Abstract

Evidence of instability of the wealth effect in the USA is presented through the estimation of a Markov switching model of the long-run aggregate consumption function. The dating of the regimes appears to bear relation to movements in asset prices. A model-based explanation of the findings is suggested, highlighting the importance of the short-run relation between consumption, income and wealth in explaining the estimated long-run coefficients.

1　Introduction

The 1990s witnessed a remarkable increase in stock prices in the USA. Between January 1995 and September 2000, the S&P 500 stock price index rose approximately by 230 percent. According to Poterba (2000), this increase accounted for more than 60 percent of the wealth creation in the USA during that period. Boom/bust periods in stock markets, and their effects on total wealth and consumption, have raised several questions for economic analysis. In particular, there is an ongoing debate on the appropriate Federal Reserve response to movements in stock prices.

Several authors have questioned the stability of the wealth effect estimates. For example, Ludvigson and Steindel (1999) estimate the wealth effect to be the usual 0.04 for their full sample, 1953-1997. However, their estimate reaches 0.1 in the 1976-1985 sub-sample, and is only 0.02 after 1986. Furthermore, Mehra (2001) corroborates the view that the estimate seems to depend on the econometric model, the measures of wealth and consumption, and on the sample. Poterba (2000) puts forward three reasons that might explain the observed signs of instability. First, the fact that only a subset of households own equity, which was the main source of shocks to aggregate wealth in that period. Second, the growing importance of equity investments that are held in tax-favored retirement accounts. Third, the falling cost of leaving bequests. In this paper we report additional empirical evidence on, and provide an explanation of, the instability of the wealth effect.

The paper is structured as follows. In the next section we use a simple cointegrated Markov switching model, which allows us to distinguish endogenously between periods with different values for the wealth effect estimate. We relate these sub-samples to periods with different levels of volatility in asset prices. We then present in section 3 a model-based explanation of the econometric

3

results. Section 4 concludes.

2   Empirical Analysis

The standard derivation of the "consumption function" (see, e.g., Lettau and Ludvigson, 2001, LL henceforth) begins by assuming that consumption tends to a stationary fraction of total wealth, which allows us to write a cointegrating relation between (the logs of) consumption (c_t) and total wealth (w_t):

$$c_t - w_t = u_t, \tag{1}$$

where u_t is a stationary process. Such a result may be obtained from the usual micro-founded model of consumption (e.g., Campbell and Mankiw, 1989) if one assumes that the period utility is well approximated by a log function of consumption. The derivation then proceeds to separate total wealth into human and non-human wealth

$$w_t \approx \omega a_t + (1 - \omega) h_t, \tag{2}$$

where a_t is log non-human wealth, h_t is log human wealth and ω is the average weight of non-human wealth in total wealth. Since human wealth is not observable, LL (2004) show that an approximation[1] may be obtained by using labor income, y_t, as a proxy for h_t, resulting in the following log consumption-wealth ratio

$$c_t - \omega a_t - (1 - \omega) y_t = u_t^*. \tag{3}$$

These authors show that c_t, a_t and y_t share a common trend, with normalized cointegration vector $(1, -\beta, -\delta)$ and cointegration residual $c_t - \beta a_t - \delta y_t$ (cay_t in brief)[2]. The coefficient β is interpreted as the "wealth effect", their estimation

---

[1]See LL (2001 and 2004) for a more detailed discussion of the assumptions employed in the approximation.

[2]Note that the coefficients β and δ need not sum to 1, since non-durable consumption and services are used as a measure of total consumption.

4

yielding $\hat{\beta} = 0.3$ and $\hat{\delta} = 0.6$.

LL (2004, section 4) discuss the stability of the long run relationship, resorting to the sup, mean and L_c tests of Hansen (1992), which produced ambiguous results. Indeed, sequential tests of this family may not be able to detect certain types of structural change, such as Markov regime shifts or threshold effects, as shown by Carrasco (2002). Therefore, a simple way of assessing instabilities in the consumption-wealth ratio is to allow the relationship to undergo occasional discrete shifts of the Markov switching type, as suggested by Hall, Psaradakis and Sola (1997). Thus, we specify the cointegration equation as

$$c_t = \mu_{s_t} + \beta_{s_t} a_t + \delta_{s_t} y_t + \eta_{s_t} \varepsilon_t, \tag{4}$$

where $\{\varepsilon_t\}$ is a stationary random sequence with mean zero and unit variance, while s_t is a discrete-valued random variable, independent of ε_{t-i} for all i. This variable indicates the unobserved regime operative at time t, forming a homogeneous first-order Markov chain with state space $\{0, 1\}$ and transition probabilities $p = \Pr(s_t = 1 | s_{t-1} = 1)$ and $q = \Pr(s_t = 0 | s_{t-1} = 0)$.

Notice that the formulation in (4) is very flexible, in that it allows the data to determine when and which parameters have shifted, be it the long run coefficients or the variance (see Hall *et al.*, 1997, for more details on the use of MS models in a cointegration setting). Other papers (Ludvigson and Steindel, 1999 and Mehra, 2001, for example) have relied on an *ad-hoc* choice of break points. This model, however, will be able to distinguish endogenously periods where, for instance, asset markets and returns may be behaving differently. This is particularly convenient to study the implications of the theoretical model developed in the next section.

Table 1 records the results of maximum likelihood estimation of the parameters of model (4) and respective asymptotic standard errors[3]. Both the

---

[3]We resort to the same dataset used in LL (2004), comprising quarterly data on aggregate

5

LR test and the model selection criteria favour the MS model over the linear cointegration specification[4]. The MS model identifies two distinct regimes: regime 1 is associated with more volatile periods, which roughly coincide with historical "bull" markets, such as those of the late 1960s and 1990s, while regime 0 is associated with "calmer" periods. Figure 1 shows the smoothed probabilities produced by the MS model, plotted against fluctuations in the consumption-wealth ratio as estimated by LL (2004), confirming the view that the identified regimes seem to capture the state of asset markets and of the economy.

In state 1, the coefficient associated with asset wealth is smaller (0.22) than in state 0 (0.29), which is consistent with the empirical evidence surveyed in Poterba (2000) and Mehra (2001). It is interesting to notice that the difference between the β's and the δ's across regimes is approximately the same (0.07). Although these fluctuations do not appear to be sizeable, the cointegration vector estimated by LL (2004) seems to be a "composite" estimate of the different regimes. The next section presents additional possible explanations for the documented instability.

3   Model-Based Explanation

LL (2001) note that the estimated coefficients (0.3 and 0.6) are what one would expect if the aggregate production was well represented by a Cobb-Douglas, since they are very close to the usual income shares of capital and labor. In fact, if aggregate output is

$$O_t = K_t^{\alpha} L_t^{1-\alpha}, \tag{5}$$

consumption, asset wealth and labor income, spanning from 1951:4 to 2003:3.

[4]AIC and BIC values for the linear model are -1248.2 and -1234.8, respectively.

then labor income is $Y_t = (1 - \alpha) O_t$ and the return to capital is $R_t = \alpha O_t$. Now note that a standard macroeconomic asset-pricing model would imply

$$Q_t = E_t \left(\frac{Q_{t+1} + D_{t+1}}{1 + r_t} \right), \tag{6}$$

where Q_t is the asset price, D_t are "dividends" and r_t is the discount rate. In steady state, one obtains

$$Q = \frac{\xi}{1 - \xi} D, \tag{7}$$

where ξ is a risk-adjusted discount factor. Noting that non-human wealth is $A = (Q + D) K$ (cum-dividend price times asset volume) and that the product $D \times K$ is just the steady-state return to capital, then

$$A = (Q + D) K = \frac{D}{1 - \xi} K = \frac{\alpha}{1 - \xi} O. \tag{8}$$

If we write consumption as $C = O - X$, where X stands for other uses of aggregate output, then for an arbitrary θ

$$C = O - X = \theta \frac{1 - \xi}{\alpha} A + (1 - \theta) \frac{1}{1 - \alpha} Y - X. \tag{9}$$

This seems to suggest that, in the long run, consumption is not related to labor income and non-human wealth alone, but also to other components of aggregate output. One implication of this is that, to be able to restore the original result, one must expect X to be somehow related to A and Y, so that it may be substituted out. One way to proceed would be to assume that A and Y capture the nonstationarity in X. Stability of the wealth effect would then have to rely on the stability of the relation of the components of X, for instance, government spending, to A and Y — given the time span covered by the data, this would appear dubious. But assume that this problem can be solved in the most simple way: set $X = 0$, which leads to the same conclusions as assuming that consumption is a constant fraction of output. In this case

$$C = \theta \frac{1 - \xi}{\alpha} A + (1 - \theta) \frac{1}{1 - \alpha} Y, \tag{10}$$

i.e., if we run the usual regression in levels, the "wealth effect" is indeterminate, since θ is arbitrary. Nevertheless, it is common to run the regression in logs. In this case the usual first order Taylor approximation gives (ignoring a "constant")

$$c = \rho_a a + \rho_y y, \tag{11}$$

where the coefficients are

$$\rho_a = \frac{\theta \frac{1-\xi}{\alpha} A}{C} = \theta \frac{O}{C} = \theta, \tag{12}$$

$$\rho_y = \frac{(1-\theta) \frac{1}{1-\alpha} Y}{C} = (1-\theta) \frac{O}{C} = 1 - \theta. \tag{13}$$

Taken literally, the Taylor approximation would imply the sum of the coefficients to equal unity. The fact that it is just an approximation may explain why this is not the case in the data — Jensen's inequality could be the reason for this. Nevertheless, our results in section 2 are consistent with matching symmetric variations in the coefficients, corresponding to changes in θ. What matters to us here is that again the aggregate long-run wealth effect is indeterminate. If this was really the case, one would expect the estimated coefficients to depend on short-run correlations between the variables. This would result in instability of the coefficients as one varied the sample. To see this, note that the previous equations relate steady state values. Let the actual values be

$$\tilde{c}_t = c + \varepsilon_t^c, \tag{14}$$

$$\tilde{a}_t = a - \varepsilon_t^a, \tag{15}$$

$$\tilde{y}_t = y - \varepsilon_t^y, \tag{16}$$

where the added disturbances reflect short-run deviations from the steady state. Then

$$\tilde{c}_t = \rho_a \tilde{a}_t + \rho_y \tilde{y}_t + \rho_a \varepsilon_t^a + \rho_y \varepsilon_t^y + \varepsilon_t^c. \tag{17}$$

Minimisation of the variance of the residual, $V\left[\rho_a \varepsilon_t^a + \rho_y \varepsilon_t^y + \varepsilon_t^c\right]$ with respect to θ leads to the following estimate of the wealth effect

$$\rho_a = \theta = \frac{\sigma_{yy} - \sigma_{ya} + \sigma_{yc} - \sigma_{ac}}{\sigma_{yy} + \sigma_{aa} - 2\sigma_{ya}}, \tag{18}$$

where $\sigma_{ij} = E\left(\varepsilon_t^i \varepsilon_t^j\right)$, with $i, j = c, a, y$, represent variances and covariances in the short run.

This result and the reasoning leading to it suggest there may be reasons for concern regarding the relevance of empirical estimates of the wealth effect in the context of this model. The estimates may reflect short-term correlations, possibly mixed with long-run parameters, as in the regression in levels. In particular, notice that, ceteris paribus, an increase in the variance of asset wealth reduces the size of the estimated wealth effect — this is exactly what the data, as reported in section 2, shows.

We developed our model from the point where LL (2001) stopped. These authors estimated the consumption equation and concluded it was consistent with the usual estimates of labor and capital income shares. We have shown that if we accept this conclusion, then the consumption function is likely to show signs of instability, and in the simple case studied here it would even lead to indeterminacy. The reader may ask whether the issue is only about relating the estimates of the consumption-function coefficients to labor and income shares. It is not. If we accept the assumptions of the standard derivation of the wealth effect — that consumption tends to a stationary fraction of wealth, that the average weight of human wealth on total wealth is stationary and that labor income captures the non-stationarity in human wealth — then the algebra of $I(1)$ variables says we should also conclude that there is cointegration between any two-element combination of consumption, wealth and labor income. This is in fact another instance of indeterminacy, but one that apparently is not upheld by the data. On the other hand, the implications from the model we

have just presented, in particular that the wealth effect should be unstable, do in fact appear to be matched by the data, as reported in section 2.

In view of the indeterminacy/instability result, what is surprising is actually the relatively small variation across regimes of the estimates reported in section 2. The empirical results and the theoretical model taken together suggest that there may be some structure in the short-run correlations between consumption, income and asset wealth — i.e., consumption, income and asset prices, which drive asset wealth in the short-run. This short-run structure reduces the magnitude of oscillation in the estimated coefficients (possibly making the traditional cointegrating relation a useful reference point), but also makes them react in a particular way to movements in asset prices.

To sum up, the usual derivation of the consumption cointegrating relation itself suggests that the estimated coefficients may be changing over time. The simple model investigated here adds to this a possible connection, through short-run correlations, between asset wealth (i.e., asset prices) and these coefficients. This warrants a more detailed study of the short-run relation between these variables, which is the subject of Gabriel, Alexandre and Bação (2005).

4   Conclusion

This paper documents patterns and sources of instability in the consumption-wealth ratio. We estimated a simple Markov switching model and found different estimates of the wealth effect associated with two regimes. These regimes seem to correspond to periods of high/low volatility in asset prices. This suggests that consumption reacts differently to asset prices depending on whether these changes are perceived to be permanent or transitory. We then show that the instability is not surprising given the way the consumption equation is derived. In this way, we add to the explanations given in Poterba (2000) a

model-based reason for instability in the wealth effect.

The magnitude of parameter instability is relatively small, and linear cointegration may perhaps be capturing the fundamental path of the relationship. Indeed, in a related paper (Gabriel *et al.*, 2005), we suggest that short term asymmetries, not long run instability, may be more important in describing the dynamics in this trivariate system.
