

This PDF is a selection from an out-of-print volume from the National Bureau of Economic Research

Volume Title: Fifty Years of Economic Measurement: The Jubilee of the Conference on Research in Income and Wealth

Volume Author/Editor: Ernst R. Berndt and Jack E. Triplett, editors

Volume Publisher: University of Chicago Press

Volume ISBN: 0-226-04384-3

Volume URL: <http://www.nber.org/books/bern91-1>

Conference Date: May 12-14, 1988

Publication Date: January 1991

Chapter Title: Issues in the Measurement and Interpretation of Saving and Wealth

Chapter Author: Michael J. Boskin

Chapter URL: <http://www.nber.org/chapters/c5975>

Chapter pages in book: (p. 159 - 184)

5 Issues in the Measurement and Interpretation of Saving and Wealth

Michael J. Boskin

5.1 Introduction

The saving and wealth accumulation behavior of an economy reveal much about it, as they reflect preferences, incentives, institutions, and demographics. However, there are numerous measurement and interpretation issues surrounding data on, adjusted measures of, and empirical analyses about postwar U.S. saving and wealth. It is by now well known, and considered conventional wisdom, that the U.S. postwar saving rate is low by international standards and has fallen since the 1950s and 1960s. This “conventional wisdom” stems primarily from the traditional National Income and Product Account (NIPA) measures of gross and net private and national saving in the United States.

There are, however, other sources for measuring saving and reasons to believe the NIPA saving figures are the beginning, not the end, of the story. Serious conceptual and measurement issues, ranging from the comprehensiveness of the definition of saving to important details concerning deflators, as well as a host of other matters, remain unresolved. Since its inception, the Conference on Research on Income and Wealth has devoted a nontrivial fraction of its efforts to dealing with these and related issues, as have numerous other studies in the last decade, including some of my own, conducted by and for the National Bureau of Economic Research.

In the first three Conference on Research in Income and Wealth volumes, saving and wealth were prominent features. Issues I discuss below were discussed even then: the treatment of capital gains and losses in the NIPA, inflation and inventory valuation adjustments, real corporate profits. In volume 1,

Michael J. Boskin is professor of economics and director of the Center for Economic Policy Research at Stanford University, as well as a research associate with the National Bureau of Economic Research.

measuring national wealth, including valuation problems, government product; in volume 2, capital gains and alternative definitions of saving; in volume 3, alternative definitions and methods of measuring saving and its components. The talent mobilized to work on these issues in the 1930s was impressive, and included Simon Kuznets, Raymond Goldsmith, Milton Friedman, Gottfried Haberler, and Solomon Fabricant, among many others.

Since a complete review of that literature would constitute a lengthy paper itself, suffice it to say that a recent Conference on Research in Income and Wealth was devoted to issues in measuring saving and investment. The conference volume (Lipsey and Tice 1989) contains a large number of important, novel, and useful papers, many of which contain partial surveys of their respective subfields within the general area of study.

The most famous book ever written in economics, Adam Smith's *Wealth of Nations*, did not come by its title as a matter of coincidence. For 200 years, issues concerning the measurement of, positive analysis of, and normative prescriptions for increasing, national wealth have been an important component of the economics profession.

These concerns about the economic costs and benefits of saving also have an interesting and checkered history (see Klein 1986). Polonius's advice was, "Neither a borrower nor a lender be." Benjamin Franklin's quip that "a penny saved is a penny earned" is perhaps the most often-quoted schoolboy maxim concerning the benefits of thrift, but in the middle third of this century, it gave way to the Keynesian notion that spending might be insufficient to support full employment. Keynes and the postwar stagnationists were deeply concerned that insufficient spending would lead to chronic and massive unemployment, so they argued for policies designed to soak up excess saving. While it is not my purpose here to present my own or a summary of other views concerning this Keynesian proposition, suffice it to say that the force of that argument has been mitigated considerably by recent analytical and empirical research in economics, and that at best, it is a weak and temporary proposition.

It is obvious, however, that we could save too much. In order to save more, we must forgo current consumption. Therefore, individuals and societies must somehow balance the benefits of increased consumption in the future against the cost of forgone consumption opportunities today. To show how we have come full circle, the current chairman of the Federal Reserve Board, Allan Greenspan, has been calling for the federal government to run a budget surplus on average, primarily to compensate for what he regards as a chronically low saving rate.

That we save too little as a nation appears to be a widespread view among economists. Some refer to the apparent (usually measured by the NIPA saving figures) historical decline in the saving rate, as well as the better aggregate performance of the U.S. economy in the 1950s and 1960s than subsequently. Whether the low saving rate is a cause of the subsequent deterioration of the

economy's performance or an effect thereof, or both, is generally left unspecified.

Others bemoan the low U.S. saving rate relative to other countries. It is clear that saving in the United States, as conventionally measured, is below that of other advanced economies. While I will discuss extended measures of saving that suggest that the traditional measures probably overstate this difference, it is still substantial. When I was a graduate student, it was common to argue that it was reasonable for the United States to have a much lower saving rate than other economies because we were so much richer than they, and they were saving rapidly to try to catch up and to finance the rebuilding of their infrastructure after the devastation from World War II (although the fact that this was still going on in the 1970s suggests convenient arguments die slowly). The rate of growth of GNP in many of these other economies exceeded that of the United States and our lower saving and investment rates were often singled out for a nontrivial share of the blame.

Recently, a new argument has claimed that the major problem with our low private and even lower national saving rate is that it falls substantially below our rate of net investment. The low investment rate is assumed to be one cause of slow productivity growth and is itself substantially below the investment rates of most other advanced economies. We appear to be unwilling to see the investment rate fall to the still lower rate of net national saving. This leads us to rely on historically large imports of foreign capital to finance a substantial fraction of our net investment and a modest fraction of our gross investment. If this continues for very long, it would imply an explosive growth of external debt and concomitant adjustment problems later on.

My own view of the relationship of domestic saving and investment is that they are indeed *eventually* linked. In the short and medium run, there is no necessary tie between domestic investment and saving, as capital is internationally quite mobile, at least over a modest fraction of the saving of any society. Eventually, however, an advanced economy such as the United States will need to finance its own domestic investment. This implies that, in the long run, domestic investment will be constrained by the available supply of private saving, an event that gives some force to the concern about an apparently low private-saving rate.

There is thus ample reason to be concerned about the measurement, interpretation, evolution, and analysis of saving and wealth in the postwar United States. Saving behavior may well be linked to our long-term growth as well as potentially to our short-run stability. As interesting as these analytical and empirical issues are (see Boskin 1988 and Bernheim 1987 for a discussion of some of these issues), my goal here is much more modest. Having raised these issues, I present a brief survey of some important issues in the definition and measurement of saving. I also present some selected recent results, identify some substantial progress made, and present some suggestions for future ave-

nues of research. I do not have the time or space, nor is it my comparative advantage given the other participants and papers in this conference and previous conferences on income and wealth, to go into great technical detail concerning many of the issues raised. For that, the interested reader is referred to some references.

To this end, section 5.2 discusses definitions, measures, and sources of information concerning saving and wealth and their relationship to theories of saving and consumption. It briefly mentions some of the potential problems, such as sampling error, measurement error, and various data sources. After a brief discussion of the NIPA saving figures, the Federal Reserve Flow of Funds, household surveys, and the estate tax data, it turns to the definition of saving for an individual, a sector, and a nation. It discusses the Keynesian emphasis on short-run flows; the life cycle/permanent income view attempting to distinguish transitory and permanent components on the one hand, or the need to develop household age- or cohort-specific balance sheets combined with demographic information on the other; the Ricardian equivalence intergenerational altruism view that only aggregate resources matter for consumption and that the distribution of resources (conditional on the level) does not affect aggregate consumption and hence age-specific balance sheets would be beside the point.

Various well-known conceptual problems with the NIPA and the Flow of Funds are discussed, such as the failure of the NIPA to measure capital gains and losses, and so on. Issues such as the measurement and valuation of human wealth and changes therein, including the valuation of human and nonhuman wealth in a world of incomplete markets, appropriate deflators, inflation adjustment, cost-of-living indices, and so on, are discussed. A comparison of the traditional NIPA saving measures with those from the Federal Reserve Flow of Funds is presented, as are new, more comprehensive extensions of the NIPA saving data that incorporate net saving in government capital and consumer durables. These comparisons are interesting and informative, although I make no pretense of delving deeply into reasons for the differences (see Wilson et al. 1989 for a discussion thereof). They reveal a somewhat more complete story concerning the evolution of private and national saving and wealth than has heretofore been available. They suggest that more comprehensive measures of saving reveal substantially higher net saving rates in the United States than those found in the traditional NIPA estimates, but they reinforce the view that the saving rate, though higher, has fallen, as has the rate of wealth accumulation.

Section 5.3 discusses aggregation and disaggregation. Various theories of private behavior and the nature of credit markets suggest alternative views of the propriety of aggregating and disaggregating saving and wealth data by sector (household, business, government), by age, or other characteristics of households, by type of asset or liability, and so on. For example, what has come to be called Denison's law has led many people to suggest that gross

private saving is the most appropriate variable to analyze for the economy, as households see through the corporate veil. I have elsewhere argued that both the gross and net numbers should be examined and that there is little stability in the net private saving rate. An asymmetric information model of the capital market which led to credit rationing would require a distinction between household saving and business saving, as the internal cost of funds to a firm would be less than external financing (see Stiglitz and Weiss 1981). Various assets and liabilities have different liquidity, risk, expected duration, and so on. These may also be important for analyzing the performance of the economy.

I also make a brief reference to my own work, with Lawrence Lau, that suggests the potential importance of taking extreme care in analyzing aggregation issues for U.S. saving.

Section 5.4 turns to some specific issues. First, I turn to consumer durables and present augmented NIPA figures, including durable purchases as saving and the rental flow from the stock of durables as consumption and income. I also mention government capital, including government tangible capital, government lending, government contingent and potential liabilities, and so on. Adjusted or augmented NIPA-type saving rates are also presented, including consumer durables and various components of government net capital formation. A comparison is made to Japan in order to highlight the potential importance such adjustments make in international comparisons of saving rates.

I also discuss education and human capital, pension and Social Security wealth, estimates of income and its components, revaluations of financial assets and liabilities due to interest rate changes or other factors, and inflation adjustment, as well as saving by Americans abroad.

For these items, I simply raise the issues surrounding them and, including them in an augmented, more comprehensive measure of saving, discuss their rough orders of magnitude and how they might affect the evolution of the saving rate in the United States and its comparisons with other countries.

Finally, in section 5.5 I conclude that we have come some distance to a better understanding of saving and wealth. I conclude that no single theory—Keynesian, permanent income, pure life cycle with no bequest motive or intergenerational altruism—is sufficient by itself to explain aggregate saving in the United States. While each of these models of saving behavior lend important insights and contain some elements of truth, none are sufficient by themselves, and all are strongly rejected in aggregate data.

We have also come a substantial way toward refining some of the adjustments to saving and wealth estimates that a more comprehensive definition of saving would entail, and the interpretation of these data depends heavily upon one's model of the economy. No one number will be the answer to all questions. For example, while many of the adjustments, such as that for consumer durables, would raise the U.S. private saving rate, there would also be a corresponding entry on the investment side, and that would do nothing to redress

the shortfall of saving relative to domestic investment that necessitates capital imports. We may be somewhat less anxious about the rate that Americans are acquiring claims to assets, but other concerns remain. Capital gains and losses, such as those in the stock market, may partly explain swings in the traditional NIPA saving measures, both because consumption and saving are affected by changes in wealth and because of the institutional features of pension funds, the majority of which are of the defined-benefit type in the United States. This in turn implies that large swings in the stock market (and/or major changes in interest rates) will substantially change contributions to these pension funds and hence personal saving (Bernheim and Shoven 1988).

My penultimate conclusion is that the United States still has a low rate of saving (although not nearly so low as the traditional NIPA measure would reveal) and a low rate of wealth creation. We start from a high level of wealth but, on a per capita, or perhaps more important, per worker basis, the rate of wealth accumulation has slowed substantially. While saving in the United States takes on a somewhat different composition than saving in other countries, we are only beginning to understand not just how to measure it but also the implications thereof, and the policies and other factors that affect that composition. For all the advances made and the insights gained, there is still a substantial shortfall of national saving relative to domestic investment.

5.2 Definitions, Measures, Sources

The potential data on saving and wealth come from several, potentially complementary, sources. The three generic types of data used are the aggregate data from the National Income and Product Accounts (NIPA), the data from the Federal Reserve Flow of Funds, and household survey data. In addition, some information on wealth and its distribution has been derived from estate tax returns, usually federal but also state. The latter are particularly useful in dealing with a truncated sample of the upper tail of the wealth distribution. The relative advantages and disadvantages of household survey data with respect to the NIPA and Flow of Funds data have been discussed in detail in several other studies (see, e.g., Curtin, Juster, and Morgan 1989). Annual surveys chronically underestimate wealth and property income. While important advances have been made in attempting to aggregate up from household data, the quality, measurement error, sampling error, and other concerns are nontrivial. Further, to measure saving from household surveys, one would not generally be able to get an accurate measure of both income and total spending in order to get at saving by subtraction, and while surveys of saving behavior are more common in some other countries (e.g., the annual Family Saving Survey and Family Income and Expenditure Survey in Japan) than in the United States, there are several surveys in which it is possible to analyze data on the same households at two different points in time and thereby attempt to

create balance sheets at those two points in time and to difference them to get a measure of saving or dissaving.

Another issue is the gray area between the business sector and the household sector in which substantial saving occurs—nonprofits, trusts, pensions, and other vehicles that may be either excluded from household surveys or in which individual responses may be subject to considerable error (e.g., accrued net saving in life insurance). Important recent data from the 1983 Survey of Consumer Finances, the 1984 Wealth Supplement to the Panel Study of Income Dynamics, and the 1984 Wealth Supplement to the Survey of Income and Program Participation are all fruitful data sources.

Numerous other household surveys contain substantial information on property income, and the question arises as to how to aggregate it to the presumably more accurate national control totals such as those in the National Income and Product Accounts, and then to capitalize them or to translate them into asset values. This is most easily done for interest-bearing assets of a fixed duration, and much more difficult to do for other types of assets and liabilities. Many of the recent studies of the dissaving behavior of the elderly (e.g., Hurd 1987; Bernheim 1984; Diamond and Hausman 1984; and others) attempt to make the best use possible of such household survey data. I shall say no more about this source of information other than that it is an important additional source that can be integrated with aggregate data on the one hand, and then disaggregated to provide details on distributions and characteristics that may be of great interest.

Before turning to NIPA and Flow of Funds saving estimates and the corresponding wealth estimates from the Flow of Funds, a few words concerning theories of saving and consumption and what sorts of data are consistent or inconsistent with them are in order.

The three leading theories of saving/consumption behavior are Keynesian (KN), life cycle/permanent income hypotheses (LCH/PIH), and intergenerational altruism (IGA). The Keynesian predilection to focus on short-run cash flows generally ignores capital gains and losses as components of income and focuses on the flow of saving out of current disposable income. In contrast, the permanent income hypothesis attempts to disentangle permanent from transitory components and has vastly different predictions concerning the response of saving to permanent and transitory components of income (including transitory components due to fiscal policy changes). It is important to note that the life-cycle hypothesis suggests that the marginal propensity to save depends upon age and that demographics are important. This leads immediately to going beyond aggregate saving data to attempt to analyze the effects of the age distribution of the population or resources on saving and suggests the calculation of age or cohort-specific balance sheets and saving rates may be quite useful in the analysis of trends in saving behavior and their responses to various policy experiments.

In sharp contrast to the LCH stands the strong implication of intergenerational altruism that aggregate consumption depends only on aggregate resources, not on their distribution across generations. Age-specific policies should have no impact on aggregate consumption and *national* saving, as private saving will adjust to public saving or dissaving. The potential usefulness of household balance sheets and age-specific saving rates for analyzing saving and its reaction to policy experiments is useful only in the context of testing Ricardian equivalence/intergenerational altruism. If one accepts the strong tenets of Ricardian equivalence, the usefulness of the data disaggregated by age disappears. In Boskin and Kotlikoff (1985), we build a finite approximation to an intergenerationally altruistic infinitely lived optimal consumption program and test whether the age distribution of resources affects consumption, given the aggregate level of resources. We reject this implication of Ricardian equivalence based on postwar U.S. time-series data. In Boskin and Lau (1988), we develop age- and cohort-specific balance sheets by combining Current Population Survey data on the age distribution of income with more usual aggregate variables. We estimate an economically important and statistically significant effect of the age distribution of human and nonhuman wealth on the share of aggregate wealth consumed. We also estimate a large, statistically significant generation effect: households headed by persons born since 1939 consume a larger share of their wealth than those born prior to 1939, at the same age. The strong implication of Ricardian equivalence is rejected.

Most aggregate time-series studies reject the simple Keynesian specification of consumption and suggest that there is tax discounting, or at least a large fraction of the population is forward looking and maximizing over a longer time horizon than the typical Keynesian short-run flows. For example, Hall and Mishkin (1982) conclude that about four-fifths of consumers could be modeled as if they are maximizing over a long time horizon, whereas one-fifth could not.

Studies of the dissaving behavior of the elderly have generally concluded that the strictest version of the LCH, an expected average propensity to consume over the lifetime of one, is inconsistent with the observed behavior, although Hurd (1987) presents data that are consistent with the LCH.

My own conclusion is that no single model of saving and consumption behavior is sufficient to explain aggregate saving fully. All of the theories are rejected in studies based on aggregate time-series data, and some are usually rejected in other studies. There appears to be substantial heterogeneity among consumers. This heterogeneity may be a function of age, income, and desired consumption profiles leading to liquidity constraints or a host of social, psychological, environmental, historical, and economic variables. I believe that there is now strong evidence that the age distribution of resources, given their aggregate level, affects aggregate consumption, and therefore there is some potential gain in attempting to integrate microeconomic (hopefully longitudi-

nal) survey data on the distribution of resources by characteristics of households with aggregate data.

Saving is usually defined as forgoing current consumption and providing funds either directly or indirectly to capital markets to channel into productive investment, whether in tangible, financial, or human capital. It is a neat concept, but there are an inordinate number of difficulties in measuring it.

Let us start with the most basic definition that saving in period t , S_t , is equal to income minus consumption in that period, Y_t and C_t . Or,

$$(1) \quad S_t = Y_t - C_t.$$

Hence, saving will equal investment *ex post*. From the Haig-Simon's definition of income,

$$(2) \quad Y_t = C_t + (W_t - W_{t-1}),$$

income is the sum of consumption plus the change in net worth, the difference is the change in the value of assets and of liabilities. Therefore,

$$(3) \quad S = W_t - W_{t-1},$$

or saving equals the change in net worth. The problem in measuring saving (and, when we integrate saving over a period of time, wealth) stem from difficulties in measuring Y , C , and W_t and W_{t-1} .

It is worth mentioning that so prominent an economist as Larry Klein (1986) has argued that "the importance of saving tends to be understated if we treat it as a mere residual." Klein emphasizes that households make genuine decisions about most asset and liability changes, whereas the residual concept was popularized from the Depression mentality as a typical representation of personal saving.

First, household saving in our national accounts is estimated as a residual, after subtracting consumer expenditures, taxes, and interest payments to business from estimated personal income. The measurement errors in these components (each of which is potentially quite large relative to net saving), will show up dollar for dollar in net saving. Suppose, heroically, that we have a good estimate of income. Then errors in the measurement of consumption that may be quite small relative to consumption translate into larger percentage errors in the measure of saving, which is much smaller. I consider this to be a problem, but much less of a problem than measuring income. Suppose we measure consumption properly, but mismeasure, say underestimate, income. Then in general, saving will be underestimated dollar for dollar. Again, I consider this to be an extremely important issue, perhaps the most important one. Numerous studies suggest that income is substantially underestimated in the national income accounts. The BEA makes an adjustment to personal income related, apparently, to IRS estimates of underreported adjusted gross income. While the range of estimates of this underestimation is substantial (see Feige 1983), I believe it is not trivial.

One extreme set of estimates based on a transactions methodology (Feige 1983) estimates that while unrecorded income was trivial in the 1950s and 1960s, by the late 1970s and early 1980s it amounted to 40% of the GNP. An unrecorded income which was primarily saved of even one-tenth this size would raise the net private saving rate by 80%, from 5% to 9% of the GNP. If net private saving runs about \$250 billion per year, and gross private saving about \$600 or \$700 billion per year, an underestimate of income by a few percentage points will lead to a serious underestimate of saving. A related problem may be the understatement of the income earned and saved done abroad.

What are the likely reasons for underestimating income? A good discussion of some of these issues is presented in Holloway (1989); it includes where one draws the boundary in the GNP accounts (e.g., placing emphasis on market transactions with only a few imputations, excluding illegal activity, excluding capital gains, to which we will return below). Much has been made recently of the underground economy, and estimates of the size of the underground economy vary by two orders of magnitude (see Feige 1983). This includes illegal activity and activity that is deliberately unreported, usually for tax reasons, such as cash payments for services that go unreported. To the extent that personal income is seriously understated, we would expect the degree of underreporting to be positively correlated with marginal effective tax rates. Barro and Sahasakul (1983) estimate that the fraction of U.S. households subject to high marginal tax rates quadrupled between 1965 and 1980. While marginal tax rates have come down some since then, this suggests that by the late 1970s and early 1980s the underreporting of personal income had probably grown substantially.

But is personal income that underreported? Since consumption is two-thirds of income, and is estimated from transactions, some of the income that is unreported for tax purposes does show up in transactions, eventually working its way back into the income figures.

Still, the net degree of underreporting of personal income is a source of some concern, especially since there is reason to believe that it has grown substantially over precisely the period in which there is great concern about the fall in the saving rate. Finally, a word should be said about international comparisons. Since U.S. marginal tax rates are now much lower than those in most other advanced economies, we would expect the degree of underreporting and the underground economy to be somewhat less in the United States than in these countries. But this is only conjecture, for this will reflect social attitudes, the nature and resources devoted to tax enforcement, and so on, and on this I believe we have little evidence. In any event, I believe it is a fruitful area for future research. As already noted, the NIPA measure of saving excludes net capital gains or losses in its measure of saving, as in its measure of income.

A third problem is the treatment of expenditures on consumer durables as

consumption rather than as saving. Finally, the treatment of government saving or dissaving in the U.S. NIPA is a rather mechanical reporting of the budgetary position, with no attempt to develop a separate capital account on the expenditure side for government units in reporting a surplus or deficit on current operating accounts (see Boskin 1982). The federal government's own budget suffers from this difficulty, but the Department of Commerce does attempt to estimate government capital stocks, investment, and depreciation. We will return to these two issues in section 5.4 below.

Let us turn to the NIPA saving figures for the United States. Table 5.1 presents estimates of gross and net national saving and their components in the United States, 1951–87. Net saving is decomposed into private saving, the state and local government surplus, and the federal government surplus. Private saving, in turn, is decomposed into personal and corporate saving. Numerous conjectures have been made concerning whether the appropriate rate to study is net or gross, private or total, or disaggregated personal and corporate saving. For example, David and Scadding (1974) find that the gross private saving rate at full employment is remarkably constant, reinforcing the finding of Denison (1958). They infer from this that households see through the corporate veil and that movements between personal and corporate saving reflect various factors such as changes in the relative tax advantages of the two forms of saving. However, they strongly reject the ultra-rationality argument that households see through the government veil, an argument associated with Martin Baily (1962) and Robert Barro (1974).

Recent theoretical work on credit markets (e.g., Stiglitz and Weiss 1981) suggests that maintaining the distinction between household and corporate saving may be quite important. Asymmetric information may lead to a situa-

Table 5.1 U.S. Gross and Net Saving, 1951–87

	1951–60	1961–70	1971–80	1981	1982	1983	1984	1985	1986	1987
Total net saving:	7.1	7.8	7.0	5.7	2.0	2.0	4.1	2.3	1.8	1.9
Net private saving:	7.5	8.2	8.0	6.6	5.5	5.7	6.8	5.7	5.3	4.3
Personal saving	4.7	4.8	5.5	5.2	4.9	3.8	4.4	3.2	3.1	2.7
Corporate saving	2.8	3.4	2.4	1.4	.6	1.9	2.5	2.5	2.2	1.7
State & local government surplus	-.2	.1	.9	1.1	1.1	1.4	1.7	1.6	1.3	1.0
Federal government surplus	-.2	-.5	-1.8	-2.1	-4.6	-5.2	-4.5	-4.9	-4.8	-3.4
Memoranda:										
capital consumption	8.7	8.4	9.8	11.4	12.1	11.6	11.0	10.9	10.8	10.7
Gross private saving	16.2	16.6	17.8	18.0	17.6	17.4	17.9	16.6	16.1	15.0

Source: U.S. Department of Commerce, National Income and Product Accounts.

Notes: Data are averages (except for 1981–87) of annual flow, as percentages of GNP. Detail may not add to totals because of rounding. 1987 figures are preliminary.

tion where the cost of internal funds is substantially below the cost of external funds, and therefore corporate cash flow may be an important separate determinant of business investment, a result consistent with investment equations in many large macroeconomic models. If this is the case, it may be important for some purposes not to aggregate private saving.

Further, focusing on gross saving and its apparent stability—although it has not been as stable through 1987—seems odd since virtually all theories are in terms of how households, firms, and even governments wish to form their *net* wealth position. In brief, any rationality hypothesis seems somewhat out of balance if it ignores the fact that depreciation is estimable. There is much less stability in the net private saving rate and in the net national saving rate than in the corresponding gross figures.

The most important items to note in table 5.1 are the levels of gross and net saving, which are low relative to that of other societies (see Blades and Sturm 1982) and the substantial decline in the net private saving rate, and especially the net national saving rate in the 1980s relative to the 1950s, 1960s, and 1970s. These data undoubtedly form the most important basis for concern over the level and trend in private and national saving in the United States.

As noted above in equation (3), saving can also be defined as the change in net worth. An alternative approach to measuring saving may be obtained from estimates of sectoral and national net worth through time. The Federal Reserve's year-end balance sheets for the U.S. economy provide just such a source of data. Recall that the NIPA saving and income measures exclude capital gains and losses. These are, in principle, captured by the Federal Reserve's balance sheets, which should also reflect some wealth accumulated in the underground economy. The Flow of Funds data have their own problems, both internally and relative to household surveys and the NIPAs (see, e.g., Curtin, Juster, and Morgan 1989; and Wilson et al. 1989). Among the more important are that bonds are carried at par (in recent years, the changes in the value of bonds will not necessarily net internally given the increase in foreign holdings), and the rudimentary treatment of the government sector in the Flow of Funds—in particular, as with the NIPA, there is no attempt to estimate changes in the value and the imputed income from government tangible capital. (I ignore the even thornier problem of contingent and potential liabilities and intangible capital discussed below.) The Flow of Funds balance sheets, however, do attempt to record the current value of all assets and liabilities in the economy, such as owner-occupied housing, consumer durables, inventories, and depreciable plant and equipment. In principle, the FOF not only includes traditional gains and losses, but revaluations of real assets caused by depreciation, obsolescence, or other sources. For business tangible capital, the estimates are of the replacement cost, not the current market value. Hence, when Tobin's q diverges systematically from one, the Flow of Funds data may over- or understate the value of tangible business capital.

Saving can now be defined as the change in net worth. Because of inflation,

with the net worth data as year-end figures, we need to estimate saving in current dollars as

$$S_t = NW_t - P_t/P_{t-1} \cdot NW_{t-1},$$

where P_t is an index of prices. Because these are end-of-year data, I use the December consumer price index. There are numerous reasons why other indices might be more appropriate, but it is much more difficult to obtain them on a year-end basis rather than quarterly or as an average over the year.

The Flow of Funds also presents considerable disaggregation with respect to the sector (e.g., households, nonfinancial corporations, government units, etc.) and type of assets and liabilities. I present in table 5.2 the private, public, and national saving rates as a percentage of GNP from the period 1948–87. These data reveal some interesting differences relative to the data in table 5.1. While they are usually substantially higher, they vary quite a bit more, and, as they reflect changes in asset values, they are even negative on occasion (e.g., see national saving in 1982 and 1985). Table 5.3 presents estimates on a decade-by-decade average basis for private, public, and national saving. The net private saving rate in the 1950s is more than 150% as large as that reported in the NIPA. In the 1960s, it is somewhat larger, although it had fallen somewhat relative to the 1950s. The net private saving rate from the Flow of Funds rebounds in the 1970s and again is more than one and one-half times that of the corresponding data from NIPA. The data for the first half of the 1980s from the Flow of Funds reveals the tremendous fall in both the private saving rate and the national saving rate. As table 5.3 reveals, the public saving rate was about zero in the 1950s, 1960s, and 1970s, as traditionally measured budget deficits in the 1970s were offset by accumulation of financial assets by the public sector. The net national saving rates, therefore, are almost identical with the net private saving rates and, again, are much larger than the NIPA numbers. Net national saving has fallen tremendously in the 1980s, as both net private saving has fallen and the public sector has turned into a dis saver, even when one accounts for its accumulation of financial assets (although not of tangible assets).

Let us now turn our attention to measures of wealth and the rate of growth of wealth. Table 5.4 presents estimates, derived from the Flow of Funds, of private, public, and national net worth in billions of constant 1982 dollars, for the period 1948–87. Recall that the public sector data include only financial assets, not tangible assets. These data suggest that private real net worth has more than tripled in the period 1948–87 and that national real net worth has almost quadrupled in the same period. On a per capita basis, real net worth has about doubled.

Table 5.5 presents estimates of the rate of growth of net worth (i.e., the rate of change of net worth, both private and national). This reflects the rate of private and national saving in the numerator, including revaluations, and the preexisting level of net worth in the denominator. While there is substantial

year-to-year variation in both the private and national growth rates of net worth, it is clear that the rate of growth of real net worth in the U.S. economy has slowed substantially in the period 1979–87 relative to any other extended subperiod since World War II.

Perhaps the most serious omission from these measures of net worth is that they reflect only nonhuman capital. The capitalized value of expected future earnings, human wealth, is not included. There have been many attempts to estimate measures of human wealth, and/or to incorporate them in analyses of consumption and saving behavior (see, e.g., Boskin and Lau 1988; Jorgenson and Fraumeni 1989). There are many difficulties in obtaining such estimates, including capitalization rates, the appropriate expected earnings process for forecasts, questions of differential risk, discounting, liquidity, bequeathability, and so on. Roughly speaking, about three-quarters of national income is a return to labor; ignoring all these differences would suggest that about three-quarters of total wealth would be human wealth. Of course, mortality, disability, and similar probabilities must be added to discount rates on future earnings; among other concerns, there is differential taxation of different sources and uses of income (although these have declined with the new tax law). Human wealth must be estimated in more indirect ways than many components of nonhuman wealth whose asset values can be determined via the market.

Finally, in discussing definitions, measures, and data needs, it is important to realize that the economy changes. The pace at which we want to augment or update measures of saving and wealth, or reclassify items, and so on, depends heavily upon the purpose in generating the data in the first place.

5.3 Aggregation and Disaggregation

Discussed above was the issue of whether to combine the household and corporate sectors following Denison's law, as enunciated and reconfirmed (as of that time) by David and Scadding (1974) or, at the other extreme, whether to separate household and business saving because of credit rationing. Additional distinctions might be drawn on the type of assets and liabilities, for example, their liquidity properties, fixed costs in shifting in and out of them, their duration, and so forth. I might also mention that a strong Ricardian

might aggregate all resources, ignoring their age distribution, and, depending upon the view of the substitutability of public and private capital, might even aggregate private and public saving, and focus only on national saving, as changes in public saving or dissaving might be exactly offset according to the theory by private saving.

The purpose of this section is to highlight two other issues of aggregation. First, within the household sector there have been tremendous changes in household formation, dissolution, the age structure of households, average household size, life expectancy, and household composition. Particularly when we begin to analyze consumer durables, the value of housing, and life-cycle or age-specific balance sheet data, it is important to keep these changes

in mind. For example, Boskin and Lau (1988) document that slightly more than half of the average annual percentage increase in real consumption in the period 1950–80 was due to the growth in the number of households as opposed to the annual percentage increase in real consumption per household.

Thus, one might wish to decompose changes in the aggregate saving rate into the sum of the rates of change per household and the rate of change in the number of households. We know, for example, that in equation (1)

$$S_t = \sum_i \sum_j S_{ijt},$$

where we index households of type i , age j in year t . The households might differ by size, asset values, net worth, or access to credit markets, family composition, and so forth; age may be important for life cycle or other reasons. We know from survey data that some households are saving and others dissaving and that the aggregate saving rate is the sum of these household-specific saving rates. Probing a little deeper, changes in saving caused, for example, by changes in an exogenous (to the household) variable z , we note that the elasticity of aggregate saving with respect to z is a weighted average of the percentage changes of the saving of the different household types with respect to the given percentage change of the variable for them, with the weights being the share (possibly negative) of aggregate saving accounted for by that type or, mathematically,

$$\frac{d \ln S_t}{d \ln z_t} = \frac{\sum_i \sum_j N_{ijt} S_{ijt} \frac{d \ln S_{ijt}}{d \ln z_t}}{\sum_i \sum_j N_{ijt} S_{ijt}},$$

where N_{ijt} refers to the number of households of type i and age j in year t and S_{ijt} to the saving or dissaving of a household of type i , age j , in year t .

Thus, analyses of aggregate saving must come to grips with the problems of aggregation to the extent that households are heterogeneous (see Jorgenson, Lau, and Stoker 1982; and Boskin and Lau 1988). Quite apart from Lucas-type critiques, analyses of the effects of various variables on aggregate saving may be quite misleading if the shares of saving, or of income and wealth, held by households of different types and ages change through time. We know, for example, there have been tremendous changes in the age distribution of income in the United States (see, e.g., Boskin, Kotlikoff and Knetter 1985). Perhaps the most important aspect of this change has been the tremendous increase in the relative economic well-being of the elderly, which some theories of saving suggest should be dissaving during retirement.

5.4 Some Specific Issues

The NIPA treat expenditures on consumer durables as consumption rather than as saving. Many have argued (and I have generally been sympathetic to

the argument) that it would be preferable to treat expenditures on consumer durables and the imputed rental flow of the durables as consumption (see David and Scadding 1974; Boskin, Robinson, and Huber 1989; Holloway 1989; and Hendershott and Peek 1989, among others). Recall that estimates of the value of consumer durables are included conceptually in the Flow of Funds estimates. Various issues arise in valuing the services of consumer durables (Katz 1983). In table 5.6 I present NIPA saving rates augmented to include consumer durables for a few years. Note that this adds about 5 percentage points to the NIPA estimate of gross saving. Of course, as mentioned in the introduction, it would also be included on the investment side and does nothing for the shortfall of our domestic saving relative to our investment. U.S. citizens invest much more in consumer durables than persons in other societies. This undoubtedly reflects a number of factors, including the size of homes. The difference is particularly important relative to Japan, where the durables adjustment closes the saving rate differential substantially (see table 5.6 for some comparisons with Japan, including durables adjust-

^aGNP and NNP augmented to include corresponding rental flows.

ments and also government capital). It might well be useful for the BEA to supplement (*not* replace) the current saving data with such estimates for durables.

Government tangible capital, as well as contingent and potential liabilities, are also of potential importance. Governments in all countries own, use, and provide services from capital. Differences in the rates of growth of public capital and differences in levels across societies can lead to misconceptions about aggregate national well-being and aggregate saving rates. Of course, government saving and investment do not pass the same kind of market tests as private saving and investment. In Boskin, Robinson, and Huber (1989), new estimates of government saving, capital formation, and wealth for the United States in the period 1947–85 are estimated. Table 5.6 includes estimates of NIPA saving figures augmented to include net government saving in the form of nonmilitary capital and total capital. Again, the saving rate rises several percentage points, but recall that government capital depreciates and that our ability to estimate that depreciation is subject to even more difficulties than our ability to estimate the depreciation of private tangible assets. The comparison with Japan is instructive, since, as a percentage of GNP, government military capital formation in the United States is substantially larger, but total government capital formation is substantially smaller, than in Japan.

Revaluations of assets and liabilities are presumably captured approximately by market values and represented in the Flow of Funds. Obviously, they do not do so precisely. Estimated revaluations of tangible capital for the NIPA estimates would be adjusted upward, reflecting generally positive real revaluations. These are caused by a variety of factors, but especially by the decline in investment goods prices relative to the overall price level. Revaluations of financial assets and liabilities other than general real interest rate changes should net internally as one household's capital gain is another's capital loss or, conversely, between the public and private sectors. Of course, a general mood of pessimism or optimism tending to change the rate at which future incomes are discounted could cause a substantial overall revaluation. Further, to the extent that there are foreign holdings by Americans and holdings of U.S. assets by foreigners, the real revaluations will not necessarily cancel for the United States as a whole. Indeed, the saving abroad by U.S. citizens is quite difficult to measure.

I noted in the introduction and in section 5.2 that the measurement of income was undoubtedly a major issue in the measurement of saving. Underreporting and measurement errors play a role and are likely to change systematically over time. The measurement of real income is even more difficult. Distortions caused by inflation create difficulties in computing changes in real corporate balance sheets, as well as other components of income. It is beyond the scope of this paper to go into detail here, but not only is the measurement of real income tremendously difficult and important (especially for corporate

profits) but an appropriate real cost-of-living index would include the price of future consumption in it, and this obviously varies with the *ex ante* expected real net (of taxes) rate of return, which has varied over time.

Human capital, whether in education, health, nutrition, and so on, has been discussed very briefly above. Clearly, the United States spends a much larger fraction of its GNP on education than most other societies. This is especially true for higher education. Difficulties of comparability, however, abound. It is alleged, for example, that students in the United Kingdom or Japan are much further along when they finish high school than are U.S. students. A distinction between investment and consumption in educational expenditures is not easy to draw empirically. Estimates of the rate of return must rely on some estimate of the amount of such investment, and thus a certain amount of indirection is necessary in obtaining estimates. Despite improvements in correcting for sample selection bias, among other procedures, we are still some distance from estimating gross investment and saving in human capital. Some estimates (e.g., Kendrick 1976) place the amount of human capital investment at approximately the same level as nonhuman investment in the economy. Estimating *net* saving and investment in human capital is even more difficult. At what rate do knowledge and skill acquired in education, or on the job, depreciate or become obsolete? Clearly, unlike financial assets or tangible non-human capital, they cannot be bequeathed, although they may be an input into human investment in one's children. Again, I refer the interested reader to Jorgenson and Fraumeni (1989), and, perhaps just as important, Rosen's (1989) discussion, to gain a feel for some of the issues involved.

The appropriate treatment of private pensions in saving statistics is a subject of much dispute. Currently, for example, employer contributions of defined-benefit pension plans show up in the private saving statistics. Some have argued for a concept of pension wealth, that is, the expected present value of future pension payments. An analogous argument has been made for Social Security. It is not my purpose to review here the voluminous literature of the potential impact of Social Security wealth on real economic activity, such as saving choices, or the analogous literature on private or state and local and other government partially funded liabilities. At various points in history, currently unfunded liabilities have been large, subject to substantial variation depending upon assumed patterns of economic and demographic trends, and subject to enormous change through minor changes in the rules relating to benefit calculations or taxes. Further, Social Security has begun a systematic move away from pay-as-you-go finance toward building a historically large surplus.

How to define the expected obligations of the Social Security system, for example, is also open to much controversy. Under a closed group approach, the expected future taxes and benefits paid by particular cohorts—for example, all those alive or all those currently above a certain age, such as 18—would be calculated, discounted to the present, and compared. The difference

between the expected present value of benefits and taxes would be the surplus or deficit. This concept, using current participants as a group, is adopted by Arthur Anderson & Co (1986). Such an estimate would add \$100 billion or more per year to the federal government deficit. Likewise, to the extent there were accruing unfunded liabilities in state and local government or private pension funds, these would need to be netted out (to the extent that they were not netted explicitly or via market valuation of corporate equities in Flow of Funds or other data). Recall that the state and local surplus in recent years has been over 1% of GNP, but that much of it is in pension funds, whose simultaneously accruing liabilities are not included in the national saving statistics.

Under an open group concept, the expected present value of benefits and taxes paid over some time period, often taken to be 75-year actuarial projection period of the Social Security Administration, would be compared, with the difference being the surplus or deficit. Thus, taxes paid in the early working years of the currently unborn and benefits paid to persons during retirement who are not yet in the labor force would be counted. Social Security in the United States, as well as similar programs in most other advanced economies, has become so large and contains so many features, including insurance features, it may well affect private saving behavior. I believe the best we can do is provide some supplemental information to the traditional NIPA treatment of Social Security in the budget, simply netting the excess of taxes over outlays as positive government saving, currently offsetting the larger deficit in that part of the budget not including Social Security. The substantial unfunded liabilities I have dealt with elsewhere (see Boskin, Robinson, and Huber 1989).

I do not think it is sensible to include OASI contributions as part of personal saving, as suggested by Hendershott and Peek (1989). This would double the net private saving rate, but while it is true that some individuals believe that their contributions are a sort of saving, legally and by nature of the formulae in use at any point in time, there is no necessary relationship between an individual's marginal contribution and their own marginal returns. Of course, for the nation as whole, the aggregate saving is captured by the difference in the cash flow in the system plus (by no means easy to estimate) the change in expected real net accrued liabilities. For those interested in the relationship of marginal Social Security taxes paid and expected marginal benefits for households of different income levels, family type and ages, see Boskin, Kotlikoff, Puffert, and Shoven (1987).

I do not have the space to go into contingent liabilities by sector, such as those generated in the thrift industry or pension plans. The nature of deposit and pension insurance is to provide a put option and create a heads-I-win-tails-the-taxpayer-loses type situation, which may encourage excessive risk taking. I have dealt with these issues in the context of a more appropriate budgetary treatment elsewhere (Boskin, Barham, Cone, and Ozler 1987).

5.5 Conclusion

My conclusion is quite simple. We have come some way toward understanding, measuring, interpreting, and analyzing saving and wealth. While there is a substantial need for continued research into analyzing saving behavior and wealth accumulation, the following conclusions deserve emphasis.

1. While the United States has a saving rate that is low by historical and international standards, that saving rate is substantially higher when more comprehensive measures of saving are developed. While there are substantial difficulties in developing such augmented measures of national saving, various data sources and estimation methodologies all conclude that adjustments for net saving in durables, government capital, capital gains and losses, revaluations, and so on, are substantial.

2. The adjustments for durables and government capital are likely to narrow the saving-rate gap between the United States and Japan, and to a lesser extent between the United States and the European economies. This reduction in the saving-rate gap is much greater for gross saving than net saving.

3. No one saving-rate measure is the answer to all questions one might pose about saving and wealth accumulation. Often there will be offsetting tendencies by sector, asset type, and so on. A decrease in the traditional NIPA saving figures may reflect a rise in the stock market, which may decrease saving either because of direct adjustment on the part of households or mechanical adjustments due to the actuarial formulae for pension plans.

4. The reasonable, even permissible, level of aggregation, across types of households, ages of households, sectors of the economy, and types of assets and liabilities, depends heavily upon one's beliefs concerning an appropriate model of the economy (e.g., of credit markets in deciding whether to combine household and corporate saving, and of household behavior in deciding whether to analyze private saving and government saving separately from national saving).

5. Innumerable technical issues remain, ranging from appropriate deflators to valuation in nonmarket situations. While these often revolve around technical issues, they also involve components of saving and of wealth that can be large relative to the more traditional components, for example, Social Security, the contingent liabilities of the banking system, and so on. The remarkable change in the U.S. net international lending position in recent years suggests that the traditional argument that most capital gains and losses, and revaluations, will net internally is no longer accurate.

6. Perhaps the most important measurement issue for traditional saving estimates is improving the measures of personal income to include as much unrecorded income as plausible.

7. Supplementing the aggregate data with age-cohort-specific data may be of great value.

Many of these issues were addressed for the economy as a whole or for important subsectors of the economy, and important subsets of these issues, at the Conference on Research in Income and Wealth reported in Lipsey and Tice (1989). I have no doubt whatsoever that when future generations of economists celebrate subsequent major anniversaries of the Conference on Research in Income and Wealth, they will bear witness to considerable additional value added in measuring, interpreting, and analyzing saving and wealth.
