JEL No. O3

### ABSTRACT

The Q-theory of investment says that a firm's investment rate should rise with its Q. We argue here that this theory also explains why some firms buy other firms. We find that

1. A firm's merger and acquisition (M&A) investment responds to its Q more -- by a factor of 2.6 -- than its direct investment does, probably because M&A investment is a high fixed cost and a low marginal adjustment cost activity,
2. The typical firm wastes some cash on M&As, but not on internal investment, i.e., the "Free-Cash Flow" story works, but explains a small fraction of mergers only, and
3. The merger waves of 1900 and the 1920's, '80s, and '90s were a response to profitable reallocation opportunities, but the '60s wave was probably caused by something else.

# The Q-Theory of Mergers

Boyan Jovanovic and Peter L. Rousseau\*

January 2002

The  $Q$ -theory of investment says that a firm's investment rate should rise with its  $Q$ . We argue here that this theory also explains why some firms buy other firms. We find that

1. A firm's merger and acquisition (M&A) investment responds to its  $Q$  more – by a factor of 2.6 – than its direct investment does, probably because M&A investment is a high fixed cost and a low marginal adjustment cost activity,
2. The typical firm wastes some cash on M&As, but not on internal investment, i.e., the “Free-Cash Flow” story works, but explains a small fraction of mergers only, and
3. The merger waves of 1900 and the 1920's, '80s, and '90s were a response to profitable reallocation opportunities, but the '60s wave was probably caused by something else.

*Two distinct used-capital markets.*—Used equipment and structures sometimes trade unbundled in that firm 1 buys a machine or building from firm 2, but firm 2 continues to exist. At other times, firm 1 buys firm 2 and thereby gets to own all of firm 2's capital. In both markets, the traded capital gets a new owner. In a sale of used “disassembled” capital, the capital also gets a new manager, whereas in the M&A market, capital gets a new manager when a merger entails a restructuring. Such a merger is reallocative in the same sense that a used capital trade is.

*Mergers as used-capital trades.*—Our model treats M&As like used-capital-market transactions. This seems apt, since trading volume in the two markets for used capital – bundled and disassembled – moves together. Figure 1 shows this fact. It plots acquired capital and direct purchases of used capital among exchange-listed firms as percentages of their investment. The series cover all firms common to the University

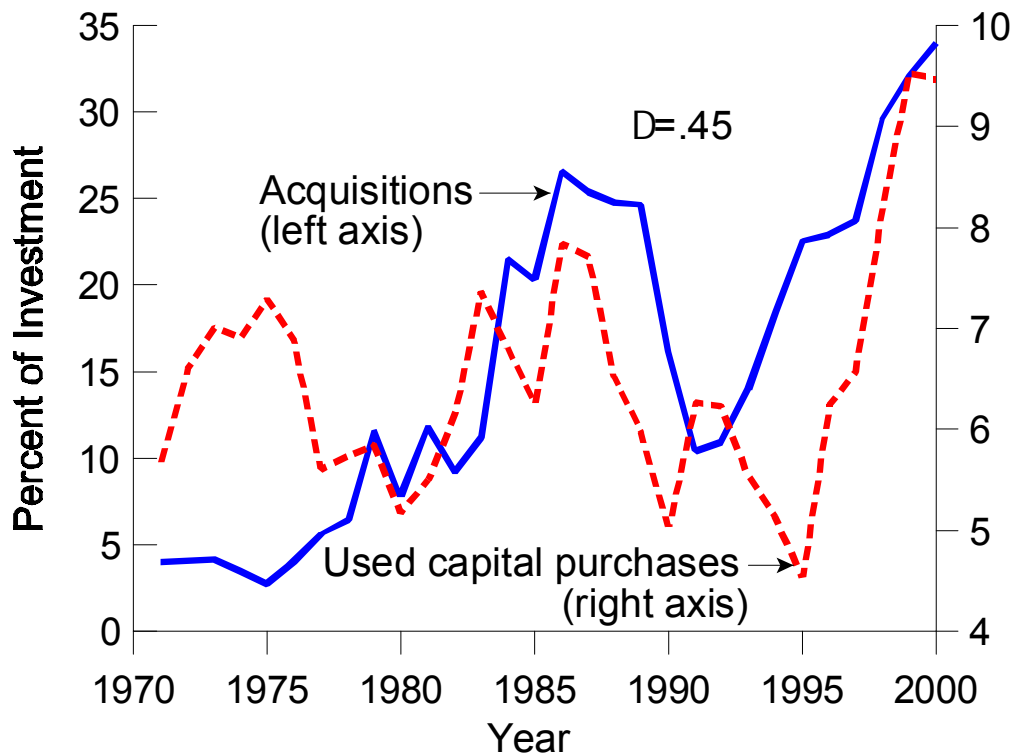

Figure 1: Used and Acquired Capital as Percentages of Total Investment, 1971-2000

of Chicago’s Center for Research in Securities Prices (CRSP) database and Standard and Poor’s Compustat.<sup>1</sup> The two series do not overlap in coverage, and so they add up to the fraction of investment spent on buying used capital. This fraction was 10 percent in 1975, and a much higher 43.5 percent in 2000. The correlation coefficient between the two series is 0.45. Clearly, the merger waves of the ‘80s and ‘90s coincided with waves of trading disassembled used capital.

*Prior evidence.*—High- $Q$  firms usually buy low- $Q$  firms. Gregor Andrade, Mark Mitchell and Erik Stafford (2001) report that in more than two-thirds of all mergers since 1973, the acquirer’s  $Q$  exceeded the target’s  $Q$ . And Henri Servaes (1991) finds that total takeover returns (defined as the abnormal increase in the combined values of the merging parties) are larger when the target has a low  $Q$  and if the bidder had a high  $Q$ . Thus mergers are a channel through which capital flows to better projects and better management, and our model reflects that fact.

<sup>1</sup>Capital sales include property, plant, and equipment (Compustat item 107). Acquisitions include funds used for and costs related to the purchase of another company in the current year or an acquisition in a prior year that was carried over to the current year (item 129). Investment is the sum of acquired capital (item 129) and direct capital expenditures (item 128). We compute the ratios in Figure 1 after summing each data item across active firms in each year.

# I. Model

A firm's state of technology is  $z$  and its capital stock is  $K$ . Its production function is

$$\text{output} = zK. \tag{1}$$

The parameter  $z$  follows the Markov process

$$\Pr \{z_{t+1} \leq z' \mid z_t = z\} = F(z', z), \tag{2}$$

and it is firm-specific.

*Markets for  $K$ .*—Firms can buy new or disassembled used capital at a price of unity. The cost of disassembly is  $1 - s$  per unit of capital, and any firm that disassembles its  $K$  gets a salvage value of  $s < 1$  per unit of  $K$ . The firm can also place itself on the M&A market where all acquired capital trades at a common price of  $q$  per unit. If the salvage and the acquired capital markets are both open, we must have  $q = s$ , and this is what we shall assume.

*No markets for  $z$ .*—The firm must accept whatever  $z$ -draw that nature endows it with each period.

*Growth of capacity.*—Let  $X$  be the firm's direct investment in capital (new or used but unbundled) and  $Y$  its acquisitions of bundled capital. Next period, its capital stock will be

$$K' = (1 - \delta)K + X + Y. \tag{3}$$

*Costs of growth.*—Aside from the payment for  $X$  and  $Y$ , the firm also faces the following foregone-output cost of growth:

$$C(x, y)K, \quad \text{where } x = \frac{X}{K}, \text{ and } y = \frac{Y}{K}. \tag{4}$$

*Merger gains.*—The firm transfers its  $z$  to all new and *all* used capital that it buys. The joint gains to a merger are thus largest when the target's  $z$  is low, and the buyer's  $z$  is high. Let the bidder's state be  $(z_1, K_1)$  and let the target's state be  $(z_2, K_2)$ . The output of the combined firm would be  $z_1(K_1 + K_2)$ , which is higher than the sum of the two firms' pre-merger outputs by the amount  $(z_1 - z_2)K_2$ .

*The  $Q$  equation.*—Because (1) and (4) are homogeneous of degree one in  $K$ ,  $X$ , and  $Y$ , the aggregation condition (2.8) of Fumio Hayashi and Tohru Inoue (1991) holds. The value of  $K$  inside a firm is of the form  $Q(z)K$ . The price of new capital is unity, and the price of used capital is  $q < 1$ . A unit of  $K$  has a profit of  $z - C(x, y) - x - qy$ , and a market value of

$$Q(z) = \max_{x \geq 0, y \geq 0} \{z - C(x, y) - x - qy + (1 - \delta + x + y)Q^*(z)\}, \tag{5}$$

where  $Q^*(z)$  is the discounted expected present value of capital tomorrow given the firm's  $z$  today. Since the firm has the option of selling its capital in the next period on the merger market at a price of  $q$  dollars per unit of capital,

$$Q^*(z) = \frac{1}{1+r} \int \max\{q, Q(z')\} dF(z', z). \quad (6)$$

*Interior maxima.*—At an interior maximum, the optimal  $x$  and  $y$  satisfy the first order conditions

$$c_1(x, y) = Q^*(z) - 1. \quad (7)$$

and

$$c_2(x, y) = Q^*(z) - q. \quad (8)$$

If  $z$  is positively autocorrelated,  $Q^*$  is increasing in  $z$ , and high- $z$  firms will grow faster and, if there are no fixed costs of investment, use both  $x$  and  $y$  to achieve that growth. If we control for  $Q^*$ ,  $K$  does not matter. That is, a large firm grows as easily as a small one, and no optimal firm size exists – just optimal growth.

*Fixed costs of mergers.*—Assume a fixed cost,  $\phi$ , of acquiring the capital of other firms:

$$C(x, y) = \begin{cases} c(x, y) + \phi & \text{if } y > 0, \\ c(x, 0) & \text{if } y = 0. \end{cases}$$

This cost is per unit of  $K$ , and therefore returns to scale remain constant. Let  $i = x + y$  be the gross investment rate in *efficiency* units. A low- $i$  firm will avoid the cost  $\phi$  by setting  $y = 0$  and using only  $x$ , whereas a high- $i$  firm will use both margins. The value of  $i$ , call it  $i^*$ , at which the firm is indifferent between buying in the acquisitions market and staying out of it, solves for  $i$  the equation

$$i + c(i, 0) = \phi + \min_y \{(i - y) + qy + c(i - y, y)\}. \quad (9)$$

The left-hand side of (9) is lower when  $i$  is small, and the right-hand side is lower when  $i$  is high. Of course,  $i$  itself depends on the firm's  $z$ .

*Disappearance of firms.*—A firm may disappear either by exiting and disassembling its capital, or by being acquired. Either way, it gets  $q$  per unit of  $K$ . Let  $z_e$  be the point of indifference between staying in business and exiting. Then

$$Q(z_e) = q.$$

*Four regions for  $z$ .*—Figure 2 portrays a steady state in which the distribution of  $z$  over firms replicates itself period after period. Sustaining such a steady state requires an entry process as modeled by Hugo A. Hopenhayn (1982). Our focus is on the fate of the incumbents. Each period, firms with  $z$ 's below  $z_e$  dissolve or are

Frequency distribution of  
firm-efficiencies,  $z$

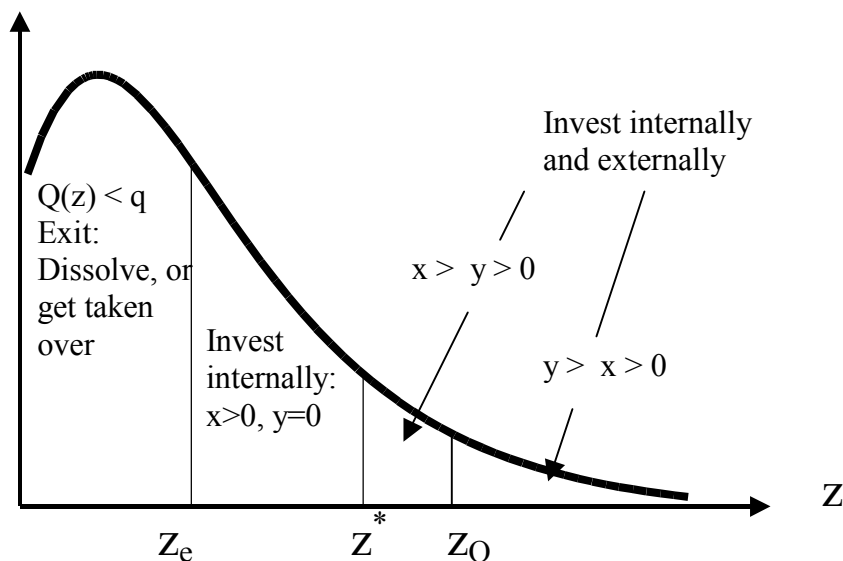

Figure 2: The Four Regions of  $z$

acquired. In the region between  $z_e$  and  $z^*$  firms remain in the market but invest only in  $x$  because the fixed cost  $\phi$  deters them from setting a positive  $y$ . Beyond  $z^*$  (the value of  $z$  that corresponds to  $i^*$ ) they also set  $y > 0$ , and beyond the “overtaking” level  $z_O$ ,  $y$  exceeds  $x$ .

*Investment-expansion path.*—Figure 3 shows the expansion path for  $x$  and  $y$  as the efficiency-units-investment rate  $i$ , represented by the parallel dashed iso-investment lines, rises. At  $i^*$ ,  $x$  drops from  $i^*$  to  $x^*$ , and  $y$  jumps from zero to  $y_{\min}$ . The figure reflects the assumption that  $c_y$  is small relative to  $c_x$ , so that the share of  $y$  in the firm’s investment portfolio grows, and the expansion path approaches the  $45^\circ$  line. At the overtaking point,  $x = y = i_O/2$ . Beyond  $i_O$ , in Figure 3,  $y$  exceeds  $x$ .

*Engel curves for  $x$  and  $y$ .*—Figure 4 shows how investment in  $x$  and  $y$  varies with  $i$ . The two schedules add up to the  $45^\circ$  line. When  $i$  reaches  $i_O$ ,  $y$  overtakes  $x$ .

*Evidence on overtaking.*—The prediction of Figure 4 is confirmed by the evidence in Figure 5. Between 1971 and 2000, small expansions did, indeed, come mainly through  $x$ , while large expansions came mainly through  $y$ . The vertical axis measures the HP-filtered means of  $x$  and  $y$  for firms that fall within each percentage point of the range of  $i$ .<sup>2</sup> Overtaking occurs at  $i_O = 1.12$ , which, after depreciation, is roughly a doubling of capacity. Data on individual years (not shown) indicate that  $i_O$  has

<sup>2</sup>In Figure 5, we pool 118,127 observations from 1971-2000. The sample thins out as  $i^*$  gets large: only 193 observations involve  $x + y$  between 1.5 and 2, and 96 observations lie between 2 and 2.5.

Figure 4: The Point of Overtaking,  $i_0$

market, and we prefer not to use it as a deflator. Instead we assume in Figure 5 and in the regression analysis below that a dollar spent on  $x$  buys the same efficiency units of capital as a dollar spent on  $y$ .

## II. Estimates of Investment and Acquisitions Equations

Assume that  $c(x, y)$  is additively separable. Then (7) and (8) are of the form  $x = f(Q^*)$ , and  $y = g(Q^* - \bar{q})$ . The  $Q$ 's may all be biased upward, but  $Q_j - \bar{q}$  should still measure firm  $j$ 's incentive to acquire the capital from other firms at the price  $\bar{q}$ . Linearized,  $f$  and  $g$  assume the same form as eq. (30) of Hayashi (1982):

$$\begin{aligned} x_{j,t} &\equiv \frac{X_{j,t}}{K_{j,t-1}} = \alpha_0^x + \alpha_1^x Q_{j,t-1} + \alpha_2^x t, \text{ and} \\ y_{j,t} &\equiv \frac{Y_{j,t}}{K_{j,t-1}} = \alpha_0^y + \alpha_1^y (Q_{j,t-1} - \bar{q}_{t-1}) + \alpha_2^y t, \end{aligned} \quad (10)$$

where  $t$  is a linear time trend. The model predicts that  $\alpha_1^x$  and  $\alpha_1^y$  should be positive. Table 1 presents the results for our panel of pooled observations from 1971-2000. We

$N$	111,039	26,383

*Notes:* The table presents estimates for Eq. 10 with T-statistics in parentheses. The regressions include dummy variables for 2-digit SICs (not reported).

Figure 6:  $Q$ 's by Investment Subgroup, 1972-2000

use the market-to-book ratio for  $Q$ .<sup>3</sup> For  $\bar{q}_t$  we use average market-to-book value of disappearing firms – the series plotted in Figure 6.

The results support the  $Q$ -theory. Hayashi had estimated the effect of  $Q$  on investment at 0.045. Our dependent variables are multiplied by 100. Our estimate of the effect of  $Q$  on  $x$  is one-sixth as large as Hayashi's, perhaps because we use total firm assets as the denominator ( $K$ ) rather than the stock of durable equipment and structures. More to the point, our estimate of the effect of  $Q - \bar{q}$  on  $y$  is highly significant and nearly three times the coefficient-estimate of  $Q$  in the  $x$  equation.

### A. Which Way Does “Free” Cash Flow?

A firm's manager may try to pursue his own objectives – growing the size of his

---

<sup>3</sup>To compute market values from the Compustat files, we start with the value of common equity at current share prices (the product of items 24 and 25), and then add in the book value of preferred stock (item 130) and short- and long-term debt (items 34 and 9). Book values are computed similarly, but use the book value of common equity (item 60) rather than the market value. We omitted firms with negative values for net common equity from the plot since they imply negative market to book ratios, and eliminated observations with market-to-book values in excess of 100, since many of these were likely to be serious data errors.

firm, for example – at shareholders’ expense. Direct investment cannot expand a manager’s empire as fast as a merger can, and Michael C. Jensen (1986) argues that managers of firms with excess cash on hand are more likely to spend it on acquisitions than to pay it out in dividends, even if an acquisition has a negative net present value.

Do firms spend their extra cash mergers? It seems so. We add cash (Compustat item 1) normalized by firm capital (again proxied by item 6) to the regressions described in (10). The results are in Table 2. Cash has little effect on  $x$ , but a positive, significant effect on  $y$ . Still,  $Q$  retains the lion’s share of explanatory power.

Table 2-Investment Regressions with Cash

	Dependent variable	
	$100x_{j,t}$	$100y_{j,t}$
$Q_{j,t-1}$	0.738 (34.41)	
$Q_{j,t-1} - \bar{q}_{t-1}$		1.916 (15.43)
$100 \times \text{cash}_{j,t-1}$	0.006 (1.32)	0.220 (9.82)
$t$	-0.121 (13.38)	0.277 (6.59)
$R^2$	.0479	.0241
N	111,039	26,383

*Notes:* The table presents estimates for Eq. 10 with the ratio of cash to total firm assets as an additional regressor, with T-statistics in parentheses. The regressions include dummy variables for 2-digit SICs (not reported).

### III. Merger Waves as Reallocation Waves

If firms all had the same  $z$ ,  $Q$  would equal  $q$ , and no M&A’s would take place. M&A’s should rise, says the model, when the interfirm dispersion of  $Q$  is high. We now ask: Was  $Q$  more dispersed during merger waves? We confirm this in two different ways. The first test is summarized by Figure 7, which shows that  $\bar{Q}_{y>x} - \bar{q}$  leads movements in acquisitions.<sup>4</sup> The correlation between  $\bar{Q}_{y>x} - \bar{q}$  at the end of year  $t$  and acquisitions in the *following* year, which is the timing shown in the Figure 7, is 0.12, but the correlation rises to 0.22 if we lag  $\bar{Q}_{y>x} - \bar{q}$  by another period, and rises to 0.31 if we lag it yet again.

<sup>4</sup>We project mergers for 2001 by observing that their value fell by 57 percent between 2000 and 2001 (*Wall Street Journal*, Jan. 2, 2002) and by assuming that firm assets in our Compustat sample grew at the same rate as GDP between the second quarters of 2000 and 2001.

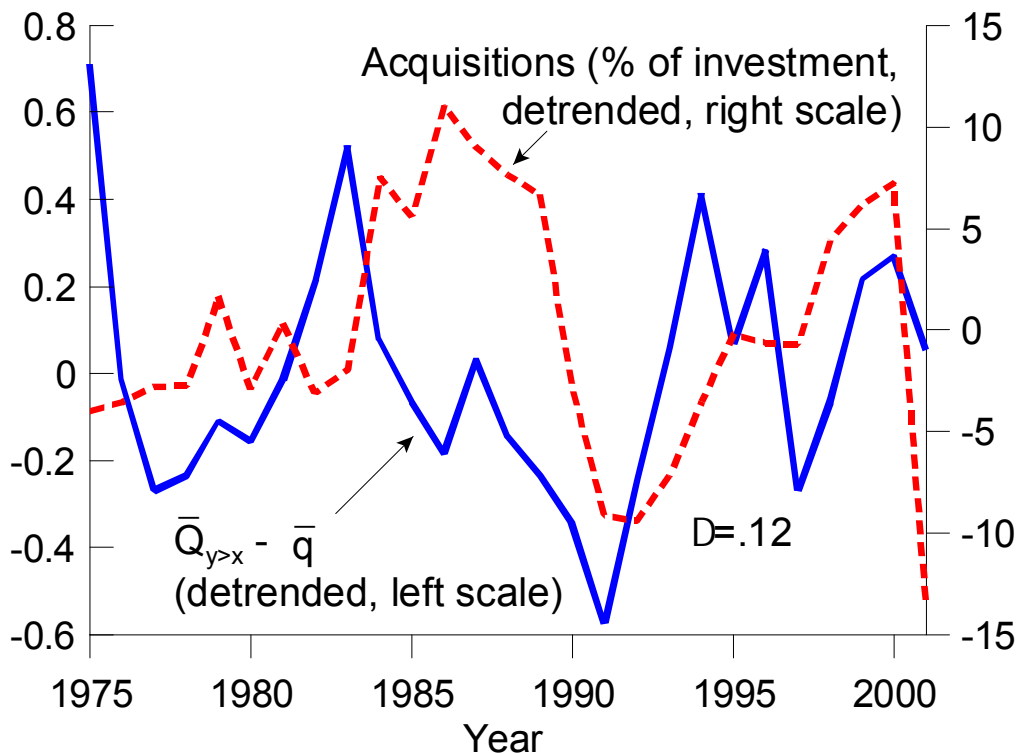

Figure 7: Acquired Capital and the Dispersion of  $Q$ , 1975-2001

Our second, and less direct test is in Figure 8. The Compustat covers too few book values before 1975 to allow a reliable estimate of the dispersion of  $Q$  before then. Instead, we infer the dispersion of  $Q$  in year  $t < 1998$  by computing the standard deviation of the year-1998  $Q$ 's among firms of vintage  $t$ , and then repeating this exercise for each  $t$  between 1890 and 1998. If the distribution of entrants'  $Q$ 's is more dispersed in years when the market at large has more dispersion of  $Q$ , and if the  $z$  process is fairly persistent, this estimate will provide a useful rough guide to waves of dispersion of  $Q$ . But because high- $z$  firms are more likely to survive, our estimator is biased increasingly towards zero the older the vintage of the firms.

Our estimate of  $Q$ -dispersion is the dashed line in Figure 8. This HP-filtered series is indeed upward sloping as a function of *vintage*. The solid line in Figure 8 shows the HP-filtered acquisition series as a fraction of total capitalization, as a function of *time*.<sup>5</sup> Thus the two series derive from two different populations. The solid line is a

<sup>5</sup>The dashed line in Figure 8 is reproduced from Figure 2 in Jovanovic and Rousseau (2001b, pp. 338, 340). The solid line is based primarily on merger data from CRSP for 1926-1998, and from work sheets for the manufacturing and mining sectors underlying Ralph L. Nelson (1959) for 1890-1930. The series includes the market value of targets acquired by exchange-listed firms in the year prior to merger. Market values after 1925 are from CRSP. Before that, they are from our extension of CRSP

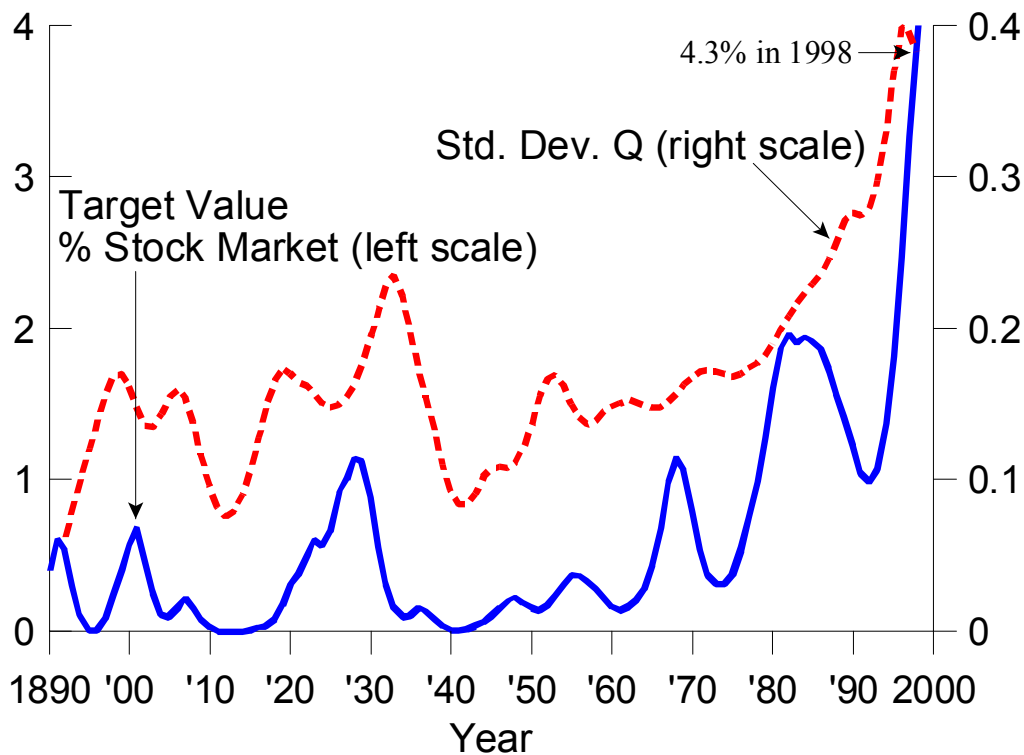

Figure 8: Acquired Capital and the Dispersion of Q by Vintage, 1890-1998

historical series, whereas the dashed line is a vintage representation of the 1998 cross section. Both lines may trend upward for reasons that the model leaves out, but even the detrended series have a correlation coefficient of 0.64! But for the “hubris” wave of the 1960’s, each merger wave was preceded by a rise in the dispersion of Q. Thus the waves of 1900, the 1920s, 1980s and 1990s were probably reallocation waves.
