more than 40 percent of offenders released within 1 day and over 85 percent were released within one week there was very little incapacitation due to arrest and imprisonment. This finding was among the first clear tests of deterrence theory and the behavioral parameter identified in this setting is of significant academic and policy import. Second, although less frequently discussed, the data from these studies also provided detailed information as to the importance of police response *relative* to other offender characteristics (such as prior criminal history, race, age, or employment status). Table 2 shows the set of covariates available in all 6 experiments, illustrating the rich individual level data obtained on a sample of calls to the police for domestic violence. It appears that the effect size from arrests is quite modest when compared to the effect of other factors, such as age or prior criminal record. This type of analysis helps contextualize the results from the experiment and provides some hints as to why it may be difficult to extrapolate from the data. Third, there appears to be some variation in the intensity of the treatment effect by demographic characteristics. While the average effect across the sites was statistically similar, the variation in the estimated effect of arrest on recidivism varied greatly. This was in part due to the different distribution of covariates in the control and treatment groups.

[TABLE 2 ABOUT HERE]

While the experimental evidence on arrests advanced our understanding of how batterers respond to arrest, there are several issues which make it difficult to generalize from even these

9

well conducted experiments.[12] First is the issue of sample contamination; this is the concern that the sample of individuals who are in the experiment are not the same as those who would be in place if a policy which increased the likelihood of arrest were implemented. In part this is due to some of the sample restrictions from the experiments which excluded serious cases (i.e felonies) as determined by the officer. In addition, officers may not of included cases they deemed to not be misdemeanor assault. The unknown true distribution of intimate partner abuse case severity and case type makes it difficult to sign the bias on this type of sample selection. In part the sample is by construction different from the policy sample.   The experimental designed ensured the initial reporting of an offense because the sample frame is based on domestic violence cases which request police presence. This means that all experimental results are the effect of arrest *conditional on reporting* and this condition is quite meaningful in the case of domestic violence. The sample could not measure whether victims would be more or less likely to report to the police because it was based on an initial report.

Second is the issue of police cooperation. The departments chosen to conduct the experiments tended be those for whom compliance would be a minimal issue (Maxwell, Garner, and Fagan, 2001). In addition, among the officers conducting experiment, most of the sample was collected by only a few officers.[13] This lends itself to ensuring high quality experimental design but not necessarily generalizability. In particular the ways in which police may choose to avoid compliance must be explicitly considered when determining how to implement a policy to achieve the experimental results.

Finally, because of the relatively small number of cases, experiments will in general *not* identify the most serious, low-probability events. Serious injury and death are relatively rare occurrences but so undesirable that policies wish to avoid any increases in these high cost outcomes.[14] Experimental results will in general lack the power to detect these low-probability events and even structural models may not be able to determine the realistic probability of such occurrences.[15]

---

[12] The subsequent discussion should not be read as a criticism of the methodology of these experiments. Indeed the initial MDVE and the five replications are among the most carefully run experiments in the crime literature.

[13] For example, in the MDVE, 9 percent of the officers produced 28 percent of the cases. (Sherman and Berk, 1984)

[14] This statement should not suggest to the reader that intimate partner homicide is at acceptable levels. Indeed women are more likely to be killed by a current or former intimate partner than anyone else. It is rather a statistical statement about the likelihood of observed an intimate partner homicide given the total sample size.

[15] A similar problem is discussed in the context of suicide due to anti-depression drugs by Ludwig, and Marcotte (2005).

Thus the experimental results leave open several questions. First, given relatively similar average effects but differences in the variance of these effects across site, can we generalize from arrests in these 6 sites to the efficacy of arrest relative to non-arrest in other locations? Second, if arrest, relative to other non-arrest police responses, reduces recidivism under experimental conditions, what is the effect of a policy which increases arrest? While the parameters estimated in the experiments are informative about both of these questions, they cannot answer them definitively without additional assumptions.

3. ARREST LAWS AND CRIMINAL BEHAVIOR IN A REPEAT INTERACTION SETTING

Although the experimental evidence from the six spousal assault experiment sites did not directly answer a policy questions, the experimental evidence on the efficacy of arrest encouraged many states to pass policies that encourage or require arrest of domestic abusers. These policies play a prominent role in the government's attempt to combat domestic violence.[16] Currently, twelve states and the District of Columbia have passed mandatory arrest laws. These laws requires police to arrest a suspect without a warrant, if there is probable cause to suspect that an individual has committed some form of assault (either misdemeanor or felonious) against an intimate partner or family member. An additional ten states have recommended arrest laws, which specify arrest as a recommended but not required when confronted with probable cause that an intimidate partner or familial assault has occurred. States in both of these groups are reported in Table 3. These laws were implemented as an explicit strategy to increase the fraction of domestic violence cases in which police arrest the suspect. Many economists may immediately note that this is not a direct application of the experimental results.[17] However, this also represents a realistic setting in which experimental evidence, when it is the *only* source of information regarding a policy, may not produce the desired outcome.

[TABLE 3 ABOUT HERE]

---

[16] For a detailed discussion of the emergence of these statutes see Iyengar (2009). For a discussion on the role of the experimental evidence in influencing policy see Maxwell, Garnder and Fagan (2001), p. 4-5

[17] Indeed the authors of the original study note that mandating arrests may not be appropriate because of potential heterogeneity in offender responses (Sherman and Berk, 1984, p.270)

To illustrate how mandatory arrest laws changed interactions between abusers and victims, consider how they changed the nature of interaction in the repeated setting of intimate partnerships. Mandatory arrest laws increase the cost of choosing violence. This effect is largely the reason why mandatory arrest laws were originally advocated. Ideally, this increase in cost would result in a situation where violence is never chosen. Unfortunately it is typically difficult to sustain such a situation, in particular because it requires victims to report whenever there is a violent incident. Since both anecdotal and sociological evidence suggest victims dislike reporting, many situations arise where batters are violent but victims do not report. Given then that reporting is uncertain, we cannot assume that violence is never chosen and as such we will observe some level of violence.

Arrest laws also change the cost of reporting abuse to the police. The problem with this is that because abusers have more freedom in adjusting their behavior than do victims, this increased cost is borne almost entirely by the victims. To illustrate this, supposed mandatory arrest laws increase the utility to victims from reporting, so that all other things equal, reporting would be more desirable after the law change. In such a situation, an abuser could adjust the probability of violence if the victim does not report relative to the probability of violence if the victim does report. This essentially allows abusers to adjust the probability of each outcome to fully account for any utility gains from reporting to the victim. Similarly suppose arrest laws decrease the utility to victims from reporting so that reporting is really a punishment strategy taken by the victim to induce better stream of behavior by the abuser in the future. In such a situation, an abuser can adjust the probability of violence if the victim reports such that any punishment strategy is unsustainable (i.e. reporting becomes too costly to make the utility gains from non-violence in the future worth seeking).

Thus, the abuser can essentially be nicer to the victim if she does not report him after a violent incident thus encouraging her not to report after violence (i.e. reducing the probability of violence conditional on not reporting). Indeed, this is often referred to by domestic violence advocates as the "honeymoon period" where abusers are extra attentive and loving. In addition, the abuser can take retributive action after reporting (i.e. increasing the probability of violence after reporting). Thus, the counter-intuitive result of arrest policies for intimate partner violence is that they may indeed increase intimate partner violence because batters have a greater ability

to determine the outcomes. Thus, the abusers are better able to shift the burden of arrest onto the victims, deterring reporting rather than deterring abuse.

To illustrate how changes in the level of homicides can be linked to the total number of abusive incidents, consider a model where with some small probability, p, domestic abuse escalates to murder. For n intimate partner incidents, the number of homicides in a jurisdiction is then pn. There are two main theories on potential responses which may result in increased homicides after arrest laws: reprisal (abuser response) and reporting (victim response). I will consider each in turn.

A different explanation for the response could be that abusers respond to arrest by punishing victims and this increases intimate partner homicides. Suppose p increases because violence becomes more severe. This could occur if abusers are very angry when returning home after arrest and so more frequently commit violence against their partners. Thus for a given n intimate partner incidents, the number of homicides pn increases. Note that if there is no deterrence effect, i.e. n is constant, then, once again, the effect on the law is to increase violence. However, if there is a decrease in incidents (n declines) then the overall effect of mandating arrest is ambiguous.   This response is consistent with evidence on victim fears. As discussed above, fear of reprisal is the most commonly cited reason for not reporting. To the extent that the fear is rational, this is consistent with the reprisal hypothesis. Moreover, when a victim leaves her relationship that she is at the greatest risk from her partner.[18] If arrest allows women to leave, then reprisal rates may increase. Evidence against this hypothesis comes from the experimental evidence, which found no significant increase in reprisal, though this may be because the abusers did not blame their victims for their subsequent arrest (instead blaming police officers).

While the experimental results may provide evidence against the reprisal hypothesis, the results are silent in the context of the reporting hypothesis. The reporting hypothesis suggests that victims are less willing to report an incident if their abuser will be arrested. Suppose that the probability of reporting given violence decreases after the passage of mandatory arrest laws. Because police presence, regardless of the police response, can disrupt a violent incident and prevent escalation to homicide, this failure to report to the police can increase the rate of intimate partner homicides. Thus, the victim's decision not to notify the police may increase p. This is

---

[18] Ronech Bachman and Linda Salzman (2000)

not the overall effect of the law since the threat of arrest deters (as it did in the MDVE), then n, may decrease. In this case, the effect of the law on homicides is ambiguous. While arrest, conditional on reporting, deters violence, the unconditional effect of arrest on violence may be small or zero if victims substantially reduce their reporting.

Domestic violence victims may decide not to report for several reasons. First, there is a psychological and emotional component of intimate partner abuse that often generates victims who remain committed to their abuser and do not wish to send him to prison. Thus, the victim's guilt may increase her/his own costs of reporting as well as the abusers.[19] Second, if abusers are arrested but no further legal action is taken they may return home within a day of their arrest and further terrorize their victim. In a non-experimental evaluation of mandatory arrest as a policy, Lyon (1999) used a logistic model to compare the likelihood of arrest under mandatory arrest laws versus pro-arrest laws in two cities in Michigan. She found that once a victim calls the police to report an incident, she is significantly less likely to call again. She posits this was likely because police intervention in the form of an arrest resulted in retribution by the abuser deterring future reporting.[20] Third, in many cases, arrest laws resulted in the victim also being arrested if there was evidence that she (or he) physically assaulted her (or his) partner. In many areas, women constitute nearly 20 percent of domestic violence arrests, a far higher percentage than the estimated proportion of female abusers.[21] Over half of these female arrestees can be identified as previous victims of intimate partner violence (Martin, 1997). Anecdotal evidence from some battered women advocates suggests that these "dual arrests" are the most serious

---

[19] Recent research finds that many women do not perceive any benefit from mandatory arrest laws, no-drop policies (requiring prosecution conditional on reporting) and mandatory medical reporting and these laws may make them less willing to report in the future. (See Smith, 2000)

[20] Rennison (2000) found that fear of reprisal from abuser was the most commonly cited cause for not reporting a domestic violence incident. This is hotly contested claim. Mills (1998), based on research by Sherman and Berk (1984), claims that arrests actually increase re-assaults. More recent work by Maxwell, Garner and Fagan (2002) find that there is no significant change in the risk of assault.

[21] For example, in Phoenix, AZ, 18 percent of domestic violence arrests are women (AZCASA). Women are thought to be abusers in less than 5 percent of intimate partner violence cases (Dobash, and Dobash, *et al* 1992). Though some work suggests there is a surprisingly high rate of female on male abuse (see Strauss and Geller (1980)) this work is problematic and, for the most part, ignores the severity and context of the violence (see Blau, 1998). This is particularly relevant in the case of intimate partner abuse. For example, suppose a husband spent years beating his wife severely. At the time of the survey, the husband shoved his wife and she immediately threatened him with a knife. The conflict tactics scale (CTS) treats the wife's behavior as aggressive when it is, in context, clearly defensive. Moreover, the CTS fails to properly differentiate acts of violence that constitute severe abuse. When severity of abuse is considered, men typically have the higher rates of the most dangerous behaviors, such as firing a gun, repeated their violence more often, and do more physical harm. For a greater discussion see DeKeserdy and Schwartz (1998).

problem with mandatory arrest.[22] Dual arrests have serious implications for victims who are immigrants and may be deported if convicted of assault. In addition, those who have children face potential loss of custody during the arrest period. This latter response can be viewed as a method by police to avoid complying with the intentions of the mandatory arrest laws. This thus represents a second way in which implementation of policies which encourage arrests may differ from experimental evaluations of arrest policies. All of these costs may result in an increased unwillingness to report abuse to the police.

Thus there is a potential that the results of a policy to increase arrest are the exact opposite of those in the experiment, even when the experimental parameter is an unbiased estimate of the deterrence effect and is externally valid to groups outside the original sample. This can be explained by recognizing that the experimental results estimated the effect of an actual arrest conditional on reporting while the estimates presented in this study estimate the unconditional effect of the certainty of arrest. The spousal abuse arrest experiments held constant the probability of reporting given violence because all cases in the experiment required an initial report of domestic abuse to the police. Thus, the spousal abuse arrest experiments estimated the effect of a decrease in batter's utility, when they abuse and are reported, on their probability of choosing violence in the future. Unfortunately, if the victim also faces an increased cost from the increased penalty, then the overall effect of these laws on abuse is theoretically ambiguous (and empirically these laws appear to increase levels of abuse).

Finally, it is worth noting that heterogeneity in responses is especially important in this case. Even if most offenders respond to arrest by reducing future violence, the risk that some may respond to arrest by increasing the severity of violence (in the extreme, committing murder) highlights the importance of considering both the mean and the variance of the treatment effect. If, as in the case of domestic violence, substantial variance in response to treatment may result in very serious outcomes, then the local average treatment effect, as estimated by the experiment (which becomes local by the non-randomness of sample selection), may be insufficient for policy making purposes.

4. ESTIMATES ON THE EFFECTIVENESS OF MANDATING ARREST

---

[22] This statement is based on conversations with individuals at battered women's coalitions in NJ, AZ, NY, CA, CT and IL.

To test the effectiveness of mandatory arrest laws, I consider the effect of these laws on intimate partner abuse. This requires special attention to the total number of incidents of domestic violence not simply the number of reported incidents because the fraction of incidents that are reported to the police is potentially affected by this policy.[23] If I cannot observe unreported incidents, changes in the number of reported incidents and change in the total number of incidents (both reported and unreported) are observationally equivalent.[24] In part because I can observe victim-offender relationship and in part because these crimes are almost perfectly reported, I use measure of intimate partner homicides as a way to measure intimate partner abuse. Assuming that police intervention can reduce the probability of violence changes in the intimate partner homicide measure may provide insight into the impact of mandatory arrest laws on intimate partner violence.[25]

To construct a dataset of intimate partner homicides, I use the FBI Uniform Crime Reports, Supplementary Homicide Reports which provide data for all homicides that took place in the years 1976 to 2003 in all 50 states and the District of Columbia with additional descriptive variables about the victim, offender, and the nature of the crime. I define an intimate partner homicide to include any homicide committed against a husband, wife, common-law husband, common-law wife, ex-husband, or ex-wife.[26] The data are constructed at the incident level with about 6.5 percent of the sample (36,442 observations) being intimate partner homicides.[27] I constructed a count of the number of relevant homicides by aggregating the incidents of intimate

---

[23]The National Incident Based Reporting System which does provide identification of the victim-offender relationships is therefore ill-suited to the purposes of this study. Because the NIBRS is comprised solely of reported incidents, analysis of this data is not useful for measuring the true incidence of domestic violence.

[24] An ideal data source for this type of analysis would be the National Crime Victimization Survey (NCVS) with state level identifiers. Although previous researchers were able to access geo-coded versions of this data (see for example Farmer and Tiefenthaler, 2003), recent changes in the administration and management of the NCVS make such access no longer possible. Some analysis using this data previous obtained suggests that mandatory arrest laws may reduce intimate partner violence but also reduce the number of cases which are reported in the system. (Dugan, 2003). Additional information about reasons why NCVS access is no longer possible is available upon request.

[25] The linkage between misdemeanor assault prevalence and intimate partner homicide is well established. See for example Gwinn and O'Dell (1993). Moreover the underlying causes are linked see Mercy and Saltzman (1989)

[26] The specific coverage of each law is reported in the legal appendix of Iyengar (2009). The distribution of sample across all groups is also described there.

[27] There is some measurement error in victim-offender relationship variable. About 1.25% of female victims reported as having a relationship to their offender that would imply she's a man and about .43% of male victims reported as having a relationship to their offender that would imply he's a woman. Together these account for about 200 observations and less than 1 percent of the total sample. This is due to the classification of multiple homicides. In multiple victim homicides the first victim-offender relationship is recorded for all of the victims. Because the selection of the "first" victim tends to be arbitrary and this constitutes a very small fraction of the overall sample, these cases are excluded from analysis.

partner homicide, as defined above, in a given state for each year from 1976 until 2003. I also aggregated the number of intimate partner homicides by the race of the victim and offender and by sex of the victim and offender. Estimates are then scaled using census estimates for state population.[28]

A plot of the trend in various types of homicides before and after mandatory arrest laws, suggests that these laws may have had a significant impact on intimate partner abuse. Figure 1 shows the rate of intimate partner and family homicide rates as a function of time since the arrest law change. There appears to be a discrete increase of about 0.4 intimate partner homicides per 100,000. There is only a small decline in the number of family violence homicides. In contrast, Figure 2 shows that recommended arrest laws have relatively little effect on intimate partner or familial homicides.

[FIGURE 1 ABOUT HERE]

[FIGURE 2 ABOUT HERE]

Comparing intimate partner homicides in states with and without arrest laws before and after the passage of these laws, I estimate a linear regression of the impact of mandatory arrest laws on the number of intimate partner homicides per 100,000 inhabitants. Column (1) of Table 4 reports some coefficients from this regression. The *mandatory arrest effect* variable is defined as 1 in states that passed mandatory arrest laws in the years after the law was passed. Similarly, *recommended arrest effect* variable equals 1 in states that passed recommended arrest laws in the years after the law was passed. The results suggest that mandatory arrest laws are responsible for an additional 0.8 murders per 100,000 people. This corresponds to a 54 percent increase in intimate partner homicides.

There does not appear to be a significant effect in recommended arrest law states. Although the coefficient is negative, it is measured relatively imprecisely. Estimates in columns (2) and (3) of Table 4 include controls for some other state characteristics and crime rates. Because these laws are between the previous discretionary arrest system and the mandatory arrest, we might expect a smaller but positive effect on homicide rates. There are several reasons why this might not happen: First, if the arrest is perceived by abusers as discretionary, then they may not blame the victim for being arrested, reducing the reprisal rate. Second, because officers

---

[28] This scaling by population seems the appropriate deflater as arrest laws often apply to unmarried couples however, the subsequent analysis has been repeated with number of married couples with little qualitative effect on the coefficients.

17

have discretion, victims may be more willing to call the police hoping to get an intermediate response. Finally, police themselves may not have changed their behavior much, opting to retain discretion and fill out paperwork rather than simply arresting.

There are several potential state-year factors that may be associated with both increased arrests and increased domestic violence. One important factor is the state crime rate, which may indicate how crime-prone society is as well as the other crimes police must deal with. To measure the violent crime rate, I used the number of rape, robbery, and assault crime reports per 100,000 people from the FBI's Uniform Crime Reports. Column (2) of Table 4 reports these results. Another concern might be state economic conditions which may increase domestic violence. I use average annual state unemployment rate derived from the Current Population Survey to control for this effect. There appears to be little effect of these limited covariates on the mandatory arrest law effect.

[TABLE 4 ABOUT HERE]

Column (3) of Table 4 includes a more rich set of covariates including state-year level variables on demographics, economic conditions and social policies. Because of racial differences in crime rates, I include some demographic controls (such as fraction of population that is black or white). I also include share of prison population in the state that is aged under 20, 20-35, 36-49 and 50 or older, which may be indicative of police behavior and crime enforcement levels in a given state. In addition to the unemployment rate used in the previous specification, I include economic covariates of crime such as state-year average log personal income and male-female employment ratio. Finally, the state social policy controls which are related to crime generally include whether the state has the death penalty and the AFDC/TANF max for a family of 3. I also included a control for when the state passed unilateral divorce laws based on Stevenson and Wolfers (2006). After including these covariates, the coefficient on the effect of mandatory arrest laws on intimate partner homicides shrinks to about 0.76, which is slightly smaller but similar in magnitude to the estimates from previous specification.

Because there was a significant secular trend in the domestic violence homicide rates, I estimated several specifications with trend variables. Column (4) reports the results when including a linear trend and column (5) includes the results when including a quadratic trend.

The inclusion of trend controls appears to increase the coefficient, suggesting that declining rates of intimate partner violence were inducing an underestimate of the full effect of the law. Column (6) reports the results from including state-specific linear trends. The coefficient is still larger than the estimates without a trend, consistent with the downward trend biasing the OLS estimates.

To estimate the effect of the adoption of these laws over time, the specifications reported in column (7) include a time since law change interaction effect. Combined with the year fixed effects this both controls for any differences at a given point in time (year fixed effect) as well as differences generated from the duration of the law (years since law change). The main effect of mandatory arrest laws corresponds to the effect of mandatory arrest laws in the initial year of passage. This effect is about half the size of previously estimated effect and insignificant. However, while the effect in the initial year is not significantly different than zero, the effect in the second year (the mandatory arrest law main effect plus the 1 year post-law change effect) is about 0.7 and is significant with a p-value of 0.02 (joint test statistics not reported in the table). The total law effect in later years is similarly significant (although the 2 years post-law effect is significant only at the 10 percent level) and there does not appear to be a significantly different effect of these laws over time. The effect does not appear to grow significantly over time (although there does appear to be a slight lag in the effect, which is to be expected). It is somewhat surprising that the effect of the law does not grow over time. There are several potential reasons why this may be the case. First is the annual nature of the data which means that monthly growth over the first and second years may be missed and is aggregated into a single point estimate. Second, because the outcome variable is homicides, it may be less sensitive to the more subtle changes over time and, thus, is a relatively blunt outcome to measure the temporal diffusion of behavior. Finally, this is consistent with a reprisal story where the behavioral response is a one-time adoption immediately after the law change. If that is the case, and most police agencies adopted the law relatively rapidly, then we would not expect to see the effect grow over time.[29]

---

[29] Thus far, little attention has been paid to the bias that unknown homicides might introduce into evidence. Underlying this is the assumption that it is less likely that family homicides are not likely to be unsolved as the offender would be a known individual (as opposed to a stranger-on-stranger crime in which the offender may be entirely unknown to the police). This assumption is not entirely accurate and indeed may produce some bias in measuring homicide rates (see Riedel, 1999). However, a broad range of studies (e.g. Williams and Flewelling, 1987; Pampel and Williams, 2000) have suggested that family homicides need substantially less adjustment than

19

Because mandatory arrest laws were an important means by which domestic violence became represented and treated as a criminal justice issue (as compared to a family or community problem), we might be concerned that these laws will have a disparate impact on communities which have greater mistrust of the criminal justice system. In particular, some studies have shown that African American women may be especially reluctant to report crimes to the police, preferring instead to handle instances within their own communities.[30] To evaluate the effect on different subgroups of interest, columns (2), (3), and (4) of Table 5 compare the effect of mandatory arrest laws on intimate partner homicides committed between white couples, African-American couples and Asian couples, respectively. The point estimate for white and blacks are similar although blacks have a larger increase in percentage terms (based on mean homicides rates reported in the first row of each column, whites have a base rate of 0.81 intimate partner homicides per 100,000, and blacks have a rate of 0.51 per 100,000). This provides some evidence that the negative effect of mandatory arrest laws is disproportionately strong in certain communities.

This is certainly consistent with some of the heterogeneity in the experimental evidence. For example, in Milwaukee, evidence suggested that African American men were more likely to escalate (rather than be deterred). In Dade County, experimental results suggested that unemployment increased the risk that the response was escalation rather than deterrence (Pate and Hamilton, 1992). Given the differences in unemployment rates across subgroups, this is also consistent with observed differences in estimate effects. While the results appear to hold for all groups, the heterogeneity may be particularly prominent in the certain communities. If we believe that certain communities may be less willing to report to police, the reporting effect might be stronger in those communities. In this case, I find some evidence of this, which may suggest that reporting by victims could explain the rise in homicides. The larger (in percent terms) effect among Blacks and Asians provides support for the reporting effect over the reprisal

intimate partner homicides and as such this assumption may not be too harmful. For sensitivity analysis see Iyengar (2009)

[30] This point is highly contested. Evidence from the National Crime Victimization Survey suggests that African American women report intimate partner violence at higher rates than do their white or Asian counterparts (see for example Rennison, 2001). However, surveys and outreach workers cite general mistrust of the police, mistreatment of the police and concerns that reporting will send partners with criminal records back to prison as reasons why under-reporting may be more prevalent in African-American communities (see Hampton, Oliver, and Magarian, 2003; Bobbit and Williams, 2006).

effect if aversion to the police in general makes the response of minority communities stronger than the response in white communities.

[TABLE 5 ABOUT HERE]

Thus far, I have given little attention to the question of fault when constructing these counts. This is relevant because the intimate partner homicide count used thus far likely includes some homicides which are eventually (but not initially) classified as self-defense or justifiable. While I cannot identify "self-defense" killings from murders, homicides of males by their female intimate partner may more closely approximate the subset of cases for which self-defense is a plausible future classification. Column (5) of Table 5 presents estimate of intimate partner homicides with only female victims killed by male intimate partners. Column (6) presents estimates of intimate partner homicides committed against male by their female intimate partners. Intimate partner homicides of females increase about 50 percent, a similar percent increase to the main, unrestricted estimate (presented in column 1 of Table 5). Similarly, homicides of males by their female intimate partners are significantly affected by mandatory arrest laws—in fact, the effect is larger in percent terms. Overall, these results are consistent with either a reporting or reprisal effect in response to the law change. Indeed to the extent that police intervention facilitate some flight or escape by victims, murder of the abuser may be a substitute for other improved outside options. This evidence is consistent with studies that suggest that battered women who kill their husbands do so more often when they have fewer extra-legal opportunities.[31]

[TABLE 6 ABOUT HERE]

In an effort to verify the difference-in-difference framework, I test the effect of mandatory arrest laws on various sets of uncovered homicides. If the difference-in-difference estimates find a significant effect of mandatory arrest laws on homicides between individuals who should be unaffected by domestic and family violence laws, then it is likely the differences identified above may be unrelated to the passage of these laws. For the purposes of these falsification tests, I define a class of homicides called "other homicides" which includes homicides committed against employees, employers, friends, other known individuals, and

---

[31] See for example O'Keefe (1997) This is also consistent with evidence that finds female perpetrated abuse is affected not by criminal justice options but by outside extra-legal resources (e.g. shelters) (Browne and Williams (1989).

strangers.[32] These homicides should be unaffected by mandatory arrest laws. I estimate two specifications, one with only state and year fixed effects, and one with the full set of covariates described above. The results from these regressions are reported in Table 6, columns (1) and (2). In both specifications, neither mandatory arrest laws nor recommended arrest laws have a significant effect on the homicide level of uncovered homicides. To more closely approximate the homicides of females, I also estimate these two specifications on a count of "other homicides" which have female victims. The results from these two regressions are reported in columns (3) and (4) of Table 6 and again, there appears to be no significant effect of these laws on homicide rates. Finally, I test the effect of arrest laws on intimate and familial homicides which are uncovered by arrest laws. These include homicides committed by boyfriends, girlfriends, homosexual partners, and non-nuclear family relatives. Because the SHR data is from police reports, the distinction between cohabiting or common law married partners is somewhat blurred. While some states do treat cohabiting and common-law married partners differently, the question of whether mandatory arrest laws are enforced in cases of cohabiting intimate partner violence is unclear and to date there does not appear any systematic evidence to answer the question. In the case of non-cohabiting intimate partners, the law will only be enforced if these groups are specifically covered. [33] The results are reported in columns (5) and (6) of Table 6. These results suggest that there is no significant effect of these laws on uncovered homicides and the estimated effects are significantly smaller.[34]

4. DISCUSSION AND CONCLUDING REMARKS

Experimental evidence from the Minnesota Domestic Violence Experiment and replication at five other sites encouraged many states seeking better responses to the problem of domestic violence to pass laws requiring the arrest of individuals believed to abuse their spouses.

---

[32] I have excluded homicides committed by individuals of "unknown relationship." While it is likely that these homicides were not committed by immediate family members or intimate partners, it is was not possible to estimate the subset of these homicides that would be covered and thus all are excluded. For additional information on this point see the data appendix

[33] Including boyfriends and girlfriends in the intimate partner counts for states in which these groups are not explicitly covered does not significantly change the results. They remain a relatively small fraction of all intimate partner homicides and while there does not seem to be a significant effect on this group, the results for common-law married, married, and formerly married couples are robust to their inclusion. Coverage varies by state and is available in the legal appendix.

[34] Fisher test for equality between mandatory and recommended arrest law coefficients is rejected at the 0.02 level. The comparison is between specifications reported in column (6) of Table 3 and column (6) of Table 5. For details on the test statistic and distribution see Fisher (1970).

An evaluation of these laws suggests that they have increased level of intimate partner homicide. This may be because abusers escalate violence after arrest as retribution for their punishment or because abuse victims may be less likely to contact the police in the face of an increased likelihood the abuser will be arrested. While experimental evidence rejected the former theory (on retribution) it could not test the latter reporting theory. However, this failure to contact the police results in fewer interventions risking an increased probability of escalating violence. The differences between in the experimental and quasi-experimental results on arrests for spousal abuse thus raise three important issues related to the broader discussion on the value of design-based versus theory-based studies.

First, if the experimental conditions had been better replicated in the policy, would the experimental results have generalized? Put differently, if holding reporting fixed we could increase arrest rates, would violence decrease as predicted by experimental evidence To test this, I considered the effect of mandatory arrest laws on homicides committed against members of the immediate family. Because mandatory arrest laws required the arrest of an abuser in a domestic situation, familial abuse was also covered by these laws. However, unlike for adults, children typically do not report their own physical abuse to police. Instead, abuse is usually detected by an outside adult (such as a teacher or a doctor).[35] In this case the probability of reporting may not be affected by increased penalties for the abusers.[36] Under these conditions, a law mandating arrests may more closely replicate the experimental conditions and therefore probability of severe violence to children by family members. To test this further, I restrict attention to only homicides of school aged children (i.e. age 6-17). It is likely that abuse of quite small children may rely more on the reporting by an individual within the household and thus be subject to the same transference of costs as direct victims of intimate partner violence. In contrast, school age children are likely to see teachers, doctors, and nurses on a regular basis. As such, heightened abuse of these children is mostly likely to generate an increased likelihood of third party

---

[35] More specifically, of the nearly 2.8 million child abuse cases reported to child protective services agencies in 2000, 56.1 percent of all reports were from law enforcement, educators, medical and mental health professionals, social services personnel, child care providers and other mandated reporters. U.S. Department of Health and Human Services, Administration on Children, Youth and Families, Child Maltreatment 2000 (Washington, DC: U.S. Government Printing Office, 2002).

[36] Actually, many professionals have legal requirements to report suspected abuse which can compensate for any potential costs they might incur from reporting abusers in their community.

reporting.[37] Comparing states with and without mandatory arrest laws before and after the laws change, I find a nearly 75 percent reduction in homicides of these children.[38] These results are consistent with the model suggesting that once arrest laws do not rely on reporting by the abused, these laws appear to function as predicted, reducing harm to victim by imposing costs on abuse. The effect size is quite similar to the IV estimates presented for the MDVE in Angrist (2006). This comparison suggests that perhaps the experimental results were inapplicable, but that were insufficient to determine in what contexts the arrest may be an effective deterrence.

The second issue raised by the difference between the experimental and non-experimental results highlights the concept stated succinctly by Deaton: "heterogeneity is *not* a technical problem." In particular, the concept of heterogeneity is intimately tied to the theory by which we extrapolate from experimental evidence. While understanding the mean effect is critical, determining the variance is crucial from determining how broadly effective a policy might be. In the case of arrest for spousal abuse, while intimate partner homicides may have increased, it is not certain that this corresponds to increased levels of intimate partner abuse. If the intimate partner homicides and intimate partner abuse are negatively correlated, then arrest laws may decrease abuse while increasing homicides. The theory of how arrests affect violence levels is thus critical in determining what to take away from both the experimental and the non-experimental evidence. Understanding the nature of this heterogeneity is critical for determining how effective arrest policies may be. For example, if heterogeneity implies that low-level violence is deterred but for some small set of individuals, arrests increase escalation leading to homicide then a policy of more stringent lethality assessment and greater non-legal resources for victims may be most appropriate. If on the other hand, heterogeneity implies that violence and homicides increase for many victims, even if they decrease for others, encouraging arrest may not be an effective response to intimate partner violence. Thus, at the heart of the policy question is the extent to which the treatment population is heterogeneous, and that aspect is as important as accurately estimating the mean treatment effect. This argument should include the caveat that the reverse is true as well. That experimental studies may be limited in their ability to fully characterize the distribution of treatment effects does not undermine the value of what they

---

[37] This mandated reported is believed to be related to the decline in familial homicides. For discussion of this trend see Durose, et al. (2005)

[38] For detailed analysis see Iyengar (2009). This specification controls for the full set of covariates included in table 4 as well as state and year fixed effects.

can contribute: a credible, unbiased measure of the treatment effect—which is no small thing and also critical to policy decisions.

This leads to the final point highlighted by the experimental and non-experimental results: the important role for quasi-experimental studies. It is clear that experimental evidence is both necessary and often insufficient for determining the full effect of many policies. In the case of violence, low probability but high costs events like homicide are unlikely to be detected by small-sample experiments but critical for decision making by policy makers. A similar claim can be made about theory-based designs, which do not lend themselves naturally to transparency for policy makers. In addition, often theory alone can have ambiguous predictions of the overall effect of a policy. Quasi-experimental designs, especially those with transparent designs, have an important role to play, not as a second-best alternative, but as an important contribution to the overall information about the efficacy of a policy.

In conclusion, this article takes some issue with the debate which appears to force economists to take a stance on the primacy of either internal or external validity. In the end, such a distinction is not helpful because failure of either internal or external validity is problematic for both academics and policymakers. Instead of imposing a hierarchy of methods I propose viewing the information provided by each method as complementary components to the knowledge necessary to make informed decisions about policy efficacy. I also wish to emphasize the point that in empirical research, humility is a virtue. There is a sad irony that a mandatory arrest law intended to deter abuse actually increases intimate partner homicides which provides an important cautionary tale. Suggesting that implementing policies with *only* experimental evidence, absent theory and some confirming non-experimental studies, may be not only ineffective but counterproductive, hurting the very people the policy seeks to help. Thus, rather than view experiments, quasi-experiments or structural estimation as procedures at odds with each other, this paper highlights the value that an integrated approach, which explicitly links randomized controlled trials, quasi-experimental studies, and structural modeling, may provide in more fully understand the effects of a desired policy interventions.

Figure 1. Intimate Partner and Familial Homicide Rates in Mandatory Arrest Law States
Notes: Means based on author's own calculations using Supplementary Homicide Reports 1976-2003. Intimate partner homicides include homicides of husbands, wives, ex-husbands, ex-wives, common-law husbands and common-law wives. Mandatory arrest states are defined as states where officers have no discretion as to whether or not to make a warrantless arrest when an intimate partner offense is reported.

Figure 2. Intimate Partner and Familial Homicide Rates in Recommended Arrest Law States
Notes: Means based on author's own calculations using Supplementary Homicide Reports 1976-2003. Intimate partner homicides include homicides of husbands, wives, ex-husbands, ex-wives, common-law husbands and common-law wives. Recommended arrest states are defined as states where officers are instructed, but not required, to make a warrantless arrest when an intimate partner offense is reported.

Table 1. Estimated Treatment Effects from 6 Experiments on Spousal Assault

| Site	N initial (N final)	Experimental Comparison	% Non-Compliers	Recidivism (Survey Reports)	Recidivism (Police Reports)
Minneapolis	314 (202)	1.Arrest 2. Advise 3. Separate	17.8	-0.131* (0.073)	-0.083*** (0.012)
Charlotte	686 (650)	1. Arrest 2. Advise/ Separate 3. Issue citation for court appearance	13.2	-0.039 (0.056)	.026 (.031)
Colorado Springs	1,660 (1,658)	1. Arrest + Protective order 2. Protective Order + counseling 3. Protective order 4. Restore order at the scene	6.9	--	-0.001 (0.022)
Metro-Dade County	916 (907)	1. Arrest 2. Non-arrest	10.0	-0.139*** (0.047)	-0.015 (0.028)
Milwaukee	1,200 (927)	1. Short Arrest 2. Overnight Arrest 3. Warning that next instance will result in arrest	0.0	0.014 (0.036)	-0.005 (0.052)
Omaha[†]	577	1. Arrest 2. Separate 3. Mediate	2.7	-0.026 (0.033)	-0.080* (0.049)

Notes: Differences calculated comparing arrest to non-arrest dispositions. All reported differences report *assigned* treatment. Estimates are calculated using reported "Recidivism" in each study. Treatment and control effect sizes are not adjusted for any covariates. Recidivism is defined as committing a new offense at least once in the 6 month period after treatment. Raw effect sizes based on sample size and number of failures
Source: Garner, Fagan and Maxwell (1995)
[†] The Omaha experiment actually consisted of two experiments; one in which offenders were arrested if present and the other issued an arrest warrant if the offender was not out. These are combined here with arrest warrant treated as the arrest disposition.

Table 2. Characteristics of Subjects from 6 Experiments on Spousal Assault

	Minneapolis	Charlotte	Colorado Springs	Metro-Dade County	Milwaukee	Omaha
	205	638	1238	906	954	296
Panel A: Incident Assignment Data						
Assigned to Arrest (%)	29	33	26	51	68	34
Actually arrested (%)	43	40	28	60	68	34
Initial Victim Interview Completion Rates (%)	62	64	83	65	60	79
Final Victim Interview Completion Rates (%)	49	50	70	42	78	73
Panel B: Suspect Characteristics						
Age (average)	32	33	31	35	31	31
Employed (%)	40	77	87	71	47	78
Prior arrest (%)	59	31	43	12	62	65
Use of intoxicant (%)	61	54	59	31	29	59
Race/Ethnicity						
African-American (%)	23	70	30	42	75	42
White(%)	58	28	54	36	20	51
Hispanic(%)	1	0	15	22	4	5
Asian/Native America/other (%)	18	2	1	0	1	3
Relationship with Victim						
Married (%)	35	48	67	79	31	46
Separated or Divorced (%)	3	2	5	5	1	1
Unmarried (%) (current or former)	47	50	28	16	68	52
Son, brother, roommate	15					
Panel C: Incident Characteristics						
Misdemeanor (%)	98	97	37	100	100	100
Victim Injured (%)	--	84	55	92	100	73

Notes: Differences calculated comparing arrest to non-arrest dispositions. All reported differences report *assigned* treatment. Categories are pooled when appropriate to facilitate comparability across studies. Omaha sample uses only the Offender-Present sample. Year Fixed Effects	Y	Y	Y	Y	Y	Y	Y
R-squared	0.6125	0.6127	0.6214	0.6275	0.6284	0.6252	0.6746

Notes: All regressions include 992 observations. The dependant variable for each column is the column title per 100,000 inhabitants. Robust standard errors, clustered by state, are reported in parentheses. Coefficients that are significant at the .05 (.01, .1) percent level are marked with ** (***, *). Intimate partner homicides include

homicides of husbands, wives, ex-husbands, ex-wives, common-law husbands and common-law wives. Mandatory arrest (MA) states are states which require an arrest conditional on a report of domestic violence. Recommended arrest (RA) states are states where officers are instructed but not required to make a warrantless arrest when an intimate partner offense is reported.

a. Crime rate controls use FBI Uniform Crime reports for the number of crimes per 100,000 inhabitants. Indexed crimes included in the violent crime variable are murder, robbery, assault, and rape. Indexed crimes included in the nonviolent crime count are burglary, larceny, motor vehicle theft and drug crimes.
b. Unemployment estimates are based on the March Current Population Survey.
c. State demographic controls are based on the March Current Population Survey and include variables for the fraction of the population that is black, white, and other race, as well as age composition indicating share of prison population that is aged 14-19, 20-49, 50 or older.
d. State economic control variables are based on the March Current Population Survey and include the variables log state personal income per capita, and female-to-male employment ratio. State social policy controls include max AFDC/TANF for a family of 3, unilateral divorce laws indicators (based on classification in Stevenson and Wolfers, 2006) and indicators for whether the state has the death penalty.

Table 5. Estimates of the Effect of Mandatory and Recommended Arrest Laws on Intimate Partner Homicides for Various Subgroups

	(1) All Intimate Partner Homicides per 100,000 inhabitants	(2) Intimate partner homicides with White victims and perpetrator	(3) Intimate partner homicides with Black victims and perpetrators	(4) Intimate partner homicides with Asian victims and perpetrators	(5) Homicides of females by male intimate partners	(6) Homicides of males by female intimate partners

Notes: All regressions include 994 observations. The dependant variable for each column is the column title per 100,000 inhabitants. Robust standard errors, clustered by state, are reported in parentheses. Coefficients that are significant at the .05 (.01, .1) percent level are marked with ** (***, *). "Other homicides" include homicides committed against employees, employers, other (non-immediate) family, friends, other known individuals, and strangers. Intimate partner homicides uncovered by law refers to relationships that are classified as intimate partner but were not specified in the state's arrest law statute. See Legal Appendix for detailed coverage by state. Mandatory arrest (MA) states are states which require an arrest conditional on a report of domestic violence. Recommended arrest (RA) states are states where officers are instructed but not required to make a warrantless arrest when an intimate partner offense is reported.
a. Crime rate controls use FBI Uniform Crime reports for the number of crimes per 100,000 inhabitants. Indexed crimes included in the violent crime variable are murder, robbery, assault, and rape.
