*World Real Interest Rates**

1. Introduction

This study began with the challenge to explain why real interest rates were so high in the 1980s in the major industrialized countries. In order to address this challenge we expanded the question to the determination of real interest rates over a longer sample, which turned out to be 1959–88. In considering how real interest rates were determined we focused on the interaction between investment demand and desired saving in an economy (ten OECD countries viewed as operating on an integrated capital market) that was large enough to justify closed-economy assumptions. Within this “world” setting, high real interest rates reflect positive shocks to investment demand (such as improvements in the expected profitability of investment) or negative shocks to desired saving (such as temporary reductions in world income). Our main analysis ends up measuring the first kind of effect mainly by stock returns and the second kind primarily by oil prices and monetary growth.

We think we have partial answers to how world real interest rates have been determined, and, more specifically, to why real interest rates were as high as they were in the 1980s. The key elements in the period 1981–86 appear to be favorable stock returns (which raised real interest rates and stimulated investment) combined with high oil prices (which also raised real interest rates, but discouraged investment).

In this paper we focus on the behavior of short-term real interest rates since 1959 in nine OECD countries: Belgium (BE), Canada (CA), France (FR), Germany (GE), Japan (JA), the Netherlands (NE), Sweden (SW), the United Kingdom (UK), and the United States (US). These countries

*We are grateful for comments from Jason Barro, Olivier Blanchard, Bill Brainard, Bob Lucas, Greg Mankiw, Larry Summers, and Andrew Warner. We appreciate the research assistance of Casey Mulligan. The statistical analysis in this paper was carried out with Micro TSP.

constitute the set of industrialized market economies for which we have been able to obtain data since the late 1950s on relatively open-market interest rates for assets that are analogous to U.S. Treasury bills. For France and Japan, the available data are money-market rates. We were unable to obtain satisfactory data on interest rates for Italy (IT) prior to the early 1970s, but we included Italian data on other variables; therefore, parts of the analysis deal with ten OECD countries. These countries accounted in 1960 for 65.4% of the overall real GDP for 114 market economies, according to the PPP-adjusted data that were constructed by Summers and Heston (1988). In 1985, the share was 63.4%. Thus, the sample of ten countries represents a substantial fraction of the world's real GDP.

We have concentrated thus far on short-term interest rates because of the difficulty in measuring medium- or long-term expected inflation and, hence, expected real interest rates. The quantification of expected inflation is difficult even for short horizons, although the results in this paper are robust to these problems. The patterns in short-term expected real interest rates reveal a good deal of persistence; for example, the rates are much higher for 1981–86 than for 1974–79, with the rates in the 1960s falling in between. Given the ease with which participants in financial markets can switch among maturities, the persisting patterns in expected real short-term rates would also be reflected in medium- and long-term rates. Therefore, we doubt that the limitation of the present analysis to short-term rates will be a serious drawback. We plan, however, to apply the approach also to longer-term rates.

2. Expected Inflation and Expected Real Interest Rates

Investment demand and desired saving depend on expected real interest rates. The data provide measures of nominal interest rates and realized real rates. We could carry out the analysis with the realized real rates, relying on a rational-expectations condition to argue that the difference between the realized and expected real rates, which corresponds to the negative of the difference between the actual and expected inflation rate, involves a serially uncorrelated random error. Because the divergences between actual and expected inflation are likely to be large in some periods, much more precise estimates could be attained by constructing reasonably accurate measures of expected inflation and expected real interest rates. Thus, we begin by estimating expected inflation rates.

We have quarterly, seasonally unadjusted data on an index of consumer prices for each country beginning in 1952:1. (For the United States, we used the CPI less shelter to avoid problems with the treat-

ment of housing costs in the data prior to 1983.) The results reported in this paper compute expected inflation for dates $t = 1958:1$ to $1989:4$ based on regression forecasts for CPI inflation. (Quarter 1 represents the annualized inflation rate from January to April, and so on.) Each regression uses data on inflation for country i from 1952:2 up to the quarter prior to date t . That is, the data before date t are equally weighted, but later data are not used to calculate forecasts.

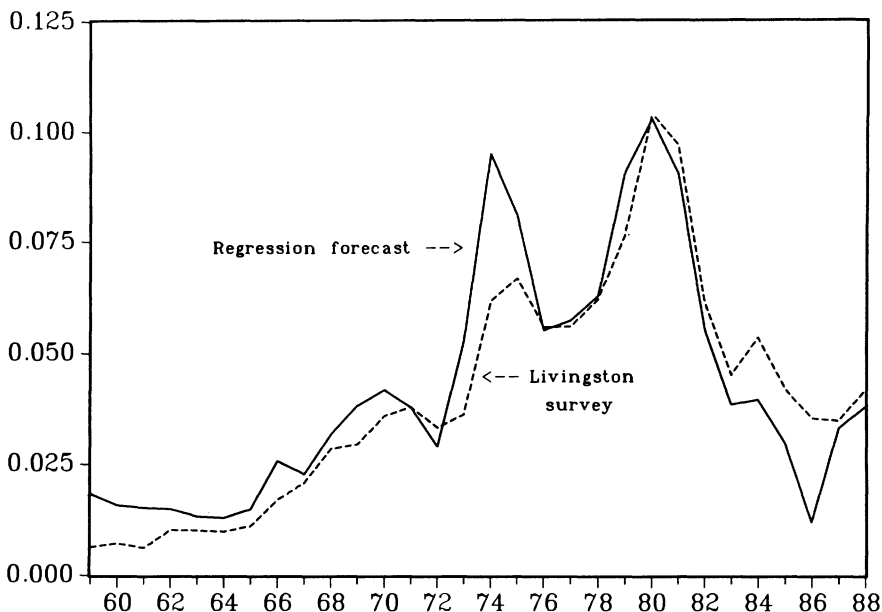

The functional form for the inflation regressions is an ARMA (1,1) with deterministic seasonals for each quarter; thus, expected inflation is based solely on the history of inflation. We considered forms in which inflation depended also on past values of $M1$ growth and nominal interest rates, but the effects on the computed values of expected real interest rates were minor. (The nature of the relation between inflation and past monetary growth and interest rates also varied considerably across the countries.) Within the ARMA (1,1) form, the results look broadly similar across the nine OECD countries; typically, the estimated $AR(1)$ coefficient is close to 0.9 and the estimated $MA(1)$ coefficient ranges between -0.4 and -0.8 . Q -statistics for serial correlation are typically insignificant at the 5% level, although they are significant in some cases. The pattern of seasonality varies a good deal across the countries. Appendix Table A1 shows the estimated equations that apply for the nine countries over the sample 1952:2–1989:3.

We computed annual measures of expected inflation by averaging the four quarterly values from the regression forecasts. Figure 1 compares the constructed annual time series for U.S. expected inflation, $\pi_{US,t}^e$, with values derived from the six-month-ahead forecasts from the Livingston survey (obtained from the Federal Reserve Bank of Philadelphia). The two series move closely together, with a correlation of .92 from 1959 to 1988. The main discrepancies are the more rapid adjustment of the regression-based series to actual inflation in the periods 1973–75 (when inflation rose) and 1985–86 (when inflation fell).

We calculated expected real interest rates, r_{it}^e , for country i in quarter t by subtracting the constructed value for π_{it}^e from the corresponding nominal interest rate, R_{it} . (The three-month Treasury bill rate in January matches up with the expected inflation rate for January to April, and so on.) We then formed an annual series for r_{it}^e by averaging the four quarterly values.

The calculated values for U.S. expected real interest rates for 1974–77 are negative and average -1.2% , whereas the values based on the Livingston survey average 0.1% and are negative only for 1975–77. A plausible explanation is that the regression estimates overstate the responsiveness of expected inflation to actual inflation in the early 1970s. Many of the

Figure 1 EXPECTED INFLATION RATES FOR THE UNITED STATES

other eight OECD countries exhibit negative values of r_{it}^e for some of the years between 1972 and 1976, and an overstatement of π_{it}^e may also explain this behavior. (If we had used the full sample of data to compute π_{it}^e , rather than just the data prior to period t , the calculated sensitivity of π_{it}^e to past inflation would have been even greater. Thus, the tendency to calculate negative values for r_{it}^e between 1972 and 1976 would have been even more pronounced.) Except for the U.K. for 1975–77 ($r_{it,UK}^e = -.115, -.027,$ and $-.058$, respectively), the computed negative values for r_{it}^e since 1959 never exceed 2% in magnitude.¹

The subsequent analysis deals with the annual time series for expected real interest rates, r_{it}^e . The limitation to annual values arises because some of the other variables are available only annually.² In any event, the high

1. Economic theory would not rule out small negative values for expected real interest rates on nearly risk-free assets; however, opportunities for low-risk real investments without substantial transaction costs (including storage of durables) would preclude expected real rates that were substantially negative. It seems likely that at least the large-magnitude negative values for r_{it}^e represent mismeasurement of expected inflation. It would be possible to recompute π_{it}^e based on the restriction that the implied value for r_{it}^e exceed some lower bound, such as zero or a negative number of small magnitude. We have not yet proceeded along these lines.
2. The main results reported below, however, involve variables that are available quarterly. We are presently working on the results for quarterly data.

Table 1 SUMMARY STATISTICS

| <i>Means and Standard Deviations of Main Variables, 1959–88</i> | | | | | | |
|---|-----------------|----------|--------------------|----------|--------------|----------|

Note: See Table A2 for definitions and sources of the variables.

serial correlation in the quarterly series on r_{it}^e suggests that we may not lose a lot of information by confining ourselves to the annual observations. The use of annual data means also that we do not have to deal with possible seasonal variations in expected real interest rates.

We constructed a world index of a variable for year t by weighting the value for country i in year t by the share of that country's real GDP for year t in the aggregate real GDP of the nine- or ten-country sample. (Henceforth, "world" signifies the aggregate of the nine- or ten-country OECD sample.) In computing the weights, we used the PPP-adjusted numbers for real GDP reported by Summers and Heston (1988). (For 1986–89, we used the shares for 1985, the final year of their data set.) None of our results changed significantly if we weighted instead by shares in world investment. Table 1 shows the average of each country's Summers-Heston GDP weight (WT) from 1959 to 1988. Note that the average share for the United States was .45, that for Japan was .13, and so on. (In 1985, the U.S. share was .44 and the Japanese was .17.)

Figure 2 shows the world values (nine-country sample excluding Italy) for actual and expected inflation from 1959 to 1989. (Because we had data on actual inflation for some countries only up to the third quarter of 1989, the value for actual inflation in 1989 is missing.) Expected and

Figure 2 WORLD ACTUAL AND EXPECTED INFLATION RATES

actual inflation move together in a broad sense, but the expected values lag behind the increases in inflation in 1969, 1972–74, and 1979–80, and behind the decreases in 1982 and 1986. Figure 3 shows the corresponding values for world actual and expected real interest rates. Although the two series move broadly together, a notable discrepancy is the excess of expected over actual real interest rates for 1972–74. The actual rates are negative over this period (averaging -2.3%), but the computed expected rates are positive (averaging 1.1%).

Figure 4 shows the breakdown of the world nominal interest rate into two components: the world expected inflation rate and the world expected real interest rate. The graph makes clear that the bulk of variations in nominal interest rates correspond to movements in expected inflation; the correlation between the nominal interest rate and the expected inflation rate is $.79$, whereas that between the nominal rate and the expected real interest rate is $.44$ (The correlation of the nominal interest rate with actual inflation is $.62$, whereas that with the actual real interest rate is $.24$.)

Many authors have argued that expected real interest rates among OECD countries differ significantly in terms of levels and time patterns (see, for example, Mishkin 1984). Although our findings do not dispute

Figure 3 WORLD ACTUAL AND EXPECTED REAL INTEREST RATES

Figure 4 WORLD NOMINAL AND EXPECTED REAL INTEREST RATES AND EXPECTED INFLATION

this conclusion, we think nevertheless that a study of the movements of real interest rates in the main OECD countries can usefully start by attempting to explain the common elements across the countries. (Blanchard and Summers 1984 take a similar view.) The comparison of U.S. behavior with that of the other countries in Figure 5 suggests that the common factors are worth investigating. The U.S. expected real interest rate moved similarly to the average for the other eight countries; the correlation from 1959 to 1989 was .73.

A simple way to summarize the overall movements of the expected and actual real interest rates, $r_{wd,t}^e$ and $r_{wd,t}$ is to consider the means of the two variables from Figure 3 over various subperiods. The average values for $r_{wd,t}^e$ ($r_{wd,t}$) were 2.0% (1.8%) for 1959–70, 1.2% (–1.0%) for 1971–73, 0.0% (–1.0%) for 1974–79, 2.4% (1.8%) for 1980, 4.2% (5.3%) for 1981–86, 2.3% (2.8%) for 1987–88, and 3.5% (3.4%) for 1989. These data suggest that it is meaningful to ask why expected and actual real interest rates were high in the early 1980s.³ In our analysis of the full-time series

3. The rates for 1981–86 would not look so high in a historical context from before World War II. Barro (1989, p. 242) shows that U.S. realized real interest rates on assets comparable to prime commercial paper averaged about 8% from 1840 to 1900 (excluding the Civil War), 3% from 1900 to 1916, and 5% from 1920 to 1940.

Figure 5 EXPECTED REAL INTEREST RATES FOR THE UNITED STATES AND EIGHT OTHER OECD COUNTRIES

since 1959, we add the questions of why the movements in rates were relatively moderate from 1959 until the early 1970s, why the rates were so low in the middle and late 1970s, and why the rates fell after 1986 and rose in 1989.

3. A Model of Investment Demand and Desired Saving

We think of “the” world expected real interest rate, $r_{wd,t}^e$ as determined by the equation in period t of world investment demand to world desired saving. This setting applies to the ten-country OECD sample if, first, these countries operated throughout the sample on integrated capital and goods markets, and second, if the ten countries approximate the world, and hence a closed economy. We get some insight later about the integration of world markets by analyzing the extent to which real interest rates in individual countries respond to own-country variables rather than world variables. The approximation that the ten countries represent the world and hence a closed economy may be tenable, first, because these countries constitute about 65% of the world’s real GDP (for market economies), and second, because the observed current-account

balance for the ten-country aggregate has been very small. We added up each country's nominal current-account balance (expressed via current exchange rates in terms of U.S. dollars) from 1960 to 1987 and divided by the total nominal GDP (also converted by exchange rates into U.S. dollars). The average value of the ratio of the aggregated current-account balance to overall GDP was 0.1%. Moreover, the largest value from 1960 to 1987 (1971) was only 0.5% and the smallest (1984) was only -0.7% .

We now construct a simple model of investment demand and desired saving. Although this model is used to interpret some of the empirical findings, the general nature of the reduced-form results does not depend on this particular framework. Hence, readers who are unimpressed by our theory may nevertheless be interested in the empirical evidence.

We measure real investment, I_t , by gross domestic capital formation (private plus public, nonresidential plus residential, fixed plus changes in stocks). Thus, I_t excludes purchases of consumer durables and expenditures on human capital. Investment demand, expressed as a ratio to GDP, is determined by a q -type variable:

$$(I/Y)_t = \alpha_0 + \alpha_1 \cdot \log[PROF_t^e / (r_t^e + \rho_t)] + u_t \quad (1)$$

where $PROF_t^e$ is expected profitability per unit of capital, r_t^e is the expected real interest rate on assets like Treasury bills, ρ_t is a risk premium, and $\alpha_1 > 0$. The error term u_t is likely to be highly persistent because, first, time-to-build considerations imply that current investment demand depends on lagged variables that influenced past investment decisions, and second, there may be permanent shifts in the nature of adjustment costs, which determine the relation between investment demand and the q variable. In first-difference form, equation (1) becomes

$$(I/Y)_t = \alpha_1 \cdot \Delta \log[PROF_t^e / (r_t^e + \rho_t)] + (I/Y)_{t-1} + u_t - u_{t-1}. \quad (2)$$

Our analysis treats the error term, $u_t - u_{t-1}$, as roughly white noise.

We use the world real rate of return on the stock market through December of the previous year $STOCK_{t-1}$, to proxy for the first difference of the q variable, $\Delta \log[PROF_t^e / (r_t^e + \rho_t)]$.⁴ This proxying is imperfect because

4. The stock-return variable for each country is the nominal rate of return for the year implied by the *IFS* December index for industrial-share prices less the December-to-December inflation rate based on the consumer price index. We had broader stock-return measures readily available for three countries—Canada, the United Kingdom, and the United States—which together comprised 57% on average of the ten-country GDP. The substitution of these numbers for the *IFS* values had a negligible impact on the regression results we report later. We took this result as an indication that the *IFS* data are probably satisfactory indicators of stock-market returns.

of distinctions between average and marginal q ,⁵ because of failure to adjust for changes in the market value of bonds and depreciation of capital stocks, and because the stock market values only a portion of the capital that relates to our measure of investment. (The investment numbers include residential construction, noncorporate business investment, and public investment.) For these reasons, the best estimate of $\Delta \log[PROF_i^e/(r_i^e + \rho_i)]$ would depend inversely on the change in r_i^e , for a given value of $STOCK_{t-1}$.⁶ Therefore, we approximate the relation for investment demand as

$$(I/Y)_t = a_0 + a_1 \cdot STOCK_{t-1} - a_2 \cdot (r_i^e - r_{i-1}^e) + (I/Y)_{t-1} + v_t \quad (3)$$

where $a_1 > 0$ and $a_2 > 0$.⁷

We assume that the desired saving rate (for the world aggregate of national saving) is given by

$$(S/Y)_t = \beta_0 + \beta_1(\tilde{Y}/Y)_t + \beta_2 r_t^e + \beta_3 \cdot (S/Y)_{t-1} + \text{error term} \quad (4)$$

where \tilde{Y}_t is current temporary income, the β_i 's are positive, and the error term is treated as white noise. Equation (4) adopts the permanent-income perspective in assuming that permanent changes in income do not have important effects on the saving rate. Temporary changes in income have little effect on consumer demand and therefore have a positive effect on the desired saving rate, as given by the coefficient β_1 . Given the temporary-income ratio, $(\tilde{Y}/Y)_t$, the saving rate would respond positively to r_t^e in accordance with the coefficient β_2 . The variable $(S/Y)_{t-1}$ picks up persisting influences on the saving rate. It turns out in our empirical estimation that $0 < \beta_3 < 1$ applies; that is, the desired saving rate appears to exhibit less persistence than the investment-demand ratio, which has a unitary coefficient on the lagged dependent variable in equation (3).

We considered using measures of temporary government purchases,

5. See Hayashi (1982) for a discussion, in particular, of the adjustments of marginal q for tax effects.
6. Let $STOCK_t = \Delta \log(q_t) + e_t$, where $q_t = [PROF_t^e/(r_t^e + \rho_t)]$ and e_t can be interpreted as a measurement error. Assume that the prior distribution is given by $\Delta \log(q_t) = \epsilon_t$, that r_t^e is observed without error, and that no direct information about ρ_t is available. Then the posterior estimate of $\Delta \log(q_t)$ gives weights to $STOCK_t$ and (as a linear approximation) to $r_t^e - r_{t-1}^e$, where the weight on $r_t^e - r_{t-1}^e$ rises with $\text{VAR}(e)/\text{VAR}(\epsilon)$. (Independent measurement error in r_t^e would lower the weight applied to $r_t^e - r_{t-1}^e$.) Our analysis uses data on stock returns only through December of the previous year (and thereby avoids some simultaneity problems). The omission of contemporaneous data on stock returns raises $\text{VAR}(e)$ and thereby raises the weight applied to $r_t^e - r_{t-1}^e$.
7. The term $(r_t^e - r_{t-1}^e)$ is approximately linear if $\rho_t \gg r_t^e$ applies.

especially defense expenditures, as influences on temporary income and hence desired national saving rates. Up to this point, however, we have been unable to isolate important temporary variations in the ratios of real government purchases to real GDP over the period since 1959 for the ten OECD countries we are studying.

We have had more success by thinking of the relative price of oil as an indicator of world temporary income. Higher oil prices are bad for oil importers, which predominate in the ten-country OECD sample. Because higher oil prices tend to reflect more effective cartelization of the market for oil, an increase in prices also represents a global distortion that is bad for the world as a whole. Moreover, high oil prices may be a signal of disruption of international markets in a sense that goes beyond oil; therefore, the effects on world income may be substantially greater than those attributable to oil, *per se*.

Our subsequent analysis of real interest rates provides some indication that the level of the relative price of oil, rather than the change in this relative price, is the variable that proxies for temporary income. This result is reasonable if the relative price of oil is perceived to be stationary; in this case, a high level for the current relative price signals a temporarily high level. In the actual time series, the relative price of oil did happen to return after 1985 to values close to those applying before 1973. But our direct analysis of the time-series properties of the relative oil price is inconclusive about stationarity.⁸

The empirical analysis uses the variable $POIL_{t-1}$, which is the relative price of crude petroleum for December of the previous year from the U.S. producer price index. The results do not change significantly if we use instead a weighted average of relative petroleum prices for each country. The precise concepts for these prices varied across the countries and the data for some countries were unavailable for parts of the sample. For these reasons, we used the U.S. variable in the main analysis.⁹

Thinking of $POIL_{t-1}$ as an inverse measure of the temporary income ratio, $(\tilde{Y}/Y)_t$, the equation for the saving rate becomes

$$(S/Y)_t = b_0 - b_1 \cdot POIL_{t-1} + b_2 \cdot r_t^e + b_3 \cdot (S/Y)_{t-1} + \text{error term} \quad (5)$$

8. Even if the relative price of oil is nonstationary, the consequences of a change in the price of oil for world income are likely to be partly transitory. In particular, the effects on income would tend to diminish as methods of production adjusted to the new configuration of relative prices.

9. The results are also similar if we use the dollar price for Venezuelan crude instead of the U.S. PPI for crude petroleum. (The Saudi Arabian price is very close to the Venezuelan price, but the *IFS* does not report the Saudi Arabian values after 1984.) The main difference between the Venezuelan and U.S. series is that the Venezuelan one shows a much larger proportionate increase in 1973.

where the b 's are positive. We assume that, given the stock return, $STOCK_{t-1}$, the variable $POIL_{t-1}$ does not shift investment demand in equation (2). That is, at least the main effects of oil prices on investment demand are assumed to be captured by the stock-market variable. With this interpretation, the variable $POIL_{t-1}$ represents a shift to desired saving that is not simultaneously a shift to investment demand.

We also assume that the stock-market return, $STOCK_{t-1}$, has primarily permanent effects on income; that is, we neglect effects on the temporary income ratio, $(\tilde{Y}/Y)_t$, and thereby on desired saving in equation (4). Given this assumption, the variable $STOCK_{t-1}$ reflects a shift to investment demand that is not simultaneously a shift to desired saving. In other words, the variables $STOCK_{t-1}$ and $POIL_{t-1}$ will allow us to identify the relations for investment demand and desired saving.

We might be able to quantify the interplay between stock returns and temporary income by using measures of current profitability, such as aftertax corporate profits. That is, we could estimate the implications of stock returns for the part of temporary income that relates to the difference between current and expected future profitability. We have thus far been unsuccessful in obtaining satisfactory measures of corporate profits for some of the countries in the sample, and therefore have not yet implemented this idea. (The main data series available from the OECD, called "operating surplus," is an aggregate that is much broader than corporate profits.) The limited data we have indicate that current stock returns or other variables lack significant predictive content for future changes in the ratio of corporate profits to GDP. It may, therefore, be roughly correct that stock returns have little interplay with the temporary income that corresponds to gaps between current and expected future corporate profits.

We now extend the analysis to consider the effects of monetary and fiscal variables. We think of these variables as possible influences on the desired saving rate in equation (4). In some models where money is nonneutral—such as Keynesian models with sticky prices or wages—a higher rate of monetary expansion raises temporary income and thereby increases the desired saving rate.¹⁰ With respect to fiscal variables, many economists (such as Blanchard 1985) argue that increases in public debt or prospective budget deficits reduce desired national saving rates.

Let DM_{t-1} be a measure of monetary expansion and F_{t-1} be a measure of

10. In the analysis of Mundell (1971), higher monetary expansion leads to higher expected inflation and thereby to a lower real demand for money. The reduction in real money balances is assumed to lead to a decrease in consumer demand and hence to an increase in the desired saving rate. Tobin (1965) gets an increase in the desired saving rate in a similar manner.

fiscal expansion, each applying up to the end of year $t-1$. Then we can expand the relation for the desired saving rate from equation (5) to

$$(S/Y)_t = b_0 - b_1 \cdot POIL_{t-1} + b_2 r_t^e + b_3 (S/Y)_{t-1} + b_4 DM_{t-1} - b_5 F_{t-1} + \epsilon_t. \quad (6)$$

The coefficients are defined so that $b_i > 0$ applies in the theoretical arguments discussed above.

Given our closed-economy assumption (for the ten-country OECD sample), r_t^e is determined by equating the investment-demand ratio, $(I/Y)_t$, from equation (3), to the desired saving rate, $(S/Y)_t$, from equation (6). The reduced-form relations for r_t^e and $(I/Y)_t$ are as follows:

$$r_t^e = \frac{1}{(a_2 + b_2)} [a_0 - b_0 + a_1 \cdot STOCK_{t-1} + b_1 \cdot POIL_{t-1} + a_2 \cdot r_{t-1}^e + (1 - b_3) \cdot (I/Y)_{t-1} - b_4 \cdot DM_{t-1} + b_5 \cdot F_{t-1} + v_t - \epsilon_t]. \quad (7)$$

$$(I/Y)_t = \frac{1}{(a_2 + b_2)} \cdot [a_0 b_2 + a_2 b_0 + a_1 b_2 \cdot STOCK_{t-1} - a_2 b_1 \cdot POIL_{t-1} + a_2 b_2 \cdot r_{t-1}^e + (b_2 + a_2 b_3) \cdot (I/Y)_{t-1} + a_2 b_4 \cdot DM_{t-1} - a_2 b_5 \cdot F_{t-1} + a_2 \epsilon_t + b_2 v_t]. \quad (8)$$

The reduced form of the model in equations (7) and (8) implies the following:

1. Higher stock returns, $STOCK_{t-1}$, raise r_t^e and $(I/Y)_t$,
2. Higher oil prices, $POIL_{t-1}$, raise r_t^e but lower $(I/Y)_t$,
3. Higher monetary growth, DM_{t-1} , lowers r_t^e and raises $(I/Y)_t$ (in models where monetary expansion stimulates desired saving),
4. Greater fiscal expansion, F_{t-1} , raises r_t^e and lowers $(I/Y)_t$ (in models where fiscal expansion reduces desired national saving).

Two additional implications that concern lagged dependent variables are more dependent on the dynamic effects built into the model structure:

5. The lagged value r_{t-1}^e has positive effects on r_t^e and $(I/Y)_t$ (because, holding fixed the other variables including $(I/Y)_{t-1}$, a higher r_{t-1}^e effectively shifts up investment demand).
6. The lagged value $(I/Y)_{t-1}$ has a positive effect on $(I/Y)_t$ because of the persistence built into investment demand and desired saving. The effect on r_t^e is positive if the persistence in investment demand is greater than that in desired saving; that is, if $b_3 < 1$.

Figure 6 WORLD RATIO OF REAL INVESTMENT TO REAL GDP

4. Empirical Analysis of Expected Real Interest Rates and Investment Ratios

Table 1 contains means and standard deviations for the main variables used in the analysis. Table A2 in the Appendix has definitions and sources for the variables. The world ratio of real investment (gross domestic capital formation) to real GDP appears in Figure 6. We use figures on gross investment because the data on depreciation are likely to be unreliable. As with the other world measures, the investment ratio is the GDP-weighted value of the numbers from the ten OECD countries. World real stock returns (December-to-December) are in Figure 7, the December values for the relative price of oil are in Figure 8, and world growth rates of M1 (December-to-December) are in Figure 9.

Figures 10–13 show various measures of fiscal stance. Figure 10 plots the ratios of real central government debt to real GDP for the United States and the nine other OECD countries.¹¹ (We presently lack data for

11. We lack data on debt for consolidated general government on a consistent basis for the ten countries in the sample. The figures that we used, which were computed in most cases from *IFS* numbers on the par value of the aggregate of domestic and foreign debt for central governments, are gross of holdings by central banks, certain government agencies, and local governments.

Figure 7 WORLD REAL STOCK RETURNS

Figure 8 RELATIVE PRICE OF CRUDE PETROLEUM (U.S. PPI)

Figure 9 WORLD GROWTH RATE OF M1

1988 on the debt of some of the countries.) Note that the pattern for the United States is broadly similar to that for the average of the other countries. Note also that the U.S. debt-GDP ratio peaked in 1987 and fell in 1988.

We define the real budget deficit to be the change during the year in the central government's outstanding real debt. Figure 11 shows world values for this concept of the real budget deficit when expressed as a ratio to real GDP. We plot the actual and cyclically adjusted values of the ratio. The cyclically adjusted values are the residuals from a regression for each country over 1958–87 of the real deficit-real GDP ratio on the current and four annual lags of the growth rate of real GDP.

Figures 12 and 13 compare the U.S. ratios for real budget deficits to real GDP with those for the nine other countries. Figure 12, which plots ratios for actual real budget deficits, shows that the recent U.S. experience did not depart greatly from that for the average of the other nine countries. Figure 13 shows, however, that recent values for the cyclically adjusted U.S. ratios were substantially higher than those for the average of the other nine countries. But the adjusted U.S. ratio fell from 4.0% in 1986 to 1.9% in 1987 and 1.0% in 1988.

Figure 12 RATIOS OF REAL BUDGET DEFICITS TO REAL GDP FOR THE UNITED STATES AND NINE OTHER OECD COUNTRIES

5. Reduced-Form Estimates for the World Expected Real Interest Rate

We begin the empirical analysis with reduced-form equations for the world (nine-country) expected real interest rate, $r_{wd,t}^e$, over the period 1959 to 1988. Table 2, column 1, shows a regression of the form of equation (7), but with monetary and fiscal variables excluded. The estimated coefficients of $STOCK_{wd,t-1}$ (.041, s.e. = .011) and $POIL_{t-1}$ (.029, s.e. = .009) are each positive and significant, with t-values of 3.7 and 3.1, respectively. Not surprisingly, the estimated coefficient of $r_{wd,t-1}^e$ is also positive and highly significant (.58, s.e. = .10). The estimated coefficient of $(I/Y)_{wd,t-1}$ is positive (.22, s.e. = .15), but not statistically significant at the 5% level.

Table 2, column 2 adds the monetary variable, $DM_{wd,t-1}$, which is the GDP-weighted average of world M1 growth through December of the previous year.¹² We were surprised to find that $DM_{wd,t-1}$ entered nega-

12. We also examined the growth rates of currency and nominal GNP as alternative measures of monetary stimulus. If the growth rate of currency through the end of year $t-1$ is added to the basic regression from Table 2, column 2 (which includes M1 growth for year $t-1$), the estimated coefficient of the new variable is insignificant and the other results change little. If the growth rate of world nominal GDP for year $t-1$ is added to the basic regression, the estimated coefficient of the new variable is $-.167$, s.e. = .093, t-value =

Figure 13 CYCLICALLY ADJUSTED RATIOS OF REAL BUDGET DEFICITS TO REAL GDP FOR THE UNITED STATES AND NINE OTHER OECD COUNTRIES

tively and significantly in the regression for $r_{wd,t}^e$ ($-.251$, s.e. = $.054$, t -value = 4.7). (We were surprised because previous research suggested difficulty in isolating these kinds of monetary effects; see, for example, Barro 1981.) Moreover, when $DM_{wd,t-1}$ is added to the regression, the estimated coefficients for the other variables become more significant: the t -values are now 6.7 for $STOCK_{wd,t-1}$ ($.064$, s.e. = $.009$)¹³ and 5.5 for $POIL_{t-1}$ ($.039$, s.e. = $.007$).¹⁴ The estimated coefficient of $(I/Y)_{wd,t-1}$ also becomes significantly positive ($.49$, s.e. = $.12$), with a t -value of 3.9 .

1.8. The other results change little; in particular, the estimated coefficient of $DM_{wd,t-1}$ is $-.250$, s.e. = $.051$, which is virtually unchanged from that shown in Table 2, column 2. (The world growth rates of M1 and nominal GDP are essentially orthogonal.) The nearly significant negative coefficient on the lag of nominal GDP growth may indicate that exogenous shifts in velocity have negative effects on expected real interest rates.

13. The estimated coefficient of $STOCK_{wd,t-1}$ changes little if the individual stock returns are weighted by each country's share of world investment, rather than GDP. With investment weights, the estimated coefficient of $STOCK_{wd,t-1}$ is $.060$, s.e. = $.010$.

14. If we add the second lag value, $POIL_{t-2}$, the estimated coefficient is $-.023$, s.e. = $.020$. The hypothesis that only the change in the relative price of oil, $POIL_{t-1} - POIL_{t-2}$, matters is rejected at the 5% level (t -value = 2.7). If we replace the U.S. relative price of oil by a GDP-weighted average of individual country relative prices, the estimated coefficient of $POIL_{t-1}$ becomes $.042$, s.e. = $.010$ (and the R^2 of the regression falls from $.892$ to $.875$).

Table 2 REGRESSIONS FOR WORLD EXPECTED REAL INTEREST RATE

| $\hat{\sigma}$ | .0074 | .0054 | .0053 | .0056 | .0054 | .0057 | .0063 |
| DW | 1.4 | 1.8 | 1.8 | 1.8 | 1.8 | 1.2 | 2.0 |

Note: Standard errors are in parentheses. $\hat{\sigma}$ is the standard error of estimate (adjusted for degrees of freedom) and DW is the Durbin-Watson Statistic. The dependent variable in columns 1–4, 6, 7 is $r_{wd,t}^e$. In column 5 it is the nominal interest rate, $R_{wd,t}$. The sample period is 1959–88 in columns 1–5. It is 1959–72 in column 6 and 1973–88 in column 7.

It is possible that the apparent effect of M1 growth represents some kind of endogenous response of money to the economy, rather than the influence of exogenous monetary growth on real interest rates. Our failure in the next section to find the predicted positive relation between $DM_{wd,t-1}$ and the investment ratio, $(I/Y)_t$, may support alternative interpretations based on endogenous money. We carried out some analysis of monetary reaction functions; these results indicate a negative response of monetary growth to oil prices and stock returns, but not to lags of expected real interest rates or investment ratios. ($DM_{wd,t}$ is itself serially uncorrelated; see Fig. 9.) Because we already held fixed the stock market and oil prices in the regression for $r_{wd,t}^e$, we do not see how our findings about monetary reaction can explain the relation between $DM_{wd,t-1}$ and $r_{wd,t}^e$ based on a story about endogenous money. Monetary growth would

have to be reflecting information about future real interest rates not already contained in the other explanatory variables.

The explanatory power of $DM_{wd,t-1}$ for $r_{wd,t}^e$ reflects in part the well-known cutback in world M1 growth in 1979 and 1980 (6.8% and 5.3%, respectively, compared with a mean of 8.0% for 1959–88). This monetary contraction matches up well with the increase in $r_{wd,t}^e$ from 0.9% in 1979 to 2.4% in 1980 and 4.7% in 1981. (With the monetary variable excluded in Table 2, column 1, the fitted values of $r_{wd,t}^e$ for 1980 and 1981 are 2.0% and 3.4%, respectively. With the monetary variable included in column 2, these fitted values become 2.5% and 4.4%.) The significance of $DM_{wd,t-1}$ in the regression for $r_{wd,t}^e$, however, does not depend on the inclusion of the observations for 1980–81. If these two years are omitted, the estimated coefficient of $DM_{wd,t-1}$ becomes $-.233$, s.e. = $.066$, and the other results do not change much from those shown in column 2.

We have carried out the estimation using the realized real interest rate, $r_{wd,t}$, rather than our constructed measure of the expected rate, $r_{wd,t}^e$. The error term in the regression can then be viewed as including the discrepancy between the actual and expected real rate. Under rational expectations, this expectational error would be independent of the explanatory variables, which are all lagged values. The estimates would therefore be consistent, but inefficient relative to a situation where $r_{wd,t}^e$ is observed directly and used as the dependent variable. Although the standard errors of the estimated coefficients are substantially higher when $r_{wd,t}$ replaces $r_{wd,t}^e$ as the dependent variable, the basic pattern of the results remains the same. Thus, the findings do not depend on our particular measure for expected inflation.

Overall, the regression equation in Table 2, column 2 does a remarkable job of explaining the variations in expected real interest rates from 1959 to 1988; see Figure 14 for a plot of actual values against fitted values and residuals. Note that the out-of-sample forecast of $r_{wd,t}^e$ for 1989 is 3.2% compared to an actual of 3.5%; for 1988, the estimated value was 1.9% and the actual was 2.3%. (We promise that we generated the forecast for 1989 before finding the data on the actual value.)

We will discuss more features of the results later, but some key elements for the 1980s are the generally favorable stock-market returns combined with high oil prices. (Blanchard and Summers 1984, argue that improved prospects for profitability—which we pick up in the stock-market returns—were an important element in the high real interest rates of the 1980s.) The experience for the 1980s contrasts with the extremely poor stock returns and lower oil prices that prevailed in the mid-1970s. The 1960s featured still lower oil prices, but better stock returns than in the mid-1970s.

Figure 14 ACTUAL & FITTED VALUES & RESIDUALS FOR WORLD EXPECTED REAL INTEREST RATE (TABLE 2, COL. 2)

Columns 3 and 4 of Table 2 add fiscal variables to the regression for $r_{wd,t}^e$. Column 3 shows a positive but insignificant coefficient on the world debt-GDP ratio, $RDEBTY_{wd,t-1}$, and a negative but insignificant coefficient on the world ratio of real budget deficits to real GDP, $RDEFY_{wd,t-1}$.¹⁵ The F -statistic for the inclusion of the two fiscal variables jointly is $F_{22}^2 = 1.6$ (5% critical value = 3.4). Column 4 replaces $RDEFY_{wd,t-1}$ with the cyclically adjusted variable, $RDEFYA_{wd,t-1}$. The adjustment of real deficits for cyclical factors would be desirable in the present context if the removal of these factors raises the forecasting power for future ratios of real deficits to real GDP. The estimated coefficient on $RDEFYA_{wd,t-1}$ is close to zero, and that on $RDEBTY_{wd,t-1}$ remains positive but insignificant. The F -statistic for the inclusion of the two fiscal variables is now only $F_{22}^2 = 0.3$.

The real budget deficit is effectively an adjustment of the nominal deficit for the effect of actual inflation on the outstanding nominal debt. An adjustment for expected rather than actual inflation is likely to be preferable from the standpoint of forecasting future real budget deficits (because unexpected inflation is unpredictable). We calculated ratios of

15. Negative estimated effects of budget-deficit variables on interest rates were reported previously by Evans (1987) (for nominal rates in six OECD countries) and Plosser (1987) (for nominal and real rates in the United States).

real budget deficits to real GDP (adjusted or unadjusted for cyclical fluctuations) in this manner, but the results differed negligibly from those found with actual inflation.

We also held fixed the ratio of government consumption purchases to GDP (which entered insignificantly) and experimented with the inclusion of current or future real budget deficits. In all cases we obtained similar results; the measures of fiscal stance that we have considered do not help significantly in explaining the time series for expected real interest rates. We are forced to conclude that the evidence supports the Ricardian view, which deemphasizes the roles of public debt and budget deficits in the determination of real interest rates.

Column 5 in Table 2 uses the world nominal interest rate, $R_{wd,t}$, as the dependent variable and adds the constructed measure of world expected inflation, $\pi_{wd,t}^e$, on the right side. Measurement error in $\pi_{wd,t}^e$ would bias the estimated coefficient toward zero, but the estimated value (.89, s.e. = .09) differs insignificantly from one. Of course, to the extent that countries levy taxes on nominal interest payments, the predicted coefficient would be somewhat above unity.

We tested for the stability of the relation between $r_{wd,t}^e$ and the explanatory variables by estimating the specification from Table 2, column 2 separately for 1959–72 and 1973–88. Thus, we split the sample before the oil crises and the main changes in the international monetary system. The estimates for the two subperiods appear in columns 6 and 7 of the table. The test for stability leads to the statistic $F_{18}^6 = 0.2$; thus, we do not reject the hypothesis that the same equation applies over both periods. To some extent, the failure to reject reflects the high standard errors that apply to the estimated coefficients for 1959–72 (column 6). For example, the standard error for the estimated coefficient of $POIL_{t-1}$ is enormous because of the small variations in relative oil prices from 1958 to 1971 (see Fig. 8).¹⁶ The data for 1959–72, however, do generate marginally significant estimated coefficients on $STOCK_{wd,t-1}$ (.047, s.e. = .028) and $DM_{wd,t-1}$ (-.240, s.e. = .132).

6. Reduced-Form Estimates for World Investment Ratio

We now consider the reduced form for the investment ratio in equation (8). Table 3 shows regressions over 1959–88 for the world ratio of real

16. The estimated coefficient of $POIL_{t-1}$ differs insignificantly from zero for samples that begin in 1959 and end as recently as 1979; for the 1959–79 sample, the estimated coefficient is -.003, s.e. = .034. If the sample ends in 1980, the estimated coefficient becomes .029, s.e. = .018. For samples that end between 1981 and 1988, the estimated coefficient is very stable, varying between .038 and .040 with a standard error between .007 and .010.

| <i>DW</i> | 1.6 | 1.7 | 1.9 | 1.8 | 1.5 | 1.7 |

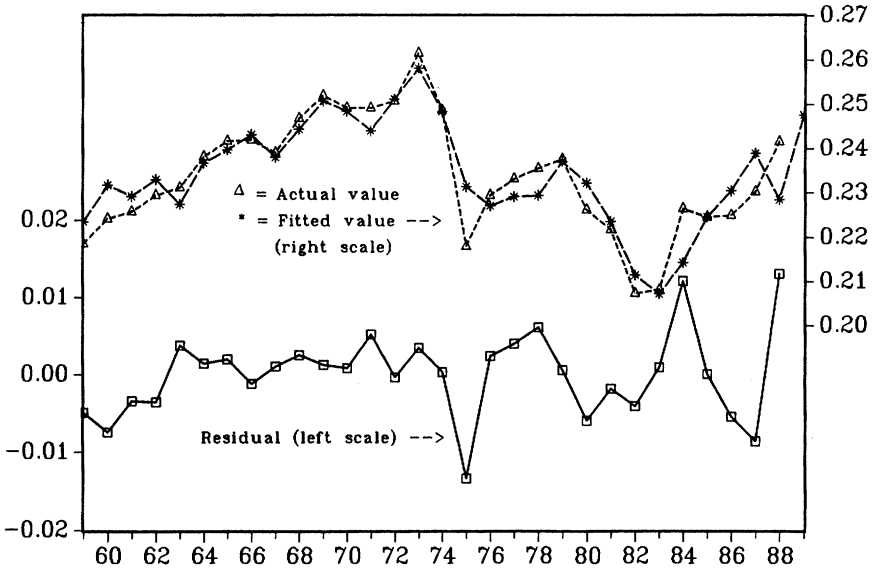

Note: The dependent variable is $(I/Y)_{wd,t}$. The sample period in columns 1–4 is 1959–88. It is 1959–72 in column 5 and 1973–88 in column 6.

investment to real GDP, $(I/Y)_{wd,t}$. The explanatory variables in these equations are the same as those used in Table 2. In the regression shown in Table 3, column 2, the main results are a significantly positive effect from $STOCK_{wd,t-1}$ (.034, s.e. = .011),¹⁷ a significantly positive effect from $POIL_{t-1}$ (-0.017, s.e. = .008), and a significantly positive effect from the lagged dependent variable $(I/Y)_{wd,t-1}$ (.79, s.e. = .14). The estimated coefficients of $r_{wd,t-1}^e$ (.00, s.e. = .08) and $DM_{wd,t-1}$ (.022, s.e. = .060) are insignificant. Figure 15 plots the actual values for $(I/Y)_{wd,t}$ along with the estimated values and residuals.

The results on the world investment ratio are consistent with the hypothesis that more favorable stock returns raise investment (along with raising real interest rates) and that higher oil prices reduce investment (along with increasing real interest rates). On the other hand, although we found before that the expected real interest rate was nega-

17. Previous results of a similar nature for the United States were reported by Fama (1981). Barro (1990) reports analogous findings for the United States and Canada.

Figure 15 ACTUAL & FITTED VALUES & RESIDUALS FOR WORLD RATIO OF INVESTMENT TO GDP (TABLE 3, COL. 2)

tively related to last year's monetary growth, the results do not reveal the expected positive response of the investment ratio.

Columns 3 and 4 of Table 3 add the fiscal variables that we considered before; column 3 uses the world variable for ratios of real budget deficits to real GDP, and column 4 the variable for cyclically adjusted ratios. The estimated effect of the debt-GDP ratio, $RDEBTY_{wd,t-1}$, is negative but insignificant in both cases. The estimated effects of the budget-deficit variables, $RDEFY_{wd,t-1}$ and $RDEFYA_{wd,t-1}$, are each significantly positive—that is, the sign opposite to that predicted by models where fiscal expansion lowers the desired national saving rate. The positive effect for the unadjusted variable, $RDEFY_{wd,t-1}$, accords with the negative coefficient for this variable in the interest-rate equation (Table 2, column 3). However, the cyclically adjusted variable, $RDEFYA_{wd,t-1}$, had a coefficient of about zero in the interest-rate equation (Table 2, column 4). The fiscal variables considered are jointly insignificant for the investment ratio at the 5% level. In the regression shown in Table 3, column 3, the statistic is $F_{22}^2 = 3.2$ (5% critical value = 3.4); for that in column 4, the statistic is $F_{22}^2 = 2.6$. Thus, as with the expected real interest rate, the fiscal variables do not have much explanatory power for the investment ratio.

We fit the equation for the investment ratio (Table 3, column 2) sepa-

rately over 1959–72 and 1973–88. A test of stability for the coefficients yields the statistic $F_{18}^6 = 1.7$ (5% critical value = 2.7). Columns 5 and 6 show the estimates obtained over the two subperiods. The standard errors for the estimated coefficients from the 1959–72 sample tend to be high; however, the estimated coefficient of $STOCK_{wd,t-1}$ is positive (.018, s.e. = .011).

7. System Estimates for World Expected Real Interest Rate and Investment Ratio

The structural model in equations (3) and (6) led to the reduced-form equations (7) and (8) for the expected real interest rate and investment ratio. In the previous sections, we estimated the two reduced-form equations separately, ignoring the overidentifying restrictions that came from the structure. In this section, we estimate the two equations as a joint system, allowing for the imposition of the model's restrictions as well as for correlation of the error terms across the equations. Table 4 shows the resulting estimates for the structural coefficients that appear in equation (3) for investment demand and in equation (6) for desired saving. Columns 1 and 2 apply to a system that includes monetary growth but excludes fiscal variables. Columns 3 and 4 add two fiscal variables: the debt-GDP ratio, $RDEBTY_{wd,t-1}$, and the cyclically adjusted real deficit–real GDP ratio, $RDEFYA_{wd,t-1}$.

We also fit the joint systems for the expected real interest rate and the investment ratio without the restrictions imposed by the structural model. Thereby we were able to compute likelihood-ratio tests of the overidentifying restrictions. For the model without fiscal variables, the test statistic (for $-2 \cdot \log[\text{likelihood ratio}]$) of 9.9 compared to a 5% critical value from the χ^2 distribution with 5 degrees of freedom of 11.1. In the model with fiscal variables, the test statistic of 13.7 compared to the 5% critical value (with 7 d.f.) of 14.1. Thus, the model's restrictions were not rejected at the 5% level in either case. Table 4 also compares the fits (in terms of R^2 and $\hat{\sigma}$ values) for restricted and unrestricted forms of each equation separately. The fits for the investment equation appear substantially more sensitive than those for the interest-rate equation to the imposition of the model's overidentifying restrictions.

The two fiscal variables are jointly insignificant when added to the restricted joint system (likelihood-ratio statistic of 5.3 compared to a 5% critical value of 6.0). Since the other results are not sensitive to the exclusion of the fiscal variables, we focus now on the estimates from the model that excludes the fiscal variables (columns 1 and 2 of Table 4).

If one takes the structural model seriously, then two interesting results

Table 4 SYSTEM REGRESSIONS FOR WORLD EXPECTED REAL INTEREST RATE AND INVESTMENT RATIO

Note: The sample period is 1959–88. The estimated coefficients apply to the model that is estimated subject to the structural restrictions. For the investment demand equation, the constant is set to 0 and the coefficient of $(I/Y)_{wd,t-1}$ is set to 1. Columns 1 and 2 apply to a model that excludes fiscal variables; columns 3 and 4 to a model that includes the two fiscal variables shown. In fit statistics apply to the restricted model and to an unrestricted form that relaxes the constraints from the structural model.

are the estimated responsiveness of the desired saving rate to the expected real interest rate (.34, s.e. = .07 from Table 4, column 2) and the estimated reaction of the investment-demand ratio to the expected real interest rate (–.44, s.e. = .13, from column 1). The last coefficient has to be interpreted as the effect of $r_{wd,t}^e$ on the investment-demand ratio while holding fixed the value of the stock market. (Recall that, when the stock

return is an imperfect measure of Δq_t , the variable $r_t^e - r_{t-1}^e$ provides some independent information about Δq_t .) The dependence of the stock return on $r_{wd,t}^e - r_{wd,t-1}^e$ suggests that the estimated coefficient $-.44$ would underestimate the magnitude of the response of the investment-demand ratio to $r_{wd,t}^e$ while holding fixed expected profitability, $PROF_t^e$, and the risk premium, ρ_t , but not the value of the stock market.¹⁸

The estimated model implies that desired national (gross) saving rates rise by .34 percentage points for each percentage-point increase in r_t^e . Although this form provides a natural unit for thinking of the responsiveness of saving rates to real interest rates, it appears to be more common to think in terms of elasticities. Because the sample mean of $(I/Y)_{wd,t}$ is .23, whereas that for $r_{wd,t}^e$ is only .020, the implied elasticities are small—only .03 at the sample means. The calculated elasticities would, however, tend to be substantially greater for net saving rates.

Column 1 of Table 4 shows that the estimated effect of $STOCK_{wd,t-1}$ on the investment-demand ratio is .051, s.e. = .010. Since the sample standard deviation of $STOCK_{wd,t-1}$ is .16, the result means that a 1 s.d. move in the stock market changes the investment-demand ratio by .008 compared to a sample s.d. for $(I/Y)_{wd,t}$ of .013. The estimated effect of $POIL_{t-1}$ on the desired saving rate in col. 2 is $-.033$, s.e. = .006. Given the sample s.d. for $POIL_{t-1}$ of .21, a 1 s.d. move in the relative oil price implies a shift in the desired saving rate by .007.

Columns 1 and 2 show that the estimated effects of the lagged dependent variable, $(I/Y)_{wd,t-1}$, are 1 for the investment-demand ratio (as constrained by the model) and .58, s.e. = .08, for the desired saving rate. The greater persistence of investment demand than of desired saving generates the positive relation in the reduced form between $r_{wd,t}^e$ and $(I/Y)_{wd,t-1}$. If the coefficient on $(I/Y)_{wd,t-1}$ in the investment-demand equation is freed up, the estimated value is .93, s.e. = .11. In this case, the estimated coefficient of $(I/Y)_{wd,t-1}$ in the saving-rate equation becomes .55, s.e. = .09. Thus, this unrestricted version of the model does indicate significantly greater persistence in investment demand than in desired saving.

Column 2 shows the positive estimated effect for $DM_{wd,t-1}$ on the desired saving rate (.183, s.e. = .037). The previous discussion of the reduced form indicated that this estimate stems from the negative relation between $r_{wd,t}^e$ and $DM_{wd,t-1}$, and not from any relation between $(I/Y)_{wd,t}$ and $DM_{wd,t-1}$.

Column 4 of Table 4 shows that the estimated effect of the debt-GDP

18. Serial correlation of the error term in the equation for $r_{wd,t}^e$ would, however, likely lead to an overestimate of the sensitivity of investment demand to a change in the expected real interest rate; see the coefficient a_2 in equations (3) and (7).

ratio on the desired saving rate is negative but insignificant ($-.026$, *s.e.* = $.015$). The cyclically adjusted deficit variable has a positive and marginally significant estimated effect on desired saving ($.144$, *s.e.* = $.077$). This “wrong” sign accords with the results discussed before in Table 3.

8. Simulations for Expected Real Interest Rates and Investment Ratios

8.1 WHY WERE EXPECTED REAL INTEREST RATES SO HIGH IN 1981–86?

We can use the estimated model for the expected real interest rate and the investment ratio to assess the frequently asked question: Why have real interest rates been so high in the 1980s? We approach this question

Table 5 SIMULATED EFFECTS ON EXPECTED REAL INTEREST RATES AND INVESTMENT RATIOS (RESULTS REFER TO MEANS FOR THE PERIODS INDICATED)

Note: The column labeled "Simulated Total" refers to the change in the average simulated value of $r_{wd,t}^e$ or $(I/Y)_{wd,t}$ from the reference period to the study period. These dynamic simulations use the actual values of $STOCK_{wd,t-1}$, $POIL_{t-1}$, and $DM_{wd,t-1}$, and the actual initial values of $r_{wd,t-1}^e$ and $(I/Y)_{wd,t-1}$ at the beginnings of the reference and study periods. The column labeled "STOCK" shows the part of the change in the simulated values attributable to differences in the time series of $STOCK_{wd,t-1}$ for the study and reference periods. The other columns give the corresponding information for differences in the time series of $POIL_{t-1}$, $DM_{wd,t-1}$, and the values for $r_{wd,t-1}^e$ and $(I/Y)_{wd,t-1}$ at the start of the study and reference periods. The value $(I/Y)_{wd,t}$ for 1989 is based on incomplete data.

by comparing the period 1981-86, during which the average value of $r_{wd,t}^e$ was 4.2%, with an earlier reference period of equal length, 1975-80, during which the average of $r_{wd,t}^e$ was 0.3%. Hence, we seek to explain the increase in the average expected real interest rate from 1975-80 to 1981-86 by 3.9 percentage points.

According to the model, the differences in averages of expected real interest rates should be explicable mainly in terms of differences in stock-market returns, oil prices, and monetary growth. Some role would also be played by differences in initial conditions for $r_{wd,t-1}^e$ and $(I/Y)_{wd,t-1}$ (in 1981 compared to 1975). Note from Table 5 that the averages for $STOCK_{wd,t-1}$ were 7.7% in 1981-86 versus -6.2% in 1975-80, those for $POIL_{t-1}$ were 0.93 in 1981-86 versus 0.61 in 1975-80, and those for

$DM_{wd,t-1}$ were 7.91% in 1981–86 versus 8.80% in 1975–80. The difference in initial conditions were .0245 for $r_{wd,t-1}^e$ in 1981 versus .0061 in 1975, and .226 for $(I/Y)_{wd,t-1}$ in 1981 versus .249 in 1975.

We can simulate the estimated model to estimate the extent to which the higher average for $r_{wd,t}^e$ in 1981–86 than in 1975–80 can be attributed to differences in $STOCK_{wd,t-1}$, $POIL_{t-1}$, $DM_{wd,t-1}$, and the initial conditions for $r_{wd,t-1}^e$ and $(I/Y)_{wd,t-1}$. We consider the restricted version of the joint model as reported in Table 4 and also the unrestricted version that does not impose the overidentifying restrictions from the structure. We also neglect any interplay among $STOCK_{wd,t}$, $POIL_t$, and $DM_{wd,t}$; that is, we treat the time paths of these three variables as exogenous.¹⁹

Given the actual time paths for $STOCK_{wd,t}$, $POIL_t$, and $DM_{wd,t}$, and the actual values for $r_{wd,t-1}^e$ and $(I/Y)_{wd,t-1}$ in 1981 and 1975, dynamic simulations of the restricted model for 1981–86 and 1975–80 predict an increase in the average of $r_{wd,t}^e$ of 3.8 percentage points compared to the actual increase of 3.9 points (see the columns labeled “Simulated Total” and “Actual” in section I of Table 5). We then dynamically simulated the restricted model for 1981–86 with the values of $STOCK_{wd,t-1}$ from 1975–80 substituted year by year for those in 1981–86. This simulation implied that 2.5 percentage points of the increase in the average of $r_{wd,t}^e$ from 1975–80 to 1981–86 derived from the higher average for stock returns in the latter period (see the column labeled “*STOCK*” in the table).²⁰ Similarly, we found that 1.9 percentage points of the rise in the average of $r_{wd,t}^e$ resulted from the increase in average oil prices (the column “*POIL*”), 0.3 points from the lower average monetary growth (the column “*DM*”), and –0.9 points from the differences in initial conditions. The main change in the initial conditions is the much lower value for $(I/Y)_{wd,t-1}$ in 1981 than in 1975; this effect by itself would have lowered real interest rates for 1981–86. The results from simulations of the unrestricted model, shown in Table 5, are basically similar.

Table 5 also indicates the simulated results for investment ratios. The restricted model predicts that the average of $(I/Y)_{wd,t}$ for 1981–86 would be

19. We do find a significant negative relation between stock returns for year t and the change in oil prices during year t . Also, M1 growth has significant negative reactions to the contemporaneous change in oil prices and to lagged stock returns. We can filter the stock returns to compute the component exogenous to oil-price changes, and we can filter M1 growth to calculate the part exogenous to oil-price changes and lagged stock returns. In the discussion below we attribute changes in expected real interest rates and investment ratios to the behavior of stock returns, oil prices, and monetary growth. The breakdown among these three variables would change if we shifted from gross numbers to the filtered values.

20. The results depend not only on differences in the average value of $STOCK_{wd,t-1}$, but on differences in the time pattern. It is possible for the simulated effects to go in the direction opposite to that suggested just from a comparison of means.

0.9 percentage points below the average for 1975–80, compared to the actual shortfall of 1.1 points. The simulations attribute 0.9 percentage points of the decline in the average investment ratio to higher oil prices, –1.4 points to the more favorable stock returns (which, by themselves, would have raised the investment ratio), 0.2 points to lower monetary growth, and 1.2 points to differences in initial conditions. The main element in the initial conditions is again the lower value for $(I/Y)_{wd,t-1}$ in 1981 than in 1975. The results from the unrestricted model are again similar.

8.2 WHY WERE EXPECTED REAL INTEREST RATES SO LOW IN 1975–80?

We now compare the low average for $r_{wd,t}^e$ in 1975–80, 0.3%, with the higher value, 2.5%, that prevailed during an earlier reference period of the same length, 1965–70. (The results are similar if we pick alternative six-year reference periods in the 1960s or early 1970s.) Section II of Table 5 shows that simulations of the restricted model predict a decline of only 1.3 percentage points in the average of $r_{wd,t}^e$ from 1965–70 to 1975–80 compared with the actual decrease of 2.2 points. The model attributes 1.8 percentage points of the decline to lower stock returns, –1.1 points to higher oil prices (which, by themselves, would have raised expected real interest rates), 0.7 points to higher monetary growth, and –0.1 points to differences in initial conditions. The results from the unrestricted model are similar.

Overall, the largest factor behind the differences in expected real interest rates among the three periods, 1965–70, 1975–80, and 1981–86, is the variation in stock returns. The fall in real interest rates from 1965–70 to 1975–80 goes along with a worsening of stock returns (from 0.9% to –6.2%), and the steep rise in rates in 1981–86 reflects sharply higher stock returns (7.7%). The movements in oil prices are also important, although higher oil prices in 1975–80 compared to 1965–70 partially counteract the movement to lower real interest rates. The increase in oil prices in 1981–86 compared to 1975–80 reinforces the stock market in generating a shift toward higher real interest rates.

8.3 WHY DID EXPECTED REAL INTEREST RATES FALL IN 1987–88 AND RISE IN 1989?

The average of $r_{wd,t}^e$ fell by 1.7 percentage points from 1985–86 to 1987–88 and then rose by 1.1 percentage points from 1988 to 1989. Sections III and IV of Table 5 contain simulations for these periods. The dominant factor behind the decline in real interest rates in 1987–88 is the fall in oil prices. The main element underlying the rise in real rates in 1989 is the

much more favorable stock return in 1988 (15.0%) compared to 1987 (-8.2%).

We have assembled nearly complete data for 1989 on the variables $STOCK_{wd,t}$, $POIL_t$, $DM_{wd,t}$, $(I/Y)_{wd,t}$, and $r_{wd,t}^e$. Using these values, we can use the model to forecast the expected real interest rate and investment ratio for 1990. Remarkably, the restricted model implies a predicted value for $r_{wd,t}^e$ of 5.6% (5.5% from the unrestricted model). The forecast from the restricted model for 1990 not only constitutes an increase by 2.1 percentage points in $r_{wd,t}^e$ from the value prevailing in 1989, it also represents a level that is almost a full percentage point above the highest value of the entire previous sample, 1958-89. The five determinants of $r_{wd,t}^e$ in the model all point in the direction of higher real interest rates in 1990: the favorable stock return (17.4% in 1989 versus 14.8% in 1988) accounts for 0.1 percentage point, the increase in oil prices (.525 versus .406) for 0.5 percentage point, reduced monetary growth (3.2% versus 6.6%) for 0.8 percentage point, and the change in initial conditions (the rise in $(I/Y)_{wd,t}$ from .242 in 1988 to .247 in 1989 and the increase in $r_{wd,t}^e$ from .023 in 1988 to .035 in 1989) accounts for 0.9 percentage point. Needless to say, this prediction of a rise in the expected real interest rate to a range not seen at least in the last 30 years will provide a severe test of the model. With respect to the investment ratio, the restricted model predicts little change from 1989 (.246 in 1990 versus .247 in 1989), whereas the unrestricted model projects an increase by 0.3 percentage point.

Given the stress on fluctuations in the stock market, we would like to know what fundamental factors underlie these fluctuations. (We would, of course, also like to understand the forces that lead to changes in oil prices and monetary growth.) We interpret stock returns as reflecting changes in the expected profitability of investment, $PROF_t^e$, and in the risk premium, ρ_t . We plan to use data on actual profitability to separate the influences from these two channels. At this point, we can only note that the fluctuations in stock prices could derive from technological innovations, changing conditions of labor markets or international competition, shifts in government policies with regard to taxation and regulation, and so on. Although we have not isolated the main forces that influence stock returns, the findings suggest that these forces are crucial for the determination of expected real interest rates and investment ratios.

9. Systems for Individual Countries' Expected Real Interest Rates

In the world model with an integrated capital market, "the" expected real interest rate depends on world variables, which include world aggre-

gates of stock returns and monetary growth and the world price of oil. Thus, the reduced form in equation (7) gives an expression for r_i^e in terms of these world variables. In practice, we observe individual time series, r_{it}^e , for each country i . In the previous analysis we combined these observations into a world index, $r_{wd,t}^e$, that gives more weight to countries with higher shares in world real GDP. Then we related this world index to the world influences suggested by the structural model.

We can think of each country's expected real interest rate as determined by the hypothetical world rate—which depends on world variables in the manner suggested by the structural model—plus some own-country factors. That is,

$$r_{it}^e = r_t^e + x_{it} \quad (11)$$

where x_{it} represents variables particular to country i and r_t^e depends on the world variables as in the previous analysis. Unless the x_{it} are random errors that are perfectly correlated across the countries, we would get more efficient estimates of the determinants of r_i^e by using all the individual observations on the r_{it}^e for the nine countries, instead of combining everything into the world weighted average, $r_{wd,t}^e$. That is, we can think of equation (11) as a system of nine equations, and we can estimate the variance-covariance structure of the error terms, x_{it} , along with the estimation of the coefficients for the variables that determine r_t^e .

When we look empirically at the values of r_{it}^e for an individual country, we typically find a good deal of serial persistence about the rate, r_{it}^e , that can be explained by worldwide forces. We can allow for this effect more or less equivalently by including $r_{i,t-1}^e$ as an element of x_{it} or by treating x_{it} as an error term that is serially correlated. Because it is simpler in the systems discussed below and also delivers somewhat better fits (at least relative to an AR(1) model for the x_{it}), we take the approach of including $r_{i,t-1}^e$ as a regressor.²¹ We do not make any structural interpretations for the statistical significance of this lagged dependent variable. It could reflect a variety of own-country forces that we do not hold constant, including serially correlated measurement error in nominal interest rates or expected inflation and persisting differences across countries in riskiness of real returns or the tax treatment of these returns.

If the world capital and goods markets are fully integrated, shifts to a single country's investment demand or desired saving affect the expected real interest rate only to the extent that these shifts affect the

21. Once we hold fixed $r_{i,t-1}^e$, the determinants of $r_{i,t-1}^e$ (which are second lags of the world variables) are insignificant in the equations for r_{it}^e .

world aggregate of investment demand or desired saving. Therefore, own-country variables like country i 's stock return and monetary growth would matter for r_{it}^e only to the extent that they contribute to the world aggregates of stock returns and monetary growth. With the world variables held constant, the importance of these own-country variables for r_{it}^e will provide some evidence about the extent of country i 's integration into world markets. If the own-country variables are unimportant for country i , we cannot conclude unambiguously that country i is well integrated; that is, country i could be isolated from the rest of the world, but r_{it}^e may nevertheless be insensitive to the own-country explanatory variables we consider. We get clearer evidence from observations in the reverse direction; if r_{it}^e depends in an important way on the own-country variables for country i , then we have an indication that the country is not well integrated into world markets.

Table 6 contains system estimates for r_{it}^e for nine countries over 1959–88. The estimation is by generalized least squares, which allows for estimation of each country's error variance and of contemporaneous covariances across the countries. Roughly speaking, the method of estimation differs from that in Table 2 in that the weight for each country now depends mainly on the estimated error variance, rather than on the relative GDP.

We begin with a model that, aside from $r_{i,t-1}^e$ and individual constants for each country, includes only the world variables we considered before: $STOCK_{wd,t-1}$, $POIL_{t-1}$, $(I/Y)_{wd,t-1}$, and $DM_{wd,t-1}$. These results are in column 1 of Table 6. The estimated coefficients on each of the independent variables, including the lagged dependent variable, are constrained to be the same for each country. In this form, the estimates are similar to those from the comparable equation for $r_{wd,t}^e$ (Table 2, column 2). The main difference (with the increase in the overall number of observations from 30 to 270) is the reduction in the standard errors for the estimated coefficients.

Column 2 of Table 6 adds three own-country variables: $STOCK_{i,t-1}$, $(I/Y)_{i,t-1}$, and $DM_{i,t-1}$. (We assume that $POIL_{t-1}$ takes on the same value for each country; therefore, we cannot distinguish world from own-country values in this case.) We constrain the coefficients of the three own variables to be the same across the nine countries. In this form, a test of the hypothesis that the coefficients on the three own-country variables are all zero leads to the likelihood-ratio statistic 2.7 compared to the 5% critical value of 7.8. Thus, we accept the hypothesis that own-country expected real interest rates depend on the world variables and not own-country variables (aside from the individual constant and the lagged dependent variable).

Table 6 NINE-COUNTRY SYSTEMS FOR EXPECTED REAL INTEREST RATES

Note: The sample period is 1959–88. The dependent variables in columns 1–6 are r_{it}^e for nine countries. In column 7 the dependent variables are the nominal interest rates, R_{it} .

Column 3 of Table 6 retains the three own-country variables added in column 2, but deletes the corresponding three world variables, $STOCK_{wd,t-1}$, $(I/Y)_{wd,t-1}$, and $DM_{wd,t-1}$. A test of the hypothesis that the coefficients of these three world variables are all zero leads to the likelihood-ratio statistic 27.8 compared to the 5% critical value of 7.8. Therefore, the data reject the hypothesis that own-country expected real interest rates depend on the own-country variables and not on the world variables.

Overall, the results in columns 1–3 provide evidence that individual country expected real interest rates depend more on worldwide forces than own-country forces. In this sense, the results suggest that the nine OECD countries were operating to a considerable extent on integrated world markets. Note, however, that the results presented thus far apply when all countries are constrained to have the same coefficients on the world and own-country variables (aside from an individual constant term).

We tested whether the system regression in Table 6, column 1 was stable over the periods 1959–72 and 1973–88. The test for equality of coefficients over the two samples is accepted (likelihood-ratio statistic of 8.8, 5% critical value with 14 restrictions of 23.7).

Column 4 of Table 6 constrains the constant terms to be the same across the countries. The hypothesis of equality is strongly rejected: the likelihood-ratio statistic is 48.1 compared to a 5% critical value of 15.5. In this sense, we confirm the general belief that the average levels of expected real interest rates differed significantly across the nine countries.

Columns 5 and 6 of Table 6 add the world fiscal variables, which we considered before. The results are similar to those found for the world real interest rate in Table 2: the debt variable is insignificant, the unadjusted deficit variable is significantly negative ($-.23$, s.e. = $.07$ in Table 5, column 5), and the cyclically adjusted deficit variable is insignificant (column 6).

Column 7 of Table 6 uses nominal interest rates, R_{it} , as dependent variables and adds the expected inflation rate, π_{it}^e , on the right side. The estimated coefficient on π_{it}^e (constrained to be the same across the countries) is now significantly less than one: $.562$, s.e. = $.034$. To some extent, this result is sensitive to the U.K. data, which exhibit sharply negative values for r_{it}^e in the mid 1970s. If the United Kingdom is allowed to have its own coefficient on $\pi_{uk,t}^e$, the estimated coefficient on $\pi_{uk,t}^e$ is $.42$, s.e. = $.05$, and that on π_{it}^e for the other eight countries rises to $.68$, s.e. = $.04$. Our conjecture is that the departure of this estimated coefficient from unity reflects measurement error in the construction of expected inflation.

Note: Columns 1 and 2 provide fit statistics for individual countries for the system regression shown in Table 6, column 1. Columns 3–5 deal with systems in which individual countries have separate coefficients on four world variables (*STOCK*, *POIL*, *I/Y*, and *DM*) and the lagged dependent variable. Column 3 gives the likelihood-ratio statistic ($-2 \cdot \log$ likelihood ratio) when these individual coefficients are introduced one country at a time. Columns 4 and 5 give fit statistics for each country in a system where all countries have individual coefficients on the five variables noted above. Columns 6–8 deal with systems in which individual countries have separate coefficients on three own-country variables (*STOCK*, *I/Y*, and *DM*), each expressed as a deviation from the corresponding world variable. Column 6 gives the likelihood-ratio statistic when these individual coefficients are introduced one country at a time. Columns 7 and 8 give fit statistics for each country in a system where all countries have individual coefficients on the three own-country variables.

Columns 1 and 2 of Table 7 provide statistics (R^2 and $\hat{\sigma}$) for the individual countries for the system regression from Table 6, column 1. Note that the model explains virtually none of the variations in expected real interest rates for Japan. For the United Kingdom, the high value of $\hat{\sigma}$ seems to reflect mainly the large negative numbers for $r_{uk,t}^e$ in the mid-1970s. The model cannot explain these values, a finding that is reasonable if these observations reflect incorrect estimates of $\pi_{uk,t}^e$.

We tested the hypothesis that the nine countries have the same coefficients on the four world variables, $STOCK_{wd,t-1}$, $POIL_{t-1}$, $(I/Y)_{wd,t-1}$, and $DM_{wd,t-1}$, and the lagged dependent variable, $r_{i,t-1}^e$. If we relax this restriction for one country at a time (with the other eight still restricted to have equal coefficients), we get the likelihood-ratio statistics shown in column 3 of Table 7. At the 5% critical level (with five restrictions), the hypothesis of equality is rejected for only two countries, Canada and Germany. For Canada, the main reason for rejection is that, unlike the other countries, the unrestricted coefficient estimate for the lagged dependent variable is close to zero ($-.05$, s.e. = $.08$).

An overall test for equality of coefficients across the nine countries (40 restrictions) leads to the likelihood-ratio statistic of 83.1 compared to the 5% critical value of 55.5. Thus, the model fails to pass the test that each country's expected real interest rate reacts in the same way to the four world variables and the lagged dependent variable. Columns 4 and 5 of Table 7 show the fit statistics (R^2 and $\hat{\sigma}$) for each country in the unrestricted form. The largest changes from columns 1 and 2 (Canada, Germany, Japan, and the United Kingdom) correspond to the likelihood-ratio statistics shown in column 3.

We also allowed each country to depend in an individual way on its own variables. We constrained the coefficients on the world variables and the lagged dependent variable to be the same across the countries, but we allowed country i to have its own coefficients on the three variables: $STOCK_{i,t-1} - STOCK_{wd,t-1}$, $(I/Y)_{i,t-1} - (I/Y)_{wd,t-1}$, and $DM_{i,t-1} - DM_{wd,t-1}$. By entering these variables as deviations from their world counterparts we constrained each country to react in the same way to equal changes in world and own variables, for example, to an equal increase in $STOCK_{wd,t-1}$ and $STOCK_{i,t-1}$. But we allowed $r_{i,t}^e$ to react in an individual way to a shift in the own-country variable, say $STOCK_{i,t-1}$, for a given value of the world variable. Presumably, the more a country is isolated from world markets the greater will tend to be the reaction of $r_{i,t}^e$ to the own variables.

We first introduced the own-country variables for one country at a time. Own variables (except for the constant and the lagged dependent variable) were excluded for the other eight countries. (Recall that the coefficients of the world variables and of the lagged dependent variable were constrained to be equal for all nine countries.) Column 6 of Table 7 shows likelihood-ratio statistics for tests of the hypothesis that the coefficients of the three own-country variables are all zero. We accept this hypothesis at the 5% critical level for all countries except Japan and the United Kingdom. Thus, the results suggest that these two countries were particularly isolated (for at least part of the sample) from international markets.

We also introduced the three own-country variables simultaneously for all nine countries. Individual coefficients on these variables were estimated for each country. An overall test that all of these coefficients were zero (27 restrictions) led to the likelihood-ratio statistic 74.4 compared to the 5% critical value of 40.1. Thus, the model fails to pass the test that own-country expected real interest rates are unresponsive in an individual way to own-country variables (given common reactions to world variables and the lagged dependent variable). Columns 7 and

8 of Table 7 show fit statistics (R^2 and $\hat{\sigma}$) for each country in the model that allows individual coefficients for all countries on the three own variables. The largest changes from columns 1 and 2 (Japan and the United Kingdom) correspond to the likelihood-ratio statistics shown in column 6.

10. System for Individual Countries' Investment Ratios

We now relate the investment ratio for each of the ten countries, $(I/Y)_{it}$, to world and own-country variables. Unlike for the expected real interest rate, r_{it}^e , the null hypothesis under integrated world markets is not that $(I/Y)_{it}$ depends only on world variables. $(I/Y)_{it}$ would depend on any variable that influences own-country investment demand—notably, the own-country stock return, $STOCK_{i,t-1}$, and the lagged investment ratio, $(I/Y)_{i,t-1}$ —and on world variables through their influence on the world expected real interest rate. Given the world variables (and hence the world expected real interest rate), $(I/Y)_{it}$ would be independent of influences on country i 's desired saving rate. Because $POIL_{t-1}$ is a common influence across countries, the only variable of this type in the previous analysis was own-country monetary growth, $DM_{i,t-1}$. (The own-country fiscal variables would also be in this category, but the fiscal variables were found to be unimportant in general.)

Table 8 shows the results for $(I/Y)_{it}$ for the ten-country system of investment ratios over the period 1959–88. The independent variables are $POIL_{t-1}$; the world and own-country lagged values of $STOCK$, (I/Y) , and DM ; $r_{wd,t-1}^e$,²² and individual constant terms. The regression in column 1 shows a significant, positive effect for $STOCK_{i,t-1}$ (.017, s.e. = .003). This result can be interpreted as an effect from changes in the expected profitability of investment in country i (or possibly changes in the risk premium applicable to these investments). The estimated coefficient of $STOCK_{wd,t-1}$, however, is also positive: .017, s.e. = .008. If the own-country stock return holds constant the expected profitability of investment (risk-adjusted), then the world stock return would influence $(I/Y)_{it}$ only through its effect on world expected real interest rates; that is, the effect of $STOCK_{wd,t-1}$ on $(I/Y)_{it}$ would be negative. It is possible, however, that stock returns in other countries provide information about the profitability of investment in country i , even for a given value of country i 's

22. Because the expected real interest rate is unavailable for Italy we entered $r_{wd,t-1}^e$ for each country. The results change little if we also include $r_{i,t-1}^e$ in the nine-country system that excludes Italy. That is, lags of expected real interest rates are unimportant in general for the investment ratios.

Table 8. TEN-COUNTRY SYSTEMS FOR INVESTMENT RATIOS

| | (1) | (2) |
|------------------|-----------------|-----------------|
| <i>Constant</i> | Separate | Separate |
| $STOCK_{wd,t-1}$ | .017 (.008) | — |
| $POIL_{t-1}$ | -.020 (.006) | -.025 (.004) |
| $(I/Y)_{wd,t-1}$ | .133 (.102) | — |
| $r_{wd,t-1}^e$ | .045 (.059) | .063 (.059) |
| $DM_{wd,t-1}$ | -.049 (.042) | — |
| $STOCK_{i,t-1}$ | .017 (.003) | .021 (.003) |
| $(I/Y)_{i,t-1}$ | .824 (.027) | .823 (.024) |
| $DM_{i,t-1}$ | .039 (.010) | .038 (.010) |

Note: The sample period is 1959–88. The dependent variables are $(I/Y)_i$ for ten countries.

stock return.²³ This outcome might arise if ownership extends across countries or if the stock-price data for some countries are poor measures of the expected profitability of investment in those countries.

As in previous results, the regression in Table 8, column 1 indicates a significantly negative effect of $POIL_{t-1}$ on the investment ratios ($-.020$, s.e. = $.006$). One puzzle is that the estimated coefficient for own-country monetary growth, $DM_{i,t-1}$, is significantly positive ($.039$, s.e. = $.010$), whereas that on world monetary growth, $DM_{wd,t-1}$, is negative but insignificant ($-.049$, s.e. = $.042$). Previously we found an inverse relation between r_{it}^e and the lag of world monetary growth, not own-country monetary growth (Table 6, column 2). Thus, the interest-rate effects suggest a positive connection between $DM_{wd,t-1}$ and $(I/Y)_{it}$, but the results indicate instead a positive coefficient on $DM_{i,t-1}$. (Recall that, for the world variables in Table 3, $DM_{wd,t-1}$ had an insignificant effect on $(I/Y)_{wd,t}$.) There may be an endogenous-money story to explain these results, but we have not yet come up with it.

Column 2 of Table 8 eliminates three world variables from the regres-

23. As a related matter, Barro (1990) finds that Canadian investment responds more to the U.S. stock market than the Canadian stock market.

sion: $STOCK_{wd,t-1}$, $(I/Y)_{wd,t-1}$, and $DM_{wd,t-1}$. Theoretically (abstracting from the possible informational role of world stock prices for own-country profitability), these variables would affect $(I/Y)_{it}$ only through their effects on the world expected real interest rate. The three world variables prove to be jointly insignificant; the likelihood-ratio statistic is 2.9 compared to the 5% critical value of 7.8.

It would be possible to consider the system of equations for investment ratios jointly with the system for expected real interest rates. The restrictions imposed by the structural model could be imposed on this overall joint system. We plan eventually to undertake this grand-system estimation.

11. Summary of Main Results

We thought of the expected real interest rate for the major industrialized countries as determined by the equation of aggregate investment demand to the aggregate of desired national saving. We used stock-market returns to isolate shifts to expected profitability of investment (or risk premia) and, hence, to investment demand. We used oil prices to capture shifts to temporary income and, hence, to desired national saving. In some models, monetary expansion would appear as a positive shock to desired national saving, and in others, fiscal expansion would enter as a negative shock.

We used the structural model to determine a reduced form for the "world" expected real interest rate and ratio of investment to GDP. The main predictions are that more favorable stock returns raise the real interest rate and investment, higher oil prices increase the real interest rate but decrease investment, higher monetary growth lowers the real interest rate and stimulates investment, and greater fiscal expansion raises the real interest rate and reduces investment.

We estimated the reduced form of the model on data for ten OECD countries over the period 1959–88. Thus far, the results pertain to annual data on short-term interest rates. (Because of data problems with Italy we included only nine countries in the equations for interest rates.) The results for world (GDP-weighted) expected real interest rates reveal significant effects in the predicted directions for world stock returns, oil prices, and world monetary growth. Fiscal variables turned out to be unimportant. The behavior of the world investment ratio was also consistent with the model, except that the hypothesized positive effect from monetary growth did not show up and fiscal variables were unimportant.

Estimates of the reduced form that were constrained by the structural restrictions led to estimates of structural coefficients, such as the responsiveness of desired national saving rates to the expected real interest rate. We find that an increase in the expected real interest rate by one percentage point raises the desired saving rate by about one-third of a percentage point.

We simulated the model to try to explain why expected real interest rates were high for 1981–86 (averaging 4.2%) and low for 1975–80 (averaging 0.3%). The dominant influence was the variation in stock returns; these returns were very low for 1974–79 and much higher for 1980–85. The increase in oil prices from the early 1970s until 1986 is also an important factor. We attributed the drop in expected real interest rates for 1987–88 (to an average of 2.3%) mainly to the decline in oil prices, and the rise in the rate for 1989 (to 3.5%) mainly to the improved stock market in 1988. The model also forecasts a dramatic rise in the expected real interest rate to 5.6% in 1990. This value is almost a full percentage point above the highest value that occurred during the period 1958–89.

We estimated systems of equations for expected real interest rates for nine OECD countries. (We also estimated systems of equations for investment ratios for ten OECD countries, including Italy.) These systems include world and own-country variables as regressors. One finding is that each country's expected real interest rate depends primarily on world factors, thereby suggesting a good deal of integration of world markets. We do find, however, significant effects of own-country variables for Japan and the United Kingdom. Our interpretation is that these countries were significantly isolated from international markets, at least over part of the period 1959–88.

The research carried out thus far suggests a number of avenues for future work. The possibilities that we are presently pursuing are the analysis of longer-term interest rates, the inclusion of measures of the profitability of investment, the addition of variables such as defense expenditures that represent exogenous shifts to desired saving, consideration of tax effects related to interest income and expenses, and the estimation of equations for expected real interest rates and investment ratios with quarterly data. We are also considering a division of investment into components that would be especially sensitive to the stock market (business nonresidential investment) and those that would be less sensitive (residential investment, public investment, and purchases of consumer durables). Finally, we are looking into the possibilities for adding more countries; Switzerland and Australia appear to be the most promising in terms of the availability of data.

Note: The dependent variable is the inflation rate for each country. Each quarterly value is expressed at an annual rate. The sample period is 1952:2–1989:3. S1 is a dummy for quarter 1 (January to April), and so on. AR(1) is the first-order autoregressive error term and MA(1) is the first-order moving-average error term. Q(4) is the Q Statistic with 4 lags.

Table A2 DEFINITIONS AND SOURCES OF VARIABLES (DATA ARE ANNUAL UNLESS INDICATED OTHERWISE)

| | |
|---------|--|
| R | 3-month Treasury bill rate for January, April, July, October, except money-market rate for France and Japan, from <i>International Financial Statistics (IFS)</i> and OECD, <i>Main Economic Indicators</i> . |
| P | Consumer price index (1980=1.0), seasonally unadjusted, for January, April, July, October, from <i>IFS</i> . |
| π_t | $4^* \log(P_{t+1}/P_t)$, quarterly. |
| r | $R - \pi$, quarterly. |
| π^e | Constructed measure of expected inflation, quarterly. |
| r^e | $R - \pi^e$, quarterly. |
| Y | Real GDP (deflator = 1.0 in 1980) from OECD <i>National Accounts</i> . |
| I | Real gross domestic capital formation (deflator = 1.0 in 1980) from OECD <i>National Accounts</i> . |
| STOCK | Real rate of return on stock market. Nominal returns are computed from <i>IFS</i> data for December on industrial share prices. Consumer price inflation (December-to-December) was subtracted from the nominal returns to calculate the real returns. |
| POIL | Ratio of U.S. PPI for crude petroleum to overall U.S. PPI (1982 base), from <i>Citibase</i> . |
| DM | Growth rate of M1, computed from December values for M1 from <i>IFS</i> . |
| RDEBTY | Ratio of end-of-year real central government debt (nominal debt at par value divided by the December CPI) to real GDP. For BE, CA, FR, GE, IT, and NE, the debt figures are the sum of domestic and foreign debt from <i>IFS</i> . For JA, the data are from <i>Monthly Statistics of Japan</i> ; for SW, <i>Monthly Digest of Swedish Statistics</i> ; for UK, Central Statistical Office, <i>Annual Statistics</i> ; for US, <i>Economic Report of the President</i> . |
| RDEFY | Ratio of real budget deficit to real GDP. The real budget deficit is the change in the real debt for the year. The real debt is the ratio of the nominal debt to the December consumer price index. |
| RDEFYA | The residual from a regression of RDEFY for each country over 1958–87 on the current and four annual lags of the growth rate of real GDP. |
| WTXX | Share of country XX in the ten-country Summers-Heston (1988) real GDP. |

Comment

WILLIAM BRAINARD

The behavior of real interest rates, particularly in the last decade, has puzzled many observers. In this paper Barro and Sala-i-Martin make a

bold attempt to explain the “world” real interest rate with a simple model in which that rate is determined by the condition that world investment be equal to world saving. The paper is stimulating to read and rich with information and puzzles. It is written in a commendable style—clear about the data, candid about contradictory results. Artful in the specification of the model, Barro and Sala-i-Martin are at the same time disarmingly diffident about the theory. Although I have reservations about both the theory and some of the authors’ conclusions, I admire their willingness to tackle an inherently difficult problem and their resourcefulness in creating a coherent picture of the experience of the last 30 years.

1. Overview of the Model

The authors’ model is “classical,” consisting simply of an investment equation and a saving equation, plus the condition that saving and investment be equal. Each equation contains only one right-hand-side endogenous variable, the real interest rate. Since nothing else is free to give, the real interest rate is determined by the equilibrium condition. Hence the real rate is determined by exogenous factors shifting investment or saving. In the authors’ specification these are few in number; investment depends on a “ q -like variable” and saving depends on transitory income and the real rate of interest.

The theoretical framework the authors use for organizing their investigation has the virtue of simplicity, but its very simplicity precludes examination of some major hypotheses about the movements of the real rates during their sample period. The classical model usually comes with the assumption that income is always at full employment. The authors do not make that assumption explicit, and indeed they allow changes in transitory income to affect the saving ratio. But, as in the classical full-employment model, adjustments in income play no role in transmitting shocks to interest rates or investment ratios and they do not test the validity of that assumption. Hence, for example, they do not examine the role that a worldwide recession may have played in explaining why real rates appear to fall following OPEC 1. Indeed the reader will not find a figure or time series for income in the paper.

Similarly, the interplay of inflation, income, money, and nominal rates is not modeled. Prices are gotten out of the way early, for most of the analysis an estimate of inflationary expectations is used simply to calculate the expected real rate from nominal rate. The classical role of prices in maintaining full employment, and their success in doing so, is not examined. The transmission mechanism for monetary policy is missing.

The authors do allow the possibility of non-neutrality of money in the short run, but in their model money enters directly in the saving schedule, with monetary expansion presumed to increase saving at a given real rate of interest. The suppression of the demand and supply for money obscures the way in which monetary events may affect investment, saving, and interest rates. Placing money in the saving function, with income exogenous, in my view does not do justice to the possible role of money. In the usual story, an increase in the expected rate of growth of money and associated inflation shifts downward the stock demand for money and decreases the required rate of return on bonds or capital. In the short run easy money, in the level or expected rate of change, lowers real rates as well as nominal because price changes do not fully offset the nominal changes. Hence, expansionary monetary encourages investment and increases income. These effects can be present even if saving is inelastic with respect to interest rates and real balances. According to the authors' model the reason tight money raised real rates in 1979 was because it decreased desired saving, not because reduction of the money supply forced up nominal rates in the money markets much more rapidly than inflation could possibly subside.

While I am somewhat skeptical about the meaningfulness of a "world" rate, particularly early in the sample period, focusing on an average of real rates for a number of countries can be a useful enterprise even if world capital markets are not perfectly integrated and the assets of different countries are not perfect substitutes. Averaging real rates, investment ratios and explanatory variables across countries wash out idiosyncratic fluctuations, giving the investigator a better chance at detecting the importance of common factors such as oil-price shocks. Such shocks to the world economy could have similar effects on many countries even if capital markets are not integrated. But the authors' analysis does provide them some evidence on the extent of integration.

How many countries need to be considered in analyzing the world interest rate is another question. The authors assume their ten countries are the entire world; hence they do not need to worry about an external sector and the role that export demand and capital flows may play in the determination of investment and interest rates. They argue that this is not an unreasonable assumption since the countries represent approximately two-thirds of world output and because the observed current—the account balance of the ten country aggregate has been small. As a theoretical matter the fact that the current account balance tends to be small is not a sufficient condition for treating a group of countries as "closed"; on the empirical level the assumption rules out a major issue surrounding the effect of the OPEC oil price increases, namely the extent

to which the OPEC nations increased their demand for imports from the oil-consuming nations, and “recycled” their increased income. In the authors’ model these oil-price increases are treated simply as a transitory reduction in income, with a negative effect on saving.

IMPLEMENTATION

Like any empirical investigation, implementation of the authors’ model requires a multitude of judgments about specification and about the empirical counterparts of the variables appearing in the theoretical model. I found most of the authors’ decisions sensible. Furthermore, the authors are well aware of many of the potential difficulties with the particular choices they have made. Nevertheless several specification issues are worth mentioning.

2. “The” Real Interest Rate

The expected real rate of interest is taken to be a short-term rate minus expected inflation. The authors’ recognize that it would be desirable to extend the analysis to the rates on assets of longer maturities and different risks. Longer rates are probably a better approximation to the cost of capital than the short rate and its behavior is, if anything, more puzzling than that of the short rate. The required rate of return on equity, presumably more relevant to investment than the required rate on nominal assets, not only contains a substantial risk premia but appears to vary relative to the rates on nominal assets. A second concern is the authors’ use of consumer price indexes in converting to a real rate. Because of OPEC and exchange rate fluctuations during the 1970s there was a substantial difference between the inflation in consumer prices and the inflation of capital goods prices relevant to the cost of capital. Most firms were not experiencing increases in their product or capital goods prices as large as those faced by consumers. Hence, the authors may substantially overstate the decline in the real rate relevant to investment—expected and actual—during that period. The authors do report two regressions with the nominal rate as the dependent variable and expected inflation as an additional explanatory variable. In these equations the coefficients on the other variables are essentially the same as in expected real rate equations, but the estimate on expected inflation is less than one. In the case of the country rate equations the point estimate is .562, over ten standard errors away from one. Taken at face value this result suggests that the expected real rate is highly negatively correlated with the level of inflation. The authors suggest that the result is likely to

reflect measurement error in expected inflation, but it should be noted that studies not subject to that problem, using the nominal rate to predict future inflation, get essentially the same result.

3. *The Investment Equation*

The investment equation is determined by “a q -like variable”; prior stock returns and the change in the real rate are used to proxy for the change in q . Investment demand is expressed as a ratio to GDP. Hence, the elasticity of investment with respect to income is assumed to be one with adjustments of investment to income entirely within the year. This assumption is inconsistent with the results of most empirical work. Since the authors use gross, not net investment, depreciation is implausibly assumed to be a fixed proportion of income.

Stock returns are taken to be a proxy for future expected profits. Empirically, stock returns do not do well in forecasting profits. For example, a simple regression of the net rate of return on capital (private, nonfarm) on two lags of the annual stock return yields insignificant coefficients and an R^2 of less than 4%. The stock market is forward looking, and it seems likely market returns reflect expectations about a variety of factors other than profits relevant to investment—including future monetary policy, income, and inflation. Hence, the interpretation of the positive coefficient on the market return is open to a wide variety of interpretations. For example, if the stock market does a good job forecasting inflation and nominal rates do not fully adjust to inflation, then periods of low market returns will be followed by low real rates (assuming inflation is bad for the market for at a given real rate). While relating investment to market returns is itself an achievement, it leaves us with an even greater need to explain the market itself.

Investment is taken to be gross domestic capital formation, which includes both residential and public investment. It does not seem likely that stock returns are a good explanatory variable for either. The inclusion of public investment also implicitly treats public investment as a perfect substitute for private. This specification could help explain why the authors find a significantly positive relationship between investment and government deficits, a result they believe is opposite that predicted by models where fiscal deficits lower national saving. If, in fact, government investment is less than a perfect substitute for private, as seems likely, then exogenous increases in public investment, correlated with the deficit, would create a positive correlation between gross capital formation and the deficit even with crowding out.

4. *The Saving Equation*

Saving, like investment, is gross of depreciation and expressed as a ratio to income. Hence, the elasticity of saving with respect to current income is one for a given ratio of transitory to permanent income. A consequence of the assumption that both the investment and saving equations are expressed in ratio form is that fluctuations in income can have substantial effects on investment and saving.

The relative price of oil is used as a measure of transitory income in the saving equation and excluded from the investment equation, providing identification. It could just as well be argued that it belongs in the investment equation. Some of the effect of changes in oil prices may be captured by stock market returns; however it can be argued that changes in the relative price of oil may change the relationship between marginal and average q . Stock returns are excluded from the saving equation, thereby providing identification. For both wealth and rate of return reasons it could be argued they belong.

Although their theoretical specification distinguishes between transitory and permanent income, in their estimation the authors simply take the relative price of oil as a measure of transitory income. The authors make no attempt to econometrically distinguish between transitory and permanent changes in income.

The authors test for Ricardian equivalence by introducing the real value of government debt and its change (the "real deficit"), both cyclically adjusted and unadjusted, in the saving function. These tests are not the centerpiece of their study, but I would have preferred a more extensive investigation of possible fiscal effects, particularly since some observers have argued that fiscal deficits are partly responsible for the current high level of real rates. There are a number of issues. I am skeptical that this measure of the deficit is an adequate summary of the effect of government fiscal policy on saving; it attempts to capture rather different fiscal events in single a variable. First, in principle government consumption, government investment, and taxes could have quite different effects. Indeed, Ricardian theory itself distinguishes among these three. The authors do report that an attempt to find effects of government consumption were unsuccessful. Second, whether it is called money illusion or a distribution effect, there is empirical evidence that the effect of a tax increase on saving is different from that of a capital loss of the same dollar value. Furthermore, changes in real wealth due to changes in the price level may have a different effect than changes in market value associated with changes in interest rates. Lastly, it would be desirable to distinguish, for any of these variables, between expected and unexpected changes.

For testing Ricardian equivalence I would also have preferred a more inclusive measure of government. The authors' fiscal measures do not include state and local governments. For the United States, at any rate, the combined government deficit is substantially different from the federal deficit in the latter part of the sample, with state and local surpluses partially offsetting central deficits.

As I believe Lucas will discuss, the model gives no role to the rate of growth of income or consumption in the determination of real rates. Such differences, in theory, should be important in explaining differences in rates across countries.

5. Results

Notwithstanding these concerns about the econometric specification, world stock returns and oil prices are estimated to have positive and significant effects on world real interest rates. The reduced form equations explain approximately 90% of the fluctuations of interest rates and 85% of investment during the 1959–1988 period. The equations do underpredict the decline in the expected real rate by approximately 1% for the period 1975–80. Unexpected inflation was positive during most of the period so the equations underpredict the actual real rate by more. (The difference between expected and actual real rates was dramatic in 1973–74.) The equations do better in predicting the rise in the expected real rate in the 1980s. The model's forecast of inflation, however, are typically low during this period; hence actual real rates average about a percent below the expected real rate.

Stock returns are the most important variable in explaining variations in the real rate over the sample. For example, the estimates attribute about 2.5% points of the approximately 4% rise in the expected real rate between 1975 to 1980 and 1981 to 1986 to higher stock returns during the later period. Oil prices are also important, their increase in 1975–1980 over the late 1960s partially offsets the increase attributed to stock prices, and further increases are estimated to add 1.9% to the expected real rate in the 1980s. Although monetary growth is significant in the rate equations, world monetary contraction explains only a small portion of the increase in real rate during the 1980s. Fiscal variables are not significant.

Investment is positively related to stock returns and negatively related to oil prices, consistent with both the theory and the rate equations. However, inconsistent with the predicted effect of monetary growth on the real rate, it appears to have no effect on investment. Similarly, the budget deficit variables appear to have substantial and significant posi-

tive effects on investment even though they appear to have essentially no effect on rates. The authors suggest the positive coefficients are inconsistent with the view that fiscal expansion lowers desired national saving. They need not be for at least two reasons. First, proponents of the view that government deficits crowd out private investment are referring to the effect on national saving with output *constant*, either because monetary policy offsets fiscal expansion or because the economy is operating at capacity. The authors do not control for output; endogenous increases in output in response to fiscal stimulus would be expected to increase saving, and could even induce increases in private investment. Second, as discussed above, the fact that the authors have included government investment in their investment series could explain a positive coefficient.

It is hard to argue against the proposition that nominal short-term rates and expected exchange rate changes are tied together in international financial markets. But given the poor performance of purchasing power parity it would be more of a surprise if real rates were tightly tied together. The authors investigate the degree of integration by introducing country variables in the various estimated equations. If capital markets are well integrated and assets close substitutes, individual countries' real rates and investment should primarily reflect world variables rather than country variables; country saving, however, should reflect individual country effects even if markets are integrated.

The authors' specification provides only a weak test of the integration hypothesis. Separate intercepts and the own-country lagged dependent variable are included in both the rate and investment equations. Hence, systematic differences in real rates are not taken as evidence against the hypothesis and differences in average values of explanatory variables across countries are not allowed to explain cross-country differences in investment or interest rates. For example, high average investment in Japan is not credited to a low-average real rate or high-average stock return. The country intercepts and coefficients on lagged own-country dependent variables that soak up these country effects are highly significant.

In the rate equations world stock returns do hold up quite well in competition with country returns. The coefficient (when constrained to be equal across countries) is roughly the same as in the world rate equation and own returns are insignificant. World money growth continues to be highly significant, whereas own money is marginally significant and of the "wrong" sign. These results suggest a high degree of integration and substitution between different countries assets; however if the markets are well integrated and the assets close substitutes, the

magnitude of the responses should also be equal. The authors' reject the hypothesis of equality but find the rejection reflects significant differences for only two of the nine countries.

The integration hypothesis does less well in the case of investment. The coefficients on world and country stock returns are about equal and half the magnitude of world returns in the world rate equation. World money, lagged world investment and real rates are all insignificant. Tested jointly, world variables are insignificant; yet all three country-specific variables are highly significant. The authors are puzzled by the importance of own-country monetary expansion given the world rate is insignificant and own money has the wrong sign in the rate equation. One possible explanation is that investment shocks, with resultant increases in the country's income, are partially accommodated by the monetary authority. The significant, and "wrong" signed coefficient on own money in the rate equation could be similarly explained; since own investment does not appear to affect interest rates the shocks to income would have to be from another source.

In some respects the paper is quite successful. The authors have clearly identified important comovements of real rates, investment, stock returns, and oil prices during this 30-year period. Furthermore, they have shown that salient features of economic performance during this period are worldwide, and that some phenomena are best explained from a world perspective. The results, however, do not give strong confirmation of the model. As the authors suggest, there is room to interpret the coefficients on the two major "exogenous" variables—stock prices and the relative price of oil—in alternative ways. Their work does add to the evidence that the movements of the stock market are intimately connected with investment and real rates—further whetting the profession's appetite for a satisfying explanation of the market's own behavior. The authors promise to continue working in this fruitful area and I look with anticipation to reading their future work.

Comment

ROBERT E. LUCAS, JR.

The paper by Barro and Sala-i-Martin deals with the determination of interest rates in nine OECD countries over the period 1959 to 1988, with particular emphasis on the question of why real rates in all these countries were so high in the 1980s and so low in the 1970s. The authors construct time series on real interest rates and other variables for each

country and then aggregate these data to obtain series on a world economy, viewed as closed in the sense that savings and investment are assumed to be equal. They report regression estimates of equations for world real interest rates and world investment (relative to output), and also report results of tests on the quality of the one-world abstraction they use.

In my comments I will focus exclusively on the interest rate results, first describing the procedures used in the study, next describing the features of the results that are of most interest to me, and then interpreting these results from a Fisherian viewpoint that differs from the theoretical framework used by the authors. After this, I offer some opinions on the sources of interest rate movements over the last 30 years.

Barro and Sala-i-Martin begin by subtracting a calculated measure of expected inflation, a distributed lag on past inflation rates, from each country's nominal interest rate series. They call the result the "expected real interest rate," and its weighted average over the countries in the sample the "world real interest rate." This variable is then regressed on its own lagged value, a lagged measure of world stock returns, lagged oil prices, the lagged ratio of investment to GNP, and the lagged rate of world money growth. Some fiscal variables are also used as regressors, but their estimated effects are negligible.

Table 1 of the paper summarizes the behavior of these world variables and of their counterparts for the individual countries. The main results for the world interest rate are reported in Table 2. The responses of the world real rate to the regressors are substantial. I will just report that we used to call the "long-run" responses, obtained by multiplying the coefficients by one minus the coefficient on the lagged dependent variable. A 1% increase in stock returns (which averaged 2.2% over the period) increases the real interest rate by 0.13%. A 10% increase in oil prices (from its mean of 0.56) would add .045% to real interest rates. A 1% increase in the world rate of money growth would reduce real rates by 0.52%. (These numbers are all taken from the coefficients in Table 2, column 2.)

I was interested in the contributions of real and monetary forces in explaining *nominal* interest rates, and so attempted to decompose the variance of nominal rates based on the statistics reported in Table 2. This is not quite possible from statistics reported in the paper, but assuming enough orthogonality in the right places, one can get close. Let r be the world nominal rate, let π be the explained part of the expected inflation component, let ρ be the explained part of the expected real component, and let ϵ be an error: $r = \rho + \pi + \epsilon$. Assume that ρ , π , and ϵ are all mutually uncorrelated, so that $\text{Var}(r) = \text{Var}(\rho) + \text{Var}(\pi) + \text{Var}(\epsilon)$. In this

notation, column 2 of Table 2 is a regression of $r - \pi$ on ρ and column (5) is a regression of r on ρ and π . Then the R^2 from column 2, .89, is an estimate of $\text{Var}(\rho)/[\text{Var}(\rho) + \text{Var}(\epsilon)]$. The R^2 from column (5), .96, is an estimate of $[\text{Var}(\pi) + \text{Var}(\rho)]/[\text{Var}(\pi) + \text{Var}(\rho) + \text{Var}(\epsilon)]$. From either column 2 or 5, $\text{Var}(\epsilon) = (.0054)^2$. Then the implied variance of the explained real rate is $\text{Var}(\rho) = (.0154)^2 = .000236$. The implied variance of the explained inflation premium is $\text{Var}(\pi) = (.0215)^2 = .000464$.

In summary, then, Barro and Sala-i-Martin view world nominal interest rates as a well understood time series, with about .96 of its variance explained. About one-third of this explained variation is due to real factors, and about two-thirds is attributed to expected inflation. According to their estimates, world real interest rates were 2 or 3% higher in the 1980s than in the 1970s. They attribute this difference to higher stock market returns in the 1980s, and slower money growth and higher oil prices.

In evaluating these conclusions, I did not find the theoretical framework offered in the paper especially helpful. Barro and Sala i Martin use a Fisherian framework to remove the expected inflation rate from each country's nominal rate series, and then switch to a kind of IS-LM set-up to interpret movements in the real rate. Both lagged oil prices and lagged money growth are introduced into a savings function, rationalized as indicators of temporary income. (Oil price increases depress temporary income, reduce savings, and increase real interest rates. Slow money growth has the same effect.) Since temporary income is easy to measure directly, I did not see the advantage of this indirect method. But my understanding of the rationale for the separate savings and investment functions the authors use an inadequate basis for any strong opinions as to what variables belong on the right side of either equation. Anyway, it is a free country and I suppose one can calculate any sample moments one likes.

For myself, I prefer a more thoroughgoing Fisherian viewpoint for thinking about real as well as monetary forces. According to Fisher, the expected real rate can be expressed both as an expected marginal rate of substitution between current and future consumption and as an expected marginal productivity of capital, so one can interpret the right hand side of Barro and Sala i Martin's real interest rate equation as a conditional expectation of either or both of these magnitudes. From this point of view, some aspects of the world real interest results reported in Table 2 seem qualitatively reasonable and some do not. An increase in stock returns or in the lagged investment rate can be taken to reflect optimism about future marginal products of capital that also raises real interest rates. Effects of lagged money growth in either direction can be rationalized, roughly speaking, in several ways. An increase in the price

of a complementary factor of production, oil, ought to reduce the expected marginal product of capital and depress real interest rates, although any quantitatively reasonable assessment of this effect that I have seen suggests it is negligible.

But there is an asymmetry in Barro and Sala-i-Martin's treatment of real and nominal forces on nominal interest rates that makes the results difficult to interpret in this Fisherian manner. The variables that agents are assumed to use to form expectations on future inflation—lagged inflation rates—have coefficients (in explaining nominal rates) that are taken from regressions of actual inflation rates on lagged rates. That is to say, expectations of inflation are required to be *rational*. The variables that agents are assumed to use to form expectations on future marginal productivities of capital—stock returns, lagged investment, and oil prices—are simply included on the right side of the real interest rate equation with coefficients left free. The authors impose *no* requirement that agents' forecasts of real returns be rational expectations of any observable magnitude. No evidence is presented that any of these regressors conveys useful information on future real returns to capital, or that the coefficients of any of these variables are consistent with this information.

I think this is the reason that Barro and Sala-i-Martin's results seem so much more successful than other recent attempts to account for interest rate behavior in terms of fundamentals—variables that provide information about the actual return on bonds. Hansen and Singleton (1983), for example, found that the way nominal Treasury bill returns react to lagged variables in U.S. monthly data does not correspond at all well to the information these variables contain on future inflation rates or future real returns. From Hansen and Singleton's viewpoint, interest rates are a poorly understood time series, and we are thus in a poor position to say why they moved however they did in any particular period. If Barro and Sala-i-Martin had required their expected real interest rate to be a rational expectation of future real returns, as Hansen and Singleton did and as they themselves did with the expected inflation component, they too would have concluded (I conjecture) that interest rates are poorly understood series.

I hope it is clear that these are difficulties that arise within my preferred framework, not within Barro and Sala-i-Martin's. They use an IS-LM framework that I do not understand and do not attempt to criticize or interpret. What I have argued is that *if* one interprets their results from a Fisherian viewpoint, both their decomposition of interest rate movements into a real and expected inflation component and their conclusion that the real component is well explained by the lagged variables they use are not especially convincing.

In fairness, I should add that while I have been referring to the Fisherian framework for thinking about interest rates, it is far from clear what this framework *is* in an application involving many countries. Does one view the entire world as operating in a full set of Arrow-Debreu markets? Or should some assets be viewed as nontradable and, if so, which and why are they not? By simply postulating investment and savings functions, Barro and Sala-i-Martin have evaded these questions, but by discussing the nine OECD countries as a single Fisherian economy, so have I.

Why *were* real interest rates so high in the 1980s? I think a discussant who disputes a paper's answer to an interesting substantive question is under some obligation to supply one of his own, and this I will do (with suitable qualification). Consumption growth (in the United States) was about 1 higher (.038) in the 1960s and 1980s than in the 1970s (.029). Since the real rate is linear in the rate of consumption growth, with a coefficient equal to the coefficient of risk aversion, one can explain perhaps a 2 difference in interest rates between the 1980s and the 1970s as real. This is an outside estimate, I think, since it assumes that the increased consumption growth was expected and because I think a risk aversion coefficient of 2 is on the high side.

Beyond this, I would attribute *all* the remaining difference in nominal rates, and most of the year-to-year variance in these rates, to changes in expected inflation rates. Throughout most of the 1970s, I think people in the OECD countries expected inflation rates to be reduced to earlier levels; throughout most of the 1980s, they expected high inflation to resume. After the fact, these beliefs were proven wrong and for many years they were less accurate than extrapolations based on inflation rates in the recent past would have been. The alternative view, within a Fisherian framework, is that people repeatedly underestimated real returns on capital throughout the 1970s and then repeatedly overestimated real returns through the 1980s.

The point is that people's expectations were wrong about *something* during this period. We can choose to interpret these errors as mistakes in forecasting the relatively smooth series on marginal rates of substitution and transformation, or we can interpret them as errors in forecasting the monetary and fiscal policies of the governments of the OECD countries. This may seem an unattractive choice to have to make, and I suppose we would all like to have some more options—but what are they?

Discussion

Barro responded to the discussants by noting that the treatment of public investment does not affect the results. He also suggested the price of oil could affect investment demand in addition to desired savings due to differences in marginal and average q or to irreversibility of investment, but that without better instruments they used just the price of oil.

Robert Hall noted in response to Robert Lucas that changes in consumption are unrelated to interest rates, suggesting that there is a good deal of noise in consumption. He also wondered whether the authors should have considered the underlying fundamentals driving the financial variables. Barro replied that this would not present an econometric problem.

Greg Mankiw noted that the paper examines ex-post interest rates and suggested looking at ex-ante rates as well. Robert Lucas asked why the authors did not interpret the issue in terms of marginal rates of substitution and transformation. John Cochrane suggested that marginal rates of substitution are roughly constant through time.

David Wilcox noted that the authors were not doing a purely Ricardian experiment since they did not control for expected government spending in the regression. He also suggested the authors could impose unified capital markets when looking at expected inflation in different countries. Barro responded that they didn't have expected spending and actual government spending was insignificant in the regressions.

Ben Bernanke suggested that the assumption that real interest rates are the same in all countries requires purchasing power parity to hold. He also noted that if the real interest rate is constant people consistently over- or underestimate inflation.

Stanley Fischer noted that the deficit measure ignores monetary financing of the deficit. Barro responded that they would look at that issue.

Mankiw suggested that the authors were correct in choosing the framework they did rather than focusing on marginal rates of substitution and transformation. He also asked whether the authors had an explanation for the relation between money changes and investment rates. Barro responded that they did not have a good explanation for this.
