Sociodemographic Effects on the Onset and Recovery of ADL Disability among Chinese Oldest-old

Danan Gu¹

Zeng Yi²

Abstract

By pooling the data from the three waves (1998, 2000, and 2002) of the Chinese Longitudinal Health and Longevity Survey, this study examines the association of sociodemographic factors with the onset and recovery of ADL disability including changes in functional status before dying. The results show that the sociodemographic factors play some specific roles in disability dynamics at very high ages even after controlling for a rich set of confounders. Our results also point out that the conventional method, which excludes the information of ADL changes before dying due to unavailability of the data, overestimates the effects of age, gender, ethnicity, and living alone on disability transitions whereas it underestimates the effects of SES, although such discrepancies are not very big compared with the results including information of ADL changes before dying.

1. Introduction

Understanding the disability dynamic mechanism could lead to better targeting of efforts to reduce or postpone disabilities at older ages (Melzer et al. 2001). A growing number of studies have shown strong associations of sociodemographic factors with the dynamic changes of disability in the elderly (e.g., Crimmins, Hayward, and Saito 1994; 1996; Gill, Robison and Tinetti 1997; Land, Guralnik, and Blazer 1994; Manton, Stallard, and Corder 1995). With few exceptions (e.g., Crimmins and Saito 1993), almost all prior studies consistently find that the incidence rate of disability increases with age, whereas the probability of getting better decreases with age (e.g., Crimmins et al. 1996; Gill et al 1997; Hayward, Crimmins, and Saito 1998; Laditka and Wolf 1998; Land et al. 1994; Manton 1988; Rogers, Rogers, and Belanger 1992). Gender difference in the dynamics of ADL disability is inconclusive. Some studies have reported that older males have an advantage in disability dynamics over older females (Crimmins et al. 1996; Hayward et al. 1998; Jagger, Arthur, Spiers et al. 2001), while some other studies provide an opposite result (i.e., elderly women have the advantage) (e.g., Crimmins and Saito 1993; Land et al 1994), and still others find that there is no significant gender difference in disability dynamics (Ferrucci et al. 1996; Guralnik et al. 1997; Rogers et al. 1992). Contradictory results of racial and ethnic difference in disability dynamics among elders are also frequently reported (Boult, Kane, Louis et al. 1994; Crimmins et al. 1996; Land et al. 1994; Mendes de Leone et al. 1997). Although most studies have shown that the higher SES could reduce the risk of the onset of disability and increase the likelihood to regain functioning at late ages (Crimmins et al. 1996; Land et al. 1994; Seeman et al. 1994), a small number of studies find that such protective effects are not significant or are weak (Melzer et al. 2001; van Groenou, Deeg, and Penninx 2001; Geroldi et al. 1996). Despite the challenges from several recent studies (e.g., Arber and Cooper 1999), the protective effects of marriage on disability at late ages have been widely recognized (Goldman, Korenman, and Weistein 1995; Murphy, Glaser, and Grundy 1997; Rogers et al. 1992). The effect of living arrangement on disability dynamics in older ages is somewhat less studied and the results are largely divided (e.g., Grundy 2001; Hebert Brayne, and Spiegelhalter 1999).

The primary limitation of previous studies on the sociodemographic effect on disability dynamics is, however, the underestimation of disability. Recent research has indicated that the underestimation of disability transition between survey intervals is one of the major problems in research on population aging (Gill, Hardy, and Williams 2002; Guralnik and Ferrucci 2002). The rate of the onset of disability at old ages is substantially underestimated in longitudinal studies, especially those with follow-up intervals of more than two years (Gill et al. 2002). Most previous studies that focus on disability transition normally assume that there is a single transition between two

adjacent surveys for survivors and have not covered the disability dynamic information of deceased persons, however. So far, six approaches to deal with the disability of the decedents between survey intervals in the longitudinal study on disability transitions have been employed: (a) excluding decedents' data from the analyses (e.g., Harris et al. 1989) (Note 1); (b) combining death and disability into a single category (e.g., Roos and Havens 1991); (c) considering death and disability as separate categories but excluding disability information for the decedents (e.g., Crimmins et al. 1996; Hayward et al. 1998); (d) assuming that the decedents' probabilities of disability transitions are the same as those of survivors with the same sex, age, health status, and some other characteristics (Manton and Land 2000); (e) estimating simulated monthly transition probabilities of disability using the microsimulation approach (Laditka and Wolf 1998); and (f) including the decedents' disability information before dying collected from the next-of-kin of the deceased respondents in the estimation of disabled life expectancy through an extended multi-state life table method (Zeng, Gu, and Land 2004). By comparing 24 monthly assessments of functional disability with a single assessment over a 24-month interval, Gill et al. (2002) found that the underestimation of disability was considerably high, and increased progressively as the length of assessment interval increased. Zeng et al. (2004) found that the disabled life expectancy was significantly underestimated if information concerning the changes in disability status before death were excluded.

The second limitation of previous studies is that the oldest-old subjects have not yet received sufficient attention when studying the correlates of disability. Over the past few decades the oldest-old have been the subpopulation with the highest increase rate both in absolute terms and as a percentage of the total population worldwide (UN 2002). However, insufficient attention has been paid to this group even though studies on the disability of the oldest-old have grown rapidly since the 1990s due to improvements in the availability of data sets (Andersen-Ranberg et al. 1999; Evert et al. 2003; Femia, Zarit, and Johansson 1997; Soldo et al. 1997; Suzman, Willis, and Manton 1992; Zeng et al. 2001; 2002). The prevalence rate of disability for the community-dwelling oldest-old has been reported as high as around 40-50% (e.g., Cornoni-Huntley et al. 1992), and the two-year incidence rate of the onset of disability is around 25% for females and 10% for males (e.g., Melzer et al. 2001). However, it was found that in most longitudinal studies quite a few of the oldest-old who, once disabled, could regain independence in their ADL function. For example, the two-year recovery rate is as high as 10-20% (Melzer et al. 2001). One recent study based on monthly survey even reports that around 80% of the respondents aged 70 and older regained ADL independence and maintained more than two months within 12 months from their initial disability; and 57% of them maintained for more than six months (Hardy and Gill 2004). Evert et al. (2003) find that nearly 20% of centenarians didn't

have onset of a disease or have not yet been diagnosed with any disease except osteoarthritis (Note 2). Another study indicates that 20% of female centenarians and 45% of male centenarians could carry out ADL independently (Andersen-Ranberg et al. 1999). These studies provide evidence that the heterogeneity of disability dynamics in very high ages does exist. Awareness of the heterogeneity of functional ability, variations in rates of changes in functioning, and their correlates among the oldest-old population is very important in the study of healthy longevity. Disability dynamics among the oldest-old have not yet been systematically examined. Thus, improvement in knowledge of dynamic patterns of disability of the oldest-old would lead to the ability to better predict their future disability transitions, develop strategies, conduct intervention programs, and formulate sound policies.

The third limitation of previous studies is that most of them have been based on populations in Western developed nations, particularly in the United States and Europe, and research on disability of the elderly in developing countries has been rare, although several recent studies have dealt with a few Asian and African countries (e.g., Lamb 1997; Liu et al. 1995; Zimmer, Martin, and Chang 2002; Zimmer et al. 1998), but none of them focused on the oldest-old. China, a developing country, has the largest number of oldest-old in the world. The number of oldest-old in China in 2000 reached 12 million, and will climb to 23 million and 100 million in 2020 and 2050, respectively, under medium scenario projection (UN 2002; Zeng and George 2000). Such an astonishing trend raises questions about the functional ability of the oldest-old, quality of life in their late age and the sustainability of the current health system of China. However, very little was known about the disability dynamics of this subpopulation in China. Given that China differs substantially from Western developed societies in living arrangement, health practice, cultural setting, and sociopolitical system including health care policy, studies on the Chinese oldest-old population could provide a better understanding of the underlying mechanisms of prevalence and dynamics of disability.

Based on the above considerations, the main purposes of this study are (1) to explore sociodemographic effects on the onset of disability and recovery from disabled status; and (2) to examine the difference in the effects of sociodemographic variables between including and not including information concerning ADL dynamics before dying. Our analyses are conducted within a comprehensive, multivariate framework focusing on sociodemographic factors including age, gender, residential type, SES, marital status, and living arrangement.

2. Data and methodology

2.1 Data source

Data is derived from the first three waves of the Chinese Longitudinal Healthy Longevity Survey (CLHLS) in 1998, 2000, and 2002 in randomly selected half of the counties/cities in 22 provinces of China. The survey was initiated to meet the needs for scientific research on the oldest-old, a sub-population about which we know very little but that is growing at extraordinary speed and needs the most help. The survey staff interviewed 8,959 voluntary participants aged 80+ in the baseline survey in 1998. Among them, 2,418 were centenarians, 3,013 were nonagenarians, and 3,528 were octogenarians. In the second wave in 2000, out of the 8,959 baseline interviewees, 4,474 (53.0%) survived to the time of the 2000 interview, 3,355 (37.4%) died before the time of 2000 interview, and 860 (9.6%) were lost to follow-up. In the 2000 wave, the total sample reached 11,161 including 6,337 newly added respondents. Among those 11,161, the number of centenarians, nonagenarian, and octogenarians are 2,431, 3,812, and 4,918, respectively. In the 2002 wave, out of the 11,161 respondents interviewed at the 2000 interview, 5,911 (53.0%) survived at the 2002 interview, 3,401 (30.5%) died before the 2002 interview, and 1,849 were lost to follow-up (16.7%). To produce more robust results, as has been done in some previous studies (e.g., Crimmins et al. 1994), all three waves of data are pooled together in this study. As a result of the pooling, we deal with the number of observations/cases rather than the number of interviewees in this study. Each interviewee has at least two but at most three observations. Time 1 refers to the start-point of each two-year interval in which a dynamics of disability may occur, whereas Time 2 refers to the endpoint of each two-year interval. In other words, Time 1 in this study could be the interview time in 1998 or 2000, and Time 2 could be the interview time in 2000 or 2002. Furthermore, as has been done in previous studies (Zeng et al. 2002; Zeng and Vaupel 2004), persons who reported age 106 or higher at Time 1 are excluded from this study due to insufficient information for us to validate their reported extremely high age. The total number of observations included in this study is 19,778 (8,447 aged 80-89, 6,825 aged 90-99, and 4,506 aged 100-105).

Extensive questionnaire data was collected in the CLHLS including demographic characteristics, family and households characteristics, life styles, diet, psychological characteristics, economic resources, family support, self-reported health, self-reported life satisfaction, lower and upper extremities performance, ADLs (Katz et al. 1963), the Mini-Mental State Examination (MMSE, Folstein, Folstein, and McHugh 1975), and chronic diseases suffered and their adverse impacts on daily life. All information was obtained through in-home interviews. Interviews were conducted with the subjects themselves, if possible. If the subject was unable to answer the questions, the interview

was conducted with a proxy respondent. This is the first nation-wide longitudinal survey research project with such a large sample size on the oldest-old ever conducted in a developing country. A detailed description about the sampling design and data quality assessment of the CLHLS can be found elsewhere (Zeng et al. 2001; 2002; Gu and Zeng 2004).

Comprehensive information concerning the date of death, cause of death, ADL status and days of ADL disability before death, days of being bedridden before death, number of episodes of suffering from serious diseases (including length of hospital stay) from last interview to death, what kind of diseases were suffered before death, whether adequate medical treatment was received when suffering disease, how many days before death the elder did not go out of doors, how many days before death the amount of time in bed was longer than that out of bed, and sociodemographic characteristics such as marital status, family income, living arrangement before dying were also obtained from the next-of-kin of those interviewees who died prior to the next wave.

The CLHLS datasets used in this study have two unique and important features. First, the CLHLS collected the information before dying from the next-of-kin for those decedents who died before the subsequent interview. Second, this study contains a total 19,778 observations (8,447 aged 80-89, 6,825 aged 90-99, and 4,506 aged 100-105). Such a large sample size makes these datasets more reliable for studying the oldest-old population.

2.2 Measuring the onset and recovery of ADL disability

Activity of daily living (ADL) refers to basic personal care tasks of every day life. As is consistent with previous studies (e.g., Beckett et al. 1996; Mendes de Leon, Glass, Beckett et al. 1999; Mendes de Leon, Gold, Glass et al. 2001), task-specific disability is defined as the inability to perform a task independently, without help from a person or specific equipment or a device. Previous studies have also shown self-reported ADL disability to be a valid measure (Weinberger et al. 1992), and Katz's scale is the most often used measure of functional disability (Wiener et al. 1990). Therefore, in this article, ADL disability is defined as self-reported difficulty with any following ADLs items: (a) bathing, (b) dressing, (c) eating, (d) indoor transferring, (e) toileting, and (f) continence (Note 3). To avoid problems of complications and small sub-sample sizes in model estimation, we simply dichotomized the ADL functional capacity into "active" (no ADL limitation) and "disabled" (at least one ADL limitation). An individual is considered having an "onset" of ADL disability if he/she moved from no ADL limitation at Time 1 to at least one ADL limitation at Time 2 or before dying. A person

is classified as having a “recovery” from ADL disability if he/she moved from at least one ADL limitation at Time 1 to no ADL limitation at Time 2 or before dying (see Note 4 for the definition of ADL status before dying). Such dichotomous classification includes $2 \times 2 = 4$ sets of rates of functional transition and remaining, which enables us to clearly focus on the onset and recovery of disability although it loses some information about the ADL functional gradations of deterioration/improvement. If, for example, three ADL categories are adopted, we would have to deal with $3 \times 3 = 9$ sets of functional transitions and remaining, which largely complicates the models and interpretations and causes problems of small sample sizes. The strategy of such dichotomous classification has also been adopted in previous studies (e.g., Land et al. 1994; Rogers et al. 1992; Zimmer et al. 1998).

2.3 Accuracy and reliability of ADL disability

The reliability of self-reported ADLs has been shown to be high and to be unaffected by age or cognitive status (e.g., Smith et al. 1990). The validity of self-reported ADL has been affirmed by several studies that have demonstrated high concordance between respondents and proxies (Magaziner et al. 1996).

The reliability coefficients of ADL (Note 5) in the CLHLS and some selected studies are presented in Table A1 in the Appendix. The value of Cronbach alpha in the CLHLS is close to or higher than that of some studies conducted in the USA (e.g., Fillenbaum 1988) and Canada (e.g., Penning and Strain 1994). These reliability coefficients are all above 0.7, the lowest criterion for group comparisons suggested by previous studies (Nunnally 1994; Stewart, Hays, and Ware 1992). Therefore, we are confident about the high data quality for ADL disability in the CLHLS.

2.4 Sociodemographic factors

Age, sex, current residence, ethnic group, SES in terms of education, economic independence, adequate financial resources, primary lifetime occupation, marital status, and living arrangement are the sociodemographic variables that we expected to be associated with the dynamics of ADL statuses in this study. All these factors were measured at Time 1.

The sample is divided into two ethnic groups: Han and minorities. Current residence is classified into urban and rural (Statistical Bureau of China 1993). For classifying educational attainment, we use reported years of schooling and merge them into two levels: 0 years (illiteracy) and one or more years of schooling because the

general education level of the Chinese oldest-old is extremely low and other alternative coding did not improve the estimates. Although the cash or asset amount income of the oldest-old was unavailable, the main income source information was collected. We classify such sources into two categories: economic independence, namely, relying mainly on pension or one's own financial source, and economic dependence, namely, relying mainly on spouse, children or other family members, government subsidy or other sources. And we also use another variable to measure whether the monetary sources are adequate to maintain the daily costs of the elderly. These two variables are a proxy of economic conditions in our study. Primary lifetime occupation of males is classified into two categories: agriculture and non-agriculture, whereas it is grouped into three categories for females: agriculture, housewife, and non-agriculture. Marital status has two categories: currently not married (including never married, divorced, and widowed) and currently married. Living arrangement is classified into living alone and not-living-alone. The distribution of above variables is listed in Table 1.

2.5 Control variables

To reduce the possibility of spurious associations, we select a set of control variables for the analysis guided by previous research in this area (e.g., Boulton et al. 1994; Seeman, Bruce, and MacAvay 1996).

There is reliable evidence to substantiate that the quality and nature of family and social support/connections have a measurable influence on functional disability (Seeman et al. 1996; Steinbach 1992; Idler and Kasl 1997; Koenig 1995). In this study, religious activities, proximity with children, playing cards, and who takes care of the elder in the daily life are considered as the proxy of family and social support/connections.

It has also been well documented that sociodemographic differences in functional status are mediated by factors of health practice such as alcohol consumption, smoking, diet, exercise (Hubert et al. 2002; LaCroix et al. 1993), and other health related variables such as cognitive function (Gill et al. 1997), self-reported health (Goldman et al. 1995; Liu et al. 1995), and depression (Gregg et al. 2002). Chronic disease conditions (see Note 2) are strongly related to an individual's ability to carry out activities of daily living (Guralnik et al. 1993; Femia et al. 1997). Hearing impairment and visual impairment are also associated with disability (e.g., Gill et al. 1997). The lower and upper extremities are associated with functional dynamics, as well (Guralnik et al. 1995).

Variability in the survival time interval between observation points for individuals requires us to add the length of the observation interval into model (Note 6). Whether

the respondents died or survived up to the next observation point was also included in the model as a dummy variable since the dynamics patterns of disability between survivors and the decedents are largely different (e.g., Melzer et al. 2001).

The presence or absence of these factors may facilitate or impede ADL decline or recovery. Neglect of the above potential confounders may lead to biases in investigating the effect of sociodemographic factors on the prevalence and dynamics of disability. Therefore, the results are more scientific and more statistically powerful if we add such variables into model as controls (Note 7).

2.6 Analytic strategies

Findings from recent studies show that mortality levels off at very high ages (e.g., Horiuchi and Wilmoth 1998; Thatcher, Kannisto, Vaupel 1998; Vaupel et al. 1998) and 20% of centenarians could avoid diseases except osteoarthritis (Evert et al. 2003). This raises our concerns that the age effect on disability dynamics may be different among octogenarians, nonagenarians, and centenarians. Another fact is that Macintyre and colleagues (1996) show that gender differences in health vary according to the life course stage. It is necessary to conduct studies of different age groups, rather than assume that the same relationships remain constant throughout the life course (Arber and Cooper 1999). Therefore, unlike most previous studies, which took age covariates in a multivariate model in analyzing disability, we run models separately for octogenarians, nonagenarians, and centenarians. It has become commonplace to analyze men and women separately in examining gender differences in the magnitude of the relationships between socio-economic characteristics and health (Arber and Cooper 1999:62), since men and women have different lifestyles, family and social roles, health and disablement outcome (Lamb 1997). Thus, we run models for males and females separately.

Previous studies have also suggested that different functional status trajectories may exist based on age, gender and other sociodemographic variables (Maddox and Clark, 1992, Wolinsky et al. 1996), the model would be more powerful if interactions between covariates were added to the model. All possible 44 two-way interactions were tested at the presence of their parent terms and all other sociodemographic variables used in this study were tested by gender among octogenarians, nonagenarians, and centenarians separately. It turns out that only the interaction between years of schooling and urban/rural residence among male nonagenarians and the interaction between economic independence and having adequate financial resources among female nonagenarians are significant. Moreover, coefficients of the main effects of variables in models among male nonagenarians and among female nonagenarians with such

significant interactions are almost identical to those without such interactions. Therefore, no interaction term was included in the final models of our analysis.

To reduce the influence of the number of respondents who were lost to follow-up or of the missing value of some variables on data analysis and inference, the multiple imputation approach was applied in this study (Allison 2002). Two types of models were constructed to examine how adding controlling variables may influence the estimates of the effects of sociodemographic factors on disability dynamics. The first type, the “sociodemographic model”, contains only sociodemographic factors, while the second type, the “full model”, contains both sociodemographic factors and the other control variables mentioned above.

The random effect logit model is employed to run all models using STATA version 8 (STATA 2003) after correcting intra-subject correlation due to some subjects’ contributing two observations to the pooled data set at a specific time (Time 1 or Time 2) (e.g., Liang and Zeger 1986) (Note 8).

3. Results

3.1 Descriptive information of sociodemographic variables and ADL dynamic changes

Table 1 provides descriptive information about percentage distributions of sociodemographic variables used in this study. The prevalence rates of ADL disability are 17% and 21% for male oldest-old and female oldest-old, respectively (Note 9). The prevalence rate increases steeply with advancing age. Those who live in urban areas have a higher prevalence rate, as compared with those living in rural areas. Minority ethnic oldest-old have a lower prevalence rate of disability than do their Han counterparts. Persons with low education or who are not currently married have higher prevalence rates. Those living alone suffer less from limitations of daily functioning than do those living with others.

Table 2 shows that for the whole oldest-old population in China, 22% of males and nearly 25% of females who were ADL active at Time 1 developed disability within the subsequent two years, whereas 35 % of males and 31% of females who were disabled at Time 1 regained their functioning in the following two-year interval. Females have a higher onset rate and lower recovery rate. The onset rate of disability of centenarians is two times higher than that of octogenarians, whereas their recovery rate is two times lower than that of octogenarians. For those who died before Time 2, their onset rate is 4 times higher than those surviving to Time 2. The bivariate differences of the rates of disability onset and recovery of different sociodemographic groups without adjusting

for any other confounding factors are also listed in Table 2. We do not discuss these bivariate cross-tabulations here since we will subsequently discuss the differentials across sociodemographic groups while controlling for other confounding factors.

3.2 Onset of disability

Figure 1a and Figure 1b reveal that male nonagenarians and centenarians have a 1.8 times and 2.7 times higher risk to develop disability over a two-year interval, respectively, compared with male octogenarians given the same sociodemographic conditions. The effect of age on disability development is more substantial among females than among males. Moreover, such age patterns do not change very much even after controlling for all other confounders although the odds ratios are lessened. This indicates that age is a strong predictor of the onset of disability.

Results shown in Figure 2a and Figure 2b indicate that, on average, female oldest-old are disadvantaged in ADL functioning, as compared with their male counterparts; the gender difference in disability dynamics, however, doesn't follow the same pattern among octogenarians, nonagenarians, and centenarians. In the full model, the gender difference in disability dynamics is the largest among nonagenarians, indicating female oldest-old in their nineties have a higher risk of experiencing the onset of disability on average compared with male oldest-old. The gender difference is not significant among octogenarians and is marginally significant among centenarians.

Figure 1a: Age effect on dynamic changes of disability, Socio-demographic model

Figure 1b: Age effect on dynamic changes of disability, Full model

Figure 2a: Gender effects on dynamic changes of disability, Socio-demographic model

Figure 2b: Gender effects on dynamic changes of disability, Full model

Table 3 illustrates the sociodemographic factors associated with the onset of disability among octogenarians, nonagenarians, and centenarians by gender, respectively. Odds ratios were obtained for each factor among persons who were active at Time 1. The left panel of Table 3 presents results obtained from the sociodemographic models, whereas the right panel provides results produced from the full models. The results in Table 3 show that the oldest-old have a higher probability of developing disability as they live longer for both males and females, although the variation of odds ratios in centenarians becomes wider. The significant difference between urban and rural residences in the onset of disability is observed among female elders aged 90 and over, while such a difference is not detected among male oldest-old. On average, minority ethnicity has a lower risk of developing disability compared with Han. But the pattern of ethnic effect in disability onset between males and females is different. For female oldest-old, ethnicity has a limited effect on disability development in the eighties, but it has a significant effect after age ninety, and the ethnic effect is stronger with the advancement of age. On the contrary, for male oldest-old, ethnicity has the highest effect in the eighties and weakens thereafter. The disadvantage effect of no education can make persons at oldest-old ages face higher risks of experiencing a disability, especially for males, although such disadvantages are reduced after adding other confounding factors into the model. Independence in financial resources reduces the risk of developing disability especially among female nonagenarians. But this effect is not observed for males. Unexpectedly, adequacy in financial resources doesn't show a beneficial effect on the onset of disability. In contrast, the results show that there is a negative association between having adequate financial resources and the capacity of daily functioning. Female oldest-old who were housewives have a higher risk of developing disability at their oldest-old ages compared with those who worked as farmers. Although the odds of risk to have an onset of disability among those who were non-agricultural workers during their lifetime were higher than those who were farmers, the estimates are not significant. The protective effect of marriage on developing disability is very weak and is observed only among male nonagenarians without controlling confounders. The results show that married females over age 90 have a higher likelihood to suffer ADL disability than their unmarried counterparts. Those living alone have a lower risk of experiencing a disability over a two-year interval than those living with others among male oldest-old. This effect is not found in females. The right panel of Table 3 suggests that the sociodemographic effects on disability development were not affected much by adding the confounding factors of family and social supports/connections, health practice and chronic conditions into the model.

3.3 Recovering from disability

Figure 1a and Figure 1b show that the odds of recovery of nonagenarians and centenarians from disability are 35% less and 50% less than that of octogenarians, respectively, in sociodemographic model, and such effects didn't change much after controlling for other confounders. This implies that age is strongly correlated with recovering from disability. But unlike its effects on the onset of disability, the magnitude of the age effect on recovering from disability among females is close to those among males. In general, females have a lower likelihood of regaining their daily functioning once they have become disabled as compared with their male peers. The gender difference is not significantly detected among octogenarians, while the gender differential effect is the biggest among nonagenarians.

Results summarized in Table 4 show that although the probabilities of moving from disabled status to active status decrease with age, the effect of increasing age on disability recovery is different among octogenarians, nonagenarians, and centenarians. The age effect is weaker with the advancement of the age group, especially for males. Urban oldest-old have a lower likelihood of recovering once they have become disabled compared with their rural peers. More interestingly, such urban-rural residential effects become stronger with the advancement of age groups among both males and females. Those minority ethnic oldest-old have a higher chance of recovering from disability as compared with those of Han oldest-old. Among male oldest-old, the ethnic effect weakens with the increase of age, whereas the patterns for females are the opposite. Although illiterate oldest-old have a disadvantage in maintaining their daily functioning, they don't have a disadvantage in recovering once they have become disabled; they have a higher chance of recovering even than literate persons, especially among people aged 90 and over. Economic independence and adequate financial resources does not improve the likelihood of recovering from a disability in our study. Female oldest-old whose primary lifetime occupations were housewives are less likely to regain their daily functioning if they lost such functioning as compared with farmers. The difference in disability recovery between lifetime farmers and non-farmers is small. The beneficial effect of marriage is observed only among female octogenarians, implying that the marriage protective effect in very old ages is limited. For males, the odds ratios of recovering from disability among those living alone are around 2-3 across three age groups as compared with those not living alone, and they are significant except for centenarians in the sociodemographic model. For females, these odds are around 1.1-1.3 and are not significant. This suggests that the effect of living alone on the dynamic changes of disability is stronger in males than in females. Results in Table 4 also show that the effects of sociodemographic factors on recovery only had a slight

change after controlling possible confounding, implying that the estimates of the sociodemographic effects are valid.

3.4 Difference between the estimates including and not including the ADL changes before dying

Results in Figure 3a to Figure 3d indicate that the magnitude of the differences of the estimates of the effects of sociodemographic factors on ADL disability dynamics between models including and not including ADL dynamics before dying is not negligible, although the patterns of effects are close (Note 10). The results suggest that the effect of age on disability onset is higher in the models not including ADL dynamic changes of the deceased persons before dying as compared with models including ADL dynamic changes before dying. The effect of age on disability recovery in the conventional approach without information of ADL changes before dying is lower than that in models including ADL transition before dying (Note 11). The conventional approach overestimated the age effect on disability dynamics. This is because the difference in ADL dynamics across ages for survivors is larger than that for the deceased persons. Our multivariate analyses based on the full model show that the odds ratios of having an onset of disability across three age groups with age 80-89 as the reference group are 1.74 ($p < 0.000$) for age 90-99 and 2.90 ($p < 0.000$) for age 100-105 among male survivors, and 1.06 ($p > 0.1$) for age 90-99 and 1.03 ($p > 0.1$) for age 100-105 among the deceased male oldest-old. Correspondingly, the odds ratios of recovering across these three age groups with age 80-89 as the reference group are 0.55 ($p < 0.000$) and 0.36 ($p < 0.000$) for male survivors and 1.12 ($p > 0.1$) and 0.94 ($p > 0.1$) for the deceased males (Note 12). Similar patterns of age differential effects between survivors and deceased persons among females are also found.

Furthermore, the conventional method overestimates the gender difference in disability dynamics. The odds ratios of the onset of disability and the recovery from disability between genders with males as the reference group in the full models including ADL changes before dying are 1.061 ($p > 0.1$) and 0.784 ($p < 0.01$), respectively. The corresponding figures in the full model not including ADL changes before dying are 1.175 ($p < 0.05$) and 0.695 ($p < 0.001$), respectively. This is also because gender difference in ADL dynamics is large among survivors while it is small among deceased persons. The gender odd ratios with males as the reference for transition from active to disabled and transition from disabled to active among survivors are 1.18 ($p < 0.05$) and 0.69 ($p < 0.01$) respectively, while the corresponding figures among the deceased persons are 1.07 ($p > 0.1$) and 0.78 ($p < 0.05$). The conventional method also overestimates the effects of ethnicity and living alone on disability dynamics. On the contrary, the conventional method underestimates the effect of SES, although the underestimation is small. Differences in the effects of marital status and urban/rural residence between the two methods are trivial, however.

4. Discussion

This study is innovative in its development of a measurement and model that include change of functional status before dying and incorporate basic sociodemographic factors under a more comprehensively multivariate framework. Our innovation has important potential implications both theoretically and practically. Our results based on the CLHLS data point out that the general patterns of sociodemographic effects on disability dynamics in the conventional method, which excludes the information of ADL changes before dying, is similar to those in our model including ADL changes before dying. The conventional method, however, overestimates the influences of age, gender, ethnicity, and living alone on disability transitions whereas it somewhat underestimates the effects of SES. This is mainly because of the difference in patterns of disability dynamics between survivors and the deceased persons. The level of mortality also plays a critical role. If the mortality rate is very low, it will offset the difference between these two methods even though the difference in ADL dynamics between survivors and the deceased persons is substantial. On the other hand, if mortality rate is relatively high, the difference could be large, indicating that including ADL transition before death is much more meaningful in aging studies, especially in the studies of the oldest-old, given that they have relatively high mortality rates. It is worthwhile to note that small discrepancies in effects (e.g., odds ratios) of sociodemographic factors on ADL dynamics between these two methods could lead to significant biases in the estimation of disabled life expectancy, as reported by Zeng et al. (2004). Although overestimation and underestimation of sociodemographic factors on ADL dynamics caused by the conventional method revealed in the present study might not have general applicability and far from conclusive, our finding indicates that it would be helpful to better understand the correlations between sociodemographic factors and the dynamics of disability if ADL dynamic information between survey intervals among both surviving and deceased interviewees was collected.

As is consistent with previous reports (Manton 1988; Wolinsky et al. 1996), our study shows that the prevalence rates of ADL disability among Chinese oldest-old are 17% and 21% for males and females, respectively, and increase steeply with the advancement of age. Over a two-year interval, more than 20% of the oldest-old developed an onset of disability among those who were active at the starting of the interval, while about 30% of the oldest-old who were disabled at the starting of the interval regained their daily functioning. Compared with some of previous studies the recovery rate in present study is somewhat higher. For example, Gill et al. (1997) find that the recovery rate was 28% for aged 70 and older, while some others find that the recovery rate was between 24-30% (e.g., Katz et al. 1983; Manton 1988; Manton, Corder, and Stallard 1993) among elderly aged 65 and over. The main possible reason

is that mortality rates were higher in China, which may make the Chinese oldest-old more robust compared with their counterparts in the Western nations. Actually, as pointed by one recent study (Hardy and Gill 2004), the recovery from disability might be considerably more common than what previous studies have documented. They find that among the respondents aged 70 and older the majority ever got recovered and more than half maintained independently for more than six months within 12 months from their initial disability. Thus, we believe that the slightly higher recovery rate from disability in this study compared with most of previous study may represent a spot or a part of a sector scattered on the full spectrum of dynamics of the disability among the elderly. The outcome in the present study suggests that the oldest-old are a frail group of people on average, on one hand. On the other hand, a sizeable number of the oldest-old, once disabled, would get recovery from disability. Such figures provide evidence to support the idea that recovering is almost as common as the onset of disability (Clark, Stump, and Hui 1998), and disability among older persons and even oldest-old persons is a highly dynamic process and is not an irreversible but often recurrent event (Gill and Kurland 2003).

Our results show that age is strongly linked to disability dynamics. Increasing age increases the chances of moving from active to disabled status, and decreases the chance that the disabled individuals will recover to active status. This reaffirms most others' reports (e.g., Crimmins et al. 1996; Hayward et al. 1998; Laditka and Wolf 1998; Rogers et al. 1992). One of the most striking findings in the relation between age and disability dynamics is that for males after age 90 and for females after age 100, an additional year of age will not deteriorate the chance to recover. Although we didn't focus on the leveling off of disability in the present study and it deserves further research, our result provides some evidence that the disability trajectory is decelerating at very old ages. This also provides supportive evidence to the argument that older age, per se, may not impede recovery but, rather, may act as a proxy for other unmeasured factors, which in turn decrease the capacity of disabled persons to recover (Gill et al. 1997: 760).

Although there is growing evidence to challenge the hypothesis that women have poor self-reported health, most studies still show that women have a lower level of functioning (Arber and Cooper 1999; Zimmer et al. 2002). In accordance with other studies (e.g., Crimmins et al. 1996; Fuchs, Blumstein, Novikov et al. 1998; Hayward et al. 1998; Land et al., 1994), our finding shows that males have a lower probability of developing disability and a higher probability to recover, suggesting that oldest-old women are significantly disadvantaged. The gender difference in our study, however, doesn't follow the same pattern among octogenarians, nonagenarians, and centenarians. The biggest gender differential effect is found among nonagenarians, and it is not significant among octogenarians. Such insignificance is possibly due to the length of

the assessment interval. Hebert et al. (1999) also reported that the interval between surveys could affect the gender difference in functional decline or improvement. This gender pattern needs further investigation.

The rural and urban difference is less salient in developed countries than in developing countries. Hence, few studies are available to date to examine the urban/rural residential relations with disability. The majority of these studies focus mainly on cross-sectional analysis and the results are not consistent (e.g., Barberger-Gateau et al. 1992; Mainous and Kohrs 1995; Gupta and Sankar 2003). For example, Mainous and Kohers (1995) find that rural elders have a higher disability prevalence rate, and this finding is confirmed by Gupta and Sankar (2003). On the other hand, some studies find that there is no significant association between urban/rural residence and disability (Barberger-Gateau et al. 1992). In our study, urban oldest-old exhibited a higher probability to have the onset of disability and lower probability to recover than their rural counterparts. (No significant residential difference in the onset of disability was found among male oldest-old.) The potential explanations for such urban-rural patterns in China are (1) the harder life and higher mortality at younger ages in rural areas results in rural oldest-old being more selected than urban oldest-old; (2) less availability of facilities to assist oldest-old persons in their daily life in rural areas may force them to perform daily life and thus they are enabled to maintain functioning; (3) the frequency of daily activities performed by urban oldest-old is less than that of rural oldest-old due to housing structure differences; (4) rural people reside in a more healthful physical environment than do those in urban areas (Zeng et al. 2001). The first two explanations may also help us to understand the fact that the elderly in some developing countries are more active than the elderly in developed countries (Chen and Jone 1989; Lamb 1999).

Although most previous studies in the U.S. have shown that minority ethnic groups' functional capacity is at lower levels, on average, than that of the majority (e.g., Crimmins et al. 1996; Land et al. 1994; Schoenbaum and Waidman 1997; Smith and Kington 1997), several recent studies find that there is a disability crossover at the oldest-old ages between ethnicities (e.g., Johnson 2000), suggesting that minorities have better ADL functioning at the oldest-old ages. Our study shows that minority ethnic oldest-old in China have a lower chance to develop disability and higher probability to recover if they were disabled. This is consistent with Johnson (2000) who finds Blacks (a minority) have better ADL functioning than Whites (the majority) at the oldest-old ages. Zimmer and colleagues (2002) also found that those Mainlanders in Taiwan (most of which are Han Chinese) have higher functional limitations as compared with minorities in Taiwan. Furthermore, it is interesting to note that the ethnicity differences in disability dynamics in this study among males and females are also different. The patterns of the ethnic difference in disability dynamics across ages

among males are weaker with the increasing age, while the patterns for females are the opposite. This is a new finding but it deserves further research. Some previous research has attributed race/ethnic differences in disability to the low SES of minorities (e.g., Boulton et al. 1994). But it is not clear whether the ethnic difference between Chinese Han and minorities is due mainly to mortality selection or other unobserved heterogeneities. More elucidation on this topic could provide a better understanding of ethnic differences in disability dynamics.

Most previous studies in western societies, which dealt with the entire elderly population aged 65+ and did not have a large sub-sample size for the oldest-old as we have, have found that education has a protective effect on disability in old ages (Crimmins et al. 1996; Land et al. 1994; Rogers et al. 1992). Our study, which focuses on the oldest-old in China with a large sample size, has found that education is not strongly associated with the dynamics of disability among Chinese oldest-old. This is partially in line with findings in Taiwan (Zimmer et al. 1998; Lee and Chuang 2003) and Japan (Liu et al. 1995). All three studies have found that education could decrease the likelihood of the onset of ADL disability but has no significant protective effect on recovery. We agree with Zimmer and colleagues (1998:271-273) that the effect of education on transitions of ADL disability involves a complicated framework including cultural background given that Mainland China has a similar cultural background as Taiwan. The dissimilarity of the effect of education on the onset of ADL disability between the present study and those in Taiwan and Japan might also be because of differences in the age range of subjects and the length of the observation interval. Like most western studies, all three studies in Taiwan and Japan dealt with the entire elderly population aged 65+ and didn't focus on the oldest old. The observation intervals of these three studies are three-year (Liu et al. 1995), four-year (Zimmer et al. 1998), and seven-year (Lee and Chuang 2003). The mechanism of the relationship between education and function at oldest-old ages in China deserves further investigation.

With advancement of age, the income of the elderly declines, while at the same time the elders have a greater likelihood of disability (Ginn and Arber 1991). The poor elders do not have adequate financial resources to compensate for their disabilities. This leads people to speculate that elders with better economic conditions should be healthier. Unexpectedly, however, economic conditions in late life were not significant factors to retard the development of disability and reduce the risk of maintaining disability in our analyses on Chinese oldest-old. Although this finding provides additional evidence to support the results reported by Ginn and Arber (1991), it differs from most others that do not focus on the oldest-old (e.g., Maddox and Clark 1992; Rogers et al. 1992; Seeman et al. 1994; Van Groenou et al. 2001). Additional research would help to shed further light on the association of economic status with disability dynamics at oldest-old ages.

It is noteworthy that those female oldest-old who were housewives in their lifetime experienced a higher risk of the onset of disability and a lower likelihood of regaining functioning as compared with farmers. This may be because farmers usually start to work during childhood and often continue to work well beyond the age of 65 and such labor activities serve as physical exercise, which may make them more active than housewives. On the other hand, the proportion of housewives who do exercises is very low, which makes them have a lower functioning as compared with farmers. Another possible explanation is that the majority (2/3) of previous farmers still reside in rural areas, and the rural environment has also made them relatively abler in daily life activities, as we discussed earlier in explaining the urban/rural residential differentials.

It is commonly stated that marriage demonstrates a beneficial effect on functional capacity (e.g., House, Landis, and Umberson 1988). Marriage provides individuals with a sense of meaning and importance that promotes health (Rogers et al., 1992). Although marriage provides health benefits for both husbands and wives, marriage confers a greater health benefit upon husbands than upon wives because wives often monitor their husband's health, but husbands usually do not provide the same service to their wives (Goldman et al. 1995; Umberson 1992; Rogers et al. 1992). This beneficial effect of marriage is not fully replicated in this study. We find that marriage doesn't have a significantly protective effect on disability dynamic transitions, indicating that the protective effect of marriage on disability dynamics is limited, or weak in the oldest-old ages in the two-year interval (Note 13). We offer the following explanations for this finding. First, mortality selection makes those not married and frail individuals drop out before they reach oldest-old ages; In other words, the currently not married oldest-old are possibly at least as robust in ADL functioning as the married oldest old. Second, we didn't examine the quality of marriage, remarriage, the length of marriage, and recent changes in marital status on disability dynamics in the present study. These factors probably affect the results. Third, the observation interval may not be enough for us to detect such effects at the oldest-old ages. Fourth, at oldest-old ages, factors other than marital status may have a stronger influence on disability, such as chronic disease conditions or genetic factors. Further research on the marital effect on disability is warranted.

An increasing strand of research has demonstrated that living arrangement may exert an effect on health (Grundy 2001; Hebert et al. 1999). Our findings show that living arrangement does have significant effects on the dynamic changes of disability among male oldest-old, reaffirming other studies that do not focus on the oldest-old (e.g., Hebert et al. 1999). In our sample, compared with those living in other settings, those living alone are more independent in daily activities and have a higher chance of regaining their daily functioning once they have become disabled. Furthermore, our study reveals that the effect of living alone is smaller among female oldest-old than

among male oldest-old. There are two-way causalities: living alone leads to good functioning, or vice versa. Hebert et al. (1999) interpreted that living alone could act as a proxy for good health at very old ages rather than as a risk factor. Although this could partially explain our result, we argue that in the Chinese cultural context, living alone might also lead to good functioning. This is because most of those oldest-old who live alone don't have children or have low proximity with children. They have to live alone, which forces them to do daily tasks by themselves and maintain their functioning well.

Unlike most of other studies, our study focuses on the oldest-old who need much more care than others, but about whom we know very little. The data set includes a large sample size, and is the first, largest longitudinal survey for the oldest-old in developing countries. Although there are a considerable number of studies focusing on functional ability among nonagenarians and centenarians (e.g., Andersen-Ranberg et al. 1999; Nybo et al. 2001), the sociodemographic effects on dynamic changes in disability have still not been fully examined. The large sample size among octogenarians, nonagenarians, and centenarians enables us to examine the effects of sociodemographic factors on the onset of or recovery from disability separately in this study under the control of various confounding effects. The results of this study provide new knowledge about the general patterns of disability dynamics of the oldest-old in developing countries, and make comparison with those in developed countries possible. Our finding contributes to a better understanding of some of the social and demographic factors associated with transitions between disabled and active statuses. Our analysis has illustrated which sociodemographic factors are the most important ones in reducing transitions to disability, and in increasing the rate of recovery.

One limitation of the present study is that information on ADL status before dying for deceased persons between the two waves is obtained from proxy, which may involve some bias, although previous studies reveal that the use of proxy responses from family members is appropriate in quality of dying research (George 2002). And we collected only one episode of data about ADL dynamics before dying, which may also suffer some limitations. How to get the more accurate information of ADL dynamics over a survey interval without increasing the frequency of surveying is still a challenge for epidemiological study. Another limitation of the present study is that information was not available on whether participants sought or received special treatments after the onset of their disability. Therefore, we could not evaluate (or adjust for) the effect of these rehabilitative efforts on the likelihood of ADL recovery.

In short, the present study shows that sociodemographic factors seem to play some specific roles in disability dynamics even after controlling for a variety of confounders. It is worth noting that the relationships between sociodemographic factors and disability dynamics are much more complex and far from conclusive. We are fully aware that not only will diversity of conceptual measures of functioning and the interval between

evaluations result in different answers (Hebert et al. 1999), but also the analytical strategies will produce different pictures, as well. One of our purposes is to draw attention to the underestimation of disability in the existing literature. Although we have included ADL dynamics information before dying, the answer is far beyond satisfied given that we lack full information concerning ADL transitions between assessments. There is still a long way to go to capture the whole picture of ADL dynamics. Given the current projections that the number of Chinese oldest-old could be reach more than 100 million by 2050 (UN 2002; Zeng and George 2000), further research on the mechanisms of ADL disability and recovery in the oldest-old population is clearly warranted.

5. Acknowledgements

We thank statisticians Dr. May M. Boggess and Dr. Brian P. Poi at STATA Corporation, both of whom provided helpful suggestions in building the statistical models used in this research. We are grateful for the invaluable and constructive comments provided by two anonymous reviewers of *Demographic Research*.

This article is based on data derived from the Chinese Longitudinal Healthy Longevity Survey conducted in 1998, 2000, and 2002, which was supported by NIA/NIH grant P01 AG 08761 awarded to Duke University and Chinese matching input towards personnel costs and some local expenses. United Nations Funds for Population Activities and China National Foundation of Social Sciences provided additional funds for adding younger interviewees aged 65-79 in our 2002 survey. The Max Planck Institute for Demographic Research provided support for international training.

Notes

1. The majority of existing studies follow this approach, which we call the “conventional method” in this paper.
2. According to previous research (e.g., Pope and Tarlov 1991; Verbrugge and Jette 1994; Jette 1999) and WHO (1980), the main pathway in the disablement process is as follows: presence of disease leads to impairments, which in turn lead to functioning limitations, which then lead to disability (difficulty in doing ADL). Therefore, the onset of a disease is normally a necessary precursor of disability (except in the case of trauma).
3. If a person receives assistance in at least one item, that person was defined as having difficulty in ADLs. Although some studies have mentioned that continence may exist without physical limitations and it is therefore no longer included in ADL disability estimates (Jagger et al. 2001: 404; Guralnik et al. 1993), we still include it in our analysis.
4. It is difficult to distinguish practically between an onset of disability in the time period before death and a disability emerging in the dying process in some cases since there is a good chance that, at some point in the dying process, a person might lose the ability to perform some tasks of ADL, e.g., bathing. In our CLHLS survey, we instructed the interviewers to inquire about the deceased subjects’ general ADL status during few weeks before dying, rather than the status at the moment of death.
5. Reliability coefficient is define as follows: $\alpha = \frac{K(\bar{r})}{1 + (K - 1)r}$, where, $\bar{r} = \frac{K}{K - 1} \left(1 - \frac{\sum_{i=1}^K S_i^2}{S_{sum}^2}\right)$, and K is the total number of items; S_i^2 denotes the variances for the k th item; S_{sum}^2 denotes the variance for the scale (i.e., sum of all items). (See, <http://www.spss.com/tech/stat/Algorithms/11.5/reliability.pdf>)
6. Normally, such data is called an unequally spaced or unbalanced data set in longitudinal studies (e.g., Willett 1988).
7. The definition of each control variable, its distribution, and odds ratio are not presented in this paper but are available upon request.

8. We have also tried logistic regression and the population-averaged logit model, along with correcting the intra-subject correlation. The latter is based on the generalized estimation equation (GEE), an extension of the theory of the generalized linear model (GLM). The results of the random-effect logit model presented in this paper are identical to those of the logistic regression model, and the results based on the population-average logit model are almost the same as those of logistic and random-effect logit model.
9. The disability prevalence rate and incidence rates are relatively lower in China as compared with those in US. This is possibly due to mortality selection. As documented by several previous studies, the physical functioning of the elders in some Asian developing countries are much better than that of those in developed countries due to mortality selection, which forces those persons who were not robust to drop out (e.g., Lamb 1999); therefore, Chinese oldest-old might have better ADL functioning than their American counterparts.
10. Figure 3a to Figure 3d are based on the full model with males and females separated. The results in the full model with males and females combined are very close to those listed in Figure 3a to Figure 3d, and hence, they are not presented in this paper but are available upon request.
11. Comparisons are made among age-combined models to avoid problems of small sample sizes of some covariates.
12. Table 2 also provides a brief result about the different patterns of ADL dynamics across age groups between survivors and the deceased persons in terms of the proportion of making ADL transitions.
13. This doesn't necessarily mean that this finding supports Arber and Cooper (1999), who find that marriage doesn't have a protective effect on ADL functioning based on a cross-sectional data set. We have run the model using cross-sectional data and found that the marriage protective effect on ADL functioning is significant for females although the protective effect for males is not significant.

Appendix

Table A1: *Distributions of reliability coefficients of ADL*

	Time 1		Time 2			
	Males	Females	Survivors		Decedents	
			Males	Females	Males	Females
Age 80-89	0.8597	0.8650	0.8680	0.8695	0.9535	0.9552
Age 90-99	0.8705	0.8679	0.8553	0.8736	0.9459	0.9399
Age 100-105	0.9390	0.8804	0.8826	0.8818	0.9335	0.9325

Note: (1) ADL includes six items: bathing, dressing, indoor transferring, toileting, continence, and eating. (2) Results are based on not imputed data.
