RELATIVE PRICE MOVEMENTS IN DYNAMIC GENERAL  
EQUILIBRIUM MODELS OF INTERNATIONAL TRADE

by David K. Backus, Patrick J. Kehoe, and Finn E. Kydland

David K. Backus is a professor of economics at the Stern School of Business, New York University; Patrick J. Kehoe is a professor of economics at the University of Pennsylvania and a consultant at the Federal Reserve Bank of Minneapolis; and Finn E. Kydland is a professor of economics at Carnegie-Mellon University, Pittsburgh, and a research associate of the Federal Reserve Bank of Cleveland. The authors thank the National Science Foundation, the Institute for Empirical Macroeconomics, and the Center for Japan-U.S. Business and Economic Studies faculty fellowship program for financial support. They also thank Ronald Jones, Maury Obstfeld, and Chris Stefanadis for helpful comments.

Working papers of the Federal Reserve Bank of Cleveland are preliminary materials circulated to stimulate discussion and critical comment. The views stated herein are those of the authors and not necessarily those of the Federal Reserve Bank of Cleveland or of the Board of Governors of the Federal Reserve System.

November 1992

## ABSTRACT

We examine the behavior of international relative prices from the perspective of dynamic general equilibrium theory, with particular emphasis on the variability of the terms of trade and the relation between the terms of trade and net exports. We highlight aspects of the theory that are critical in determining these properties, contrast our perspective with those associated with the Marshall-Lerner condition and the Harberger-Laursen-Metzler effect, and point out features of the data that have proved difficult to explain within existing dynamic general equilibrium models.

## 1 Introduction

Relative prices are a central feature of both the pure theory of international trade and open-economy macroeconomics. Although the emphasis differs in the two branches of international economics, to a great extent the same theory underlies theoretical and empirical work in each. Applications of dynamic general equilibrium theory, or international real business cycle theory, continue this tradition by extending, at the aggregate level, several of the features of static trade theory to dynamic and stochastic settings. What these applications offer, we think, is a deeper understanding of the dynamics of trade and relative prices.

The Marshall-Lerner condition is, without question, the most common link between trade theory and international macroeconomics. In trade theory, this elasticity condition on import demand functions determines the direction of many comparative statics exercises and serves as a stability condition on an otherwise static theory, telling us whether a disequilibrium adjustment process will succeed in establishing equilibrium. In international macroeconomics, the same condition is used to establish a positive association between the trade balance and the terms of trade or real exchange rate. This is the level at which the theory is presented in most textbooks and, indeed, in the popular Mundell-Fleming and Dornbusch macroeconomic models of open economies.

The macroeconomic branch of international economics has also developed insights that are largely independent of the theory of trade. The absorption approach focuses on the accounting relation connecting saving, investment, and the balance of trade. What distinguishes this work from static trade theory is its suggestion that the trade balance, or the closely related current account, reflects the dynamic decisions by agents to lend or borrow in international capital markets. A critical development for understanding

the relation between trade and relative prices is the recognition that any dependence of the trade balance on the terms of trade implies, as a matter of accounting, a similar relation with international borrowing and lending. This connection was noted by Harberger (1950) and Laursen and Metzler (1950) and later incorporated by Obstfeld (1982) and Svensson and Razin (1983) into explicitly dynamic theories of the balance of trade. These later papers emphasize the influence of terms of trade movements on permanent income, and hence on saving. They argue that persistent changes in the terms of trade have larger income effects than transitory changes, and thus give rise to potentially different relations between the trade balance and the terms of trade. The effect, in their analysis, is a comparison between two deterministic equilibria.

We approach trade and relative price dynamics from a somewhat different theoretical tradition, that of dynamic general equilibrium theory. Like much of static trade theory, we use competitive consumers and producers. Unlike that work, however, our theory is explicitly dynamic. And unlike the modern approach to the Harberger-Laursen-Metzler effect, we consider not comparisons between different deterministic equilibria, but properties of equilibria in stochastic theoretical economies. We consider in the theory the same experiment that applied economists consider in the data: the correlations between trade and relative price variables along an equilibrium path. Somewhat to our surprise, this approach leads to substantially different views of trade and price behavior than suggested by earlier work.

The application of dynamic general equilibrium theory to international trade has also led, in a rapidly growing number of papers, to attempts to quantify the theory's properties and compare them to properties of national economies. These attempts have led to a clearer understanding of which features of the data can be accounted for by the present state of theory and

which remain anomalous. This quantitative approach generates sharper predictions than qualitative theory and helps to focus further theoretical work on clearly defined issues.

We elaborate on the twin themes of theoretical development and quantitative properties in the rest of the paper. We start, in section 2, by documenting some of the salient properties of aggregate trade and relative prices for a number of industrialized countries. These properties make explicit the objects of interest in theoretical economies and serve as a basis of comparison with the theory.

We develop the theory in a series of two-country worlds, highlighting as we go the roles played by different theoretical features. Section 3 is devoted to an exchange economy in which each country specializes in a single traded good. Here, the variability of relative prices and the relation between prices and trade are governed by a single parameter: the elasticity of substitution between foreign and domestic goods. Some of the quantitative properties of this economy change when we consider preferences that are not additively separable between foreign and domestic goods and that favor consumption of home goods. This aspect of the theory is developed in section 4. We find, among other things, that agents' risk aversion plays a role in both the dynamics of trade and prices and the relation between these two variables.

In section 5, we compare this theory with alternatives based on the Marshall-Lerner condition and the Harberger-Laursen-Metzler effect. We show that our elasticity condition is not related to the Marshall-Lerner condition, which is always satisfied in our symmetric economy. With respect to the Harberger-Laursen-Metzler effect, we find that the persistence of shocks is orthogonal to the relation between relative prices and the balance of trade: for given preference parameters, the correlation between trade and

prices is the same whether price changes last one period or one hundred. In both comparisons, dynamic general equilibrium theory provides a different perspective on trade and price fluctuations than does earlier work.

In the remaining sections, we consider extensions of the theoretical structure that change some of its quantitative features and broaden the theory's predictions. In section 6, we explore shocks to government spending as well as to aggregate endowments. As one might expect, this extension has the potential to change equilibrium comovements considerably. We find, for example, that the sign of the relation between the trade balance and the terms of trade depends on the relative sizes of shocks to endowments and government spending, as well as on the elasticity of substitution.

In section 7, we embed the exchange structure of earlier sections into an economy with endogenous labor supply and capital formation. The critical element here is capital formation. With this modification, we find that the dynamics of trade now reflect, to a large extent, cyclical fluctuations in physical investment. The most striking result is an asymmetric cross-correlation function for the trade balance and the terms of trade, which we label the S-curve. This feature does not arise in exchange economies, whereby construction investment is zero and the cross-correlation function is symmetric. In this sense, the dynamics of capital formation play an important role in connecting the dynamics of the trade balance and the relative price of foreign to domestic goods.

We conclude with a few remarks on the strengths and weaknesses of existing dynamic general equilibrium theories of international trade, and suggestions for directions the theory might take in the future.

## **2 First Look at the Data**

Since the ultimate objective of our theory is to account for empirical

regularities, we start by looking at some of the properties of international relative prices. We focus here on three variables. The terms of trade, denoted  $p$ , is the ratio of the import price deflator to the export price deflator, both taken from national income and product accounts. Net exports, denoted  $nx$ , is the ratio of exports minus imports, in current prices, to output in current prices. Real output, denoted  $y$ , is GDP or GNP, depending on the country, in base-year prices (generally 1985). All three variables are constructed with data taken from the OECD's *Quarterly National Accounts*.

In table 4.1 we report various properties of the terms of trade for three countries: Japan, the United Kingdom, and the United States. These statistics refer to Hodrick-Prescott filtered variables, and both the terms of trade and real output are logarithms. Many of the same properties are reported in Backus, Kehoe, and Kydland (1992b) and Blackburn and Ravn (1991) for additional developed countries and in Mendoza (1992) for developing countries. The sample period in table 4.1 runs from 1955:2 to 1989:4, which enables us to look separately at the periods before and after the collapse of Bretton Woods.

We see, for a start, that movements in the terms of trade have been both variable and persistent. The standard deviation of terms of trade fluctuations ranges from 2.71 percent in the United Kingdom to 5.97 percent in Japan. Both here and in our earlier paper, variability of the terms of trade is considerably larger in Japan than in other countries. We are unsure, at this point, how much of this additional variability reflects true relative price movement and how much has to do with differences in the manner in which trade prices are constructed. Both Alterman (1991) and Graboyes (1991) raise questions concerning the quality of current trade prices in the United States, and these problems may be greater in earlier periods and other countries. Alterman (1991) estimates that improved price data exhibit about

30 percent less variability than those reported here. Nevertheless, we are probably on safe ground in claiming substantial variability of the terms of trade in all countries. Persistence is evident in the autocorrelations, which are generally in the neighborhood of 0.8. Table 4.1 also verifies that there has been much more variability of the terms of trade since the advent of floating exchange rates than before, a feature stressed by Mussa (1986) for real exchange rates (ratios of consumer price indexes converted at spot exchange rates). Standard deviations of the terms of trade are typically two to three times larger in the latter period.

We also include, in table 4.1, correlations of the terms of trade with net exports and real output. With respect to net exports, we find greater coherence across periods, but little across countries. The terms of trade and net exports have generally been positively correlated in the United States and negatively correlated in Japan and the United Kingdom. We see in table 4.2, which covers the post-Bretton Woods period for 10 countries, that the United States is an outlier in this regard: The correlation between the trade balance and the terms of trade is negative for every other country. With respect to output, there has been no regularity in the correlation with the terms of trade, either over time or across countries.

The contemporaneous correlation between net exports and the terms of trade fails to capture an important regularity that appears when we examine the complete cross-correlation function: the correlations, that is, between  $p_t$  and  $nx_{t+k}$ , for various leads and lags  $k$ . The contemporaneous correlation refers to  $k=0$ . For positive  $k$  the correlations pertain to net exports and past prices, and for negative  $k$  the reverse. We find for Japan and the United Kingdom that this function has an asymmetric S shape, which we call the S-curve. For Japan and the United Kingdom, this feature appears not only in the postwar period as a whole, but in the pre- and post-Bretton Woods

subperiods as well. For the United States, the same pattern is evident only in the earlier period. Our earlier paper (Backus, Kehoe, and Kydland, 1992b, figure 1) documents this pattern in eight of eleven countries.

In the remainder of the paper, we examine these properties from the perspective of a series of successively more complex dynamic general equilibrium models, bringing additional data to bear when the theory suggests it. For now, we note that the terms of trade has been highly variable and persistent in all three countries, that its correlation with net exports is generally negative, and that the cross-correlation function for net exports and the terms of trade is often asymmetric (the S-curve property).

### 3 A Dynamic Exchange Economy

One of the simplest dynamic general equilibrium models of a world economy has two countries that trade specialized endowments. Let time  $t$  run from an initial date 0 to a terminal date  $T$ , possibly infinite. The evolution of this endowment is stochastic, given by a "Debreu tree" that we describe in notation adapted from Lucas (1984). The state  $z^t$ , an element of the set  $Z^t$ , denotes the history of the economy from date 0 through  $t$ . Each of these possible states occurs with a probability  $\pi(z^t)$ . Country 1, which we call the home country, is endowed with a stream of positive quantities of the home good, denoted  $\{y_1(z^t)\}$  or, in shorthand notation, simply  $(y_1)$ . Likewise, country 2, the foreign country, is endowed with the positive sequence  $(y_2)$  of quantities of the foreign good. We denote the prices of the domestic and foreign goods in state  $z^t$  by  $q_1(z^t)$  and  $q_2(z^t)$ . As in section 2, we define the terms of trade,  $p(z^t) = q_2(z^t)/q_1(z^t)$ , as the relative price of imports to exports.

Each country is represented by a single consumer, who stands in for a large number of like agents. The preferences of the consumer of country  $i$

are characterized by the expected utility function

$$u_i = \sum_{t=0}^T \beta^t \sum_{z^t \in Z^t} \pi(z^t) U[c_i(z^t)],$$

with  $0 < \beta < 1$ ,  $U(c) = c^{1-\gamma}/(1-\gamma)$ , and  $\gamma > 0$ . We refer to  $\gamma$  as the risk aversion parameter. Both agents consume composites of the foreign and domestic goods, described by the Armington aggregator functions,

$$c_1(a_1, b_1) = G(a_1, b_1), \quad c_2(b_2, a_2) = G(b_2, a_2),$$

with

$$G(a, b) = [\omega a^{1-\alpha} + b^{1-\alpha}]^{1/(1-\alpha)},$$

where  $a_i$  and  $b_i$  are the quantities of the domestic and foreign good consumed by the agent of country  $i$ . Thus, the agents of each country consume combinations of foreign and domestic goods, as expressed in the function  $G$ . This theoretical device, due to Armington (1969), is widely used in computable static general equilibrium trade models. In this economy it is equivalent to giving consumers preferences over foreign and domestic goods directly. The two parameters,  $\alpha > 0$  and  $\omega > 0$ , govern the elasticity of substitution and shares of foreign and domestic goods. The elasticity is  $\sigma = 1/\alpha$ . With  $\omega = 1$ , the two consumers have identical preferences, and with  $\omega > 1$  they exhibit a preference for home goods: If home and foreign goods sell for the same price, agents consume more of the home good than the foreign good. The budget constraint of the domestic agent is

$$\sum_{t=0}^T \sum_{z^t \in Z^t} [q_1(z^t)a_1(z^t) + q_2(z^t)b_1(z^t)] \leq \sum_{t=0}^T \sum_{z^t \in Z^t} q_1(z^t)y_1(z^t).$$

The foreign agent faces an analogous constraint.

A competitive equilibrium in this economy consists of state-contingent quantities  $(a_i, b_i)$  and prices  $(q_i)$  such that (i) consumers maximize utility

given prices and budget constraints and (ii) quantities satisfy the resource constraints,

$$y_1(z^t) = a_1(z^t) + a_2(z^t),$$

$$y_2(z^t) = b_1(z^t) + b_2(z^t),$$

for each state  $z^t$ . We find it convenient to compute an equilibrium using the Negishi-Mantel algorithm in which, for any initial distribution of resources, a competitive allocation is associated with a Pareto optimum. Each optimum is the solution to a problem of the form: For some choice of positive welfare weights  $(\lambda_1, \lambda_2)$ , choose quantities  $(a_1, a_2, b_1, b_2)$  in each state to maximize  $\sum_i \lambda_i u_i$ , subject to the resource constraints. The supporting prices can then be identified with the Lagrange multipliers on the constraints or derived from consumers' first-order conditions. Backus (1992, section 2) describes this procedure in a similar context and discusses alternative decentralization schemes.

For the optimum problem, let us denote the Lagrange multipliers on the resource constraints in state  $z^t$  by  $q_1(z^t)$  and  $q_2(z^t)$  for the domestic and foreign goods, respectively. The Lagrange multipliers correspond to prices in the associated competitive equilibrium. If, for each  $i$ , we define spot price functions  $Q_i$  by  $q_i(z^t) = \beta^t \pi(z^t) Q_i(z^t)$ , then the optimum problem separates into a number of identical problems, one for each state  $z^t$ , of the form

$$\max_{\{a_i, b_i\}} \beta^t \pi(z^t) \{ \lambda_1 U(G[a_1(z^t), b_1(z^t)]) + \lambda_2 U(G[b_2(z^t), a_2(z^t)]) \}$$

subject to the resource constraints. The first-order conditions for each state are

$$Q_1(z^t) = \lambda_1 \omega c_1 [a_1(z^t), b_1(z^t)]^{\alpha-\gamma} a_1(z^t)^{-\alpha}$$

$$= \lambda_2 c_2 [a_2(z^t), b_2(z^t)]^{\alpha-\gamma} a_2(z^t)^{-\alpha},$$

$$\begin{aligned} Q_2(z^t) &= \lambda_1 c_1 [a_1(z^t), b_1(z^t)]^{\alpha-\gamma} b_1(z^t)^{-\alpha} \\ &= \lambda_2 \omega c_2 [a_2(z^t), b_2(z^t)]^{\alpha-\gamma} b_2(z^t)^{-\alpha}. \end{aligned}$$

The terms of trade is  $p(z^t) = q_2(z^t)/q_1(z^t) = Q_2(z^t)/Q_1(z^t)$ .

In this section, we restrict ourselves to the case of identical preferences,  $\omega=1$ , for which the analysis can be done analytically. The equilibrium allocation is then

$$a_i(z^t) = s_i y_1(z^t), \quad b_i(z^t) = s_i y_2(z^t),$$

for countries  $i=1,2$ , with consumption shares  $s_i = \lambda_i^{1/\gamma} / \sum_j \lambda_j^{1/\gamma}$  that sum to one. Backus (1992) describes how the welfare weights, and hence the shares, are related to the endowments. The properties of interest, however, do not depend on the choice of weights, so we can skip this additional step. The supporting prices are, up to a factor of proportionality,

$$Q_i(z^t) = y_i(z^t)^{-\alpha},$$

and the equilibrium terms of trade is

$$p(z^t) = [y_2(z^t)/y_1(z^t)]^{-\alpha}.$$

The trade balance in country 1 is, in units of the domestic good,

$$nx_1(z^t) = y_1(z^t) - [a_1(z^t) + p(z^t)b_1(z^t)].$$

In equilibrium, the ratio of the trade balance to output (the form of the trade variable used in table 4.1) is

$$nx_1(z^t)/y_1(z^t) = (1-s_1) - s_1 [y_2(z^t)/y_1(z^t)]^{1-\alpha}.$$

Along any equilibrium path for this economy the welfare weights,  $\lambda_i$ , are constant. The consumption shares,  $s_i$ , are functions of the welfare weights

alone, so they are constant as well. Thus, fluctuations in both the trade balance and the terms of trade are driven, along any equilibrium path, only by movements in the endowment ratio,  $y_2/y_1$ . In this sense, equilibrium prices and quantities are functions of a single state variable, the ratio  $y_2/y_1$ , and are thus indirectly related to each other.

Although the theory is fairly simple, we can start to compare some of its properties with those of the data -- in particular, the variability and persistence of the terms of trade,  $p$ , and the correlation of the terms of trade with net exports. Clearly, the variability of  $p$  is governed by the variability of the endowment ratio,  $y_2/y_1$ , and the substitution parameter,  $\sigma=1/\alpha$ . A given amount of variability of the endowment ratio can produce as much price variability as we like if  $\sigma$  is small enough. As an example, consider the standard deviation of the US terms of trade reported in table 4.1: 3 percent, for the period as a whole. This refers to the standard deviation of the Hodrick-Prescott filtered logarithm. The standard deviation of the filtered logarithm of the ratio of Japanese to US output is about 2.2. To generate the amount of price variability we see in the United States, then, we need an elasticity of about  $\sigma=0.73$  (since  $2.2/0.73=3.0$ ). This is only a rough calculation, since the data refer to a world with more than one country and in which a large part of the variability of output appears in investment, which is obviously absent here. But it is suggestive of the role played by the elasticity of substitution in generating relative price variability. As a rule, the theory can produce any amount of price variability we like if the elasticity of substitution is a free parameter.

With regard to persistence, the terms of trade inherits the autocorrelation properties of the endowment ratio. To continue our example, the autocorrelation of the Japan/US output ratio (the filtered logarithm, that is) is 0.7, so the autocorrelation of the terms of trade, in our theory,

is also 0.7. This is slightly less than we see for the US terms of trade in table 4.1, but the discrepancy is not large, either economically or statistically.

The final issue concerns the relation between the trade balance and the terms of trade. The contemporaneous relation is summarized by

*Proposition 1.* Let  $\omega=1$  in the Armington aggregator, G. Then the relation between the trade balance,  $nx_1/y_1$ , and the terms of trade,  $p$ , is governed by  $\sigma=1/\alpha$ , the elasticity of substitution between foreign and domestic goods. If  $\sigma>1$ , the two variables are positively related; if  $\sigma<1$ , they are negatively related.

More precisely, consider two states with endowment ratios  $x=y_2/y_1$  and  $x'=y'_2/y'_1$ , with  $x>x'$ . Since  $p$  is a decreasing function of the endowment ratio,  $p<p'$ . Now consider the trade balance. If  $\sigma>1$ , then  $nx/y < nx'/y'$ . In this case, the state with higher  $p$  also has higher  $nx/y$  and the two variables are, in this sense, positively related. If  $\sigma<1$ , the reverse is true. A similar result is implicit in Stockman and Svensson (1987, section 5.3). If  $\sigma=1$ , the trade balance is constant, as noted recently by Cole and Obstfeld (1991). Except for nonlinearities and nonstationarities, the correlation is either +1 or -1, unless  $\sigma=1$ , when the trade balance is constant and the correlation is not defined.

The dynamics of the relation between trade and prices, like the dynamics of prices, are determined completely by the dynamics of the endowment ratio. Except for nonlinearities and nonstationarities, the cross-correlation function for the trade balance and the terms of trade is the same as the autocorrelation function of the endowment ratio. By way of example, suppose the logarithm of the endowment ratio is AR(1), with autocorrelation  $\rho>0$ . Then if  $\sigma>1$ , the cross-correlation function for the trade balance and the

terms of trade is tent-shaped: The contemporaneous correlation is +1 and the correlation between  $p_t$  and  $nx_{t+k}$  is  $\rho^{|k|}$ . If  $\sigma < 1$ , the function is V-shaped. Even with other autocorrelation patterns, the cross-correlation function will be symmetric since the autocorrelation function is. The exchange economy, therefore, is incapable of reproducing the asymmetric correlation functions pictured in figure 4.1.

#### 4 Preference for Home Goods

When consumers in the two countries have preferences that favor their respective home goods ( $\omega > 1$  in the Armington aggregator  $G$ ), the behavior of trade and prices changes somewhat. When preferences for domestic and foreign goods are not additively separable, we find that the risk aversion parameter,  $\gamma$ , as well as the elasticity of substitution between foreign and domestic goods,  $\sigma = 1/\alpha$ , plays a role in the relation between the trade balance and the terms of trade.

The simplest case is  $\gamma = \alpha$ : risk aversion ( $\gamma$ ) is the inverse of the substitution elasticity for foreign and domestic goods ( $\sigma = 1/\alpha$ ). With this restriction, preferences, including the aggregator, are additively separable between the foreign and domestic goods, simplifying the analysis considerably. We compute an equilibrium, as before, from an optimum. The reader may verify that the equilibrium allocations, for countries  $i=1,2$ , are

$$a_i(z^t) = s_i^a y_1(z^t), \quad b_i(z^t) = s_i^b y_2(z^t),$$

where the consumption shares,  $s_1^a = (\omega\lambda_1)^{1/\gamma} / [(\omega\lambda_1)^{1/\gamma} + \lambda_2^{1/\gamma}]$ ,  $s_2^a = 1 - s_1^a$ ,  $s_1^b = \lambda_1^{1/\gamma} / [\lambda_1^{1/\gamma} + (\omega\lambda_2)^{1/\gamma}]$ , and  $s_2^b = 1 - s_1^b$ , are constant along any equilibrium path. The only difference from the symmetric case is that the consumption shares now differ across goods, with larger values of  $\omega$  leading to larger shares of home good consumption,  $s_1^a$  and  $s_2^b$ . The supporting prices are

$$Q_1(z^t) = [(\omega\lambda_1)^{1/\gamma} + \lambda_2^{1/\gamma}]^\gamma y_1(z^t)^{-\alpha},$$

$$Q_2(z^t) = [\lambda_1^{1/\gamma} + (\omega\lambda_2)^{1/\gamma}]^\gamma y_2(z^t)^{-\alpha},$$

so the equilibrium terms of trade is

$$p(z^t) = Q_2(z^t)/Q_1(z^t) = (\omega s_1^b/s_1^a)^\gamma [y_2(z^t)/y_1(z^t)]^{-\alpha}.$$

As before, the relative price  $p$  is driven by the endowment ratio. The only change is the factor of proportionality, which does not affect the properties of the logarithm of  $p$ . The variability of the terms of trade is determined by the variability of the endowment ratio,  $y_2/y_1$ , and the elasticity of substitution,  $\sigma=1/\alpha$ .

The trade balance for country 1 in this economy, expressed as a ratio to domestic output, is

$$nx_1(z^t)/y_1(z^t) = (1-s_1^a) - s_1^b [y_2(z^t)/y_1(z^t)]^{1-\alpha}.$$

We can see that preference for home goods ( $\omega>1$ ) has the effect of damping fluctuations in the balance of trade, since larger values of  $\omega$  imply smaller values of  $s_1^b$ . Comovements, however, do not change: The sign of the effect of the endowment ratio on the balance of trade once more hinges on whether  $\sigma=1/\alpha$  is greater or less than one and does not depend on any other parameters. Thus, the properties described in the previous section for identical preferences ( $\omega=1$ ) apply to this economy as well.

It should be clear, then, that any influence of the home preference parameter,  $\omega$ , on price behavior must operate through nonseparabilities between domestic and foreign goods -- different values of  $\alpha$  and  $\gamma$ . The allocation of goods between countries is influenced, in this case, by the sign of  $\alpha-\gamma$ . The first-order conditions do not admit a simple analytic solution, but the intuition behind the equilibrium allocation is fairly straightforward. As before, the variables of interest are functions of the

endowment ratio,  $x=y_2/y_1$ . In states with high values of  $x$ , the ratios of foreign to domestic good consumption,  $b_i/a_i$ , and the aggregate consumption ratio,  $c_2/c_1$ , are also high: They are increasing functions, in other words, of the endowment ratio  $x$ . Neither property is surprising: If there is relatively more of the foreign good, then in equilibrium both agents consume relatively more, and aggregate consumption favors the country whose preferences weight the foreign good more (country 2, since  $\omega>1$ ). In simple terms, let the foreign and domestic goods be bananas and apples, and suppose the foreign agent prefers bananas ( $\omega>1$ ) and the domestic agent prefers apples. Then the two statements are, first, that in states with relatively more bananas, both agents consume relatively more bananas than apples and, second, that aggregate consumption by the foreign agent, who has a stronger preference for bananas, rises proportionately more than consumption by the domestic agent. Proofs of both of these statements are included in the appendix.

From this starting point, we can deduce the effects on the relative price of the foreign good and the balance of trade. Consider the price. From the first-order conditions, reported in the previous section, we see that the terms of trade satisfies the relations

$$p = \omega^{-1}(b_1/a_1)^{-\alpha} = \omega (b_2/a_2)^{-\alpha},$$

where for convenience we have dropped explicit dependence of variables on the state,  $z^t$ . Since  $b_1/a_1$  and  $b_2/a_2$  are increasing functions of the endowment ratio  $x$ , the terms of trade is a decreasing function. Thus, an increase in the relative supply of the foreign good lowers its relative price. With somewhat greater effort we can characterize the magnitude of the decline. The first step is to relate the endowment ratio to  $b_1/a_1$ . The resource constraints imply

$$x = y_2/y_1 = s_1^b(b_1/a_1) + (1-s_1^b)(b_2/a_2) = [s_1^b + \omega^{2/\alpha}(1-s_1^b)](b_1/a_1),$$

where  $s_1^b = b_1/y_2$  is the (possibly state-dependent) share of foreign good consumption by the agent of country 1. Thus, with  $\omega > 1$ , the proportional change in  $b_1/a_1$  can be either greater or less than the proportional change in  $x$ , depending on whether  $s_1^b$  increases or decreases with  $x$ . The second step follows from the first-order conditions for the foreign good:

$$(b_1/b_2)^\alpha = [s_1^b/(1-s_1^b)]^\alpha = (\omega\lambda_2/\lambda_1)(c_2/c_1)^{\gamma-\alpha}.$$

Since  $c_2/c_1$  is an increasing function of the endowment ratio,  $s_1^b$  is increasing in  $x$  if  $\gamma > \alpha$ , decreasing if  $\gamma < \alpha$ , and constant if  $\gamma = \alpha$  (this being the additively separable case described earlier). Thus, the (absolute value of the) slope of the relation between the logarithms of the terms of trade,  $p$ , and the endowment ratio,  $x$ , is greater than  $\alpha$  if  $\gamma > \alpha$ , less than  $\alpha$  if  $\gamma < \alpha$ , and equal to  $\alpha$  (as we've already seen) if  $\gamma = \alpha$ . Other things equal, greater risk aversion tends to increase the variability of the terms of trade relative to that of the endowment ratio.

The contemporaneous relation between the trade balance and the terms of trade is characterized by

*Proposition 2.* Let  $\omega > 1$  (preference for home goods). Then there exists a positive number  $\sigma^*$  such that if  $\sigma > \sigma^*$ , the trade balance,  $nx_1/y_1$ , is positively related to the terms of trade,  $p$ , and if  $\sigma < \sigma^*$ , the two variables are negatively related. Furthermore, if  $\gamma > 1$ , then  $\sigma^* < 1$ .

Thus, the risk aversion parameter,  $\gamma$ , has an influence on comovements between the trade balance and the terms of trade. The proof consists largely of expressing the ratio of the trade balance to output in a convenient form. As in Proposition 1, both the trade balance and the terms of trade are monotonic

functions of the endowment ratio  $x=y_2/y_1$ . The terms of trade is, for all parameter values, decreasing in  $x$ . As for the trade balance, we let

$$nx_1/y_1 = (a_2 - pb_1)/y_1 = 1 - s_1^a [1 + \omega^{-1} (b_1/a_1)^{1-\alpha}].$$

With  $\omega=1$ ,  $s_1^a$  is constant. Since  $b_1/a_1$  is, as we have shown, increasing in the endowment ratio  $x=y_2/y_1$ , the proposition follows immediately with  $\sigma^*=1$ . With  $\omega>1$ , the dependence of  $s_1^a$  on  $x$  introduces an additional element of dependence on  $x$ . If  $\gamma>1$  and  $\alpha<\gamma$ ,  $s_1^a$  is increasing in  $x$ . Thus, for  $\alpha\leq 1$  the trade balance is decreasing in  $x$ . Since the solution is continuous in the parameters, this is true for values of  $\alpha$  slightly greater than 1 as well. For large values of  $\alpha$ , however, the trade balance is increasing in  $x$ , as we show in the appendix (result [A4]). Thus, there are numbers  $\alpha^*>1$  and  $\sigma^*=1/\alpha^*<1$  that divide regions of positive and negative comovement between the trade balance and the terms of trade.

In short, this economy is much like that of the previous section. Its similarities and differences are illustrated by the following example.

*Example.* Let there be two states, with unconditional probabilities  $(1/2, 1/2)$ . (Nonlinearities are irrelevant here, since two points can always be connected by a straight line.) Let the aggregate endowments  $(y_1, y_2)$  of the domestic and foreign goods be  $(1+\varepsilon, 1-\varepsilon)$  in state 1,  $(1-\varepsilon, 1+\varepsilon)$  in state 2, with  $\varepsilon>0$ . Thus, the standard deviations of  $y_1$  and  $y_2$  are  $\varepsilon$  and the standard deviation of the logarithm of the endowment ratio  $y_2/y_1$  is, for small  $\varepsilon$ , approximately  $2\varepsilon$ . The transition probabilities between states  $i$  and  $j$  are

$$[\pi_{ij}] = \begin{bmatrix} (1+\rho)/2 & (1-\rho)/2 \\ (1-\rho)/2 & (1+\rho)/2 \end{bmatrix}.$$

The persistence parameter  $\rho$  governs the autocorrelation function for any random variable adapted to the state, with the  $k$ -order autocorrelation equal to  $\rho^k$ .

Case 1: identical preferences ( $\omega=1$ ). The terms of trade is

$$p = (y_2/y_1)^{-\alpha},$$

which equals  $[(1+\varepsilon)/(1-\varepsilon)]^{-\alpha}$  in state 1 and  $[(1-\varepsilon)/(1+\varepsilon)]^{-\alpha}$  in state 2. The standard deviation of the logarithm of  $p$  is, for small  $\varepsilon$ , approximately  $\alpha(2\varepsilon)$ . With  $\varepsilon=0.05$  and  $\alpha=5$ , the standard deviation is 0.500. The ratio of the trade balance to output is

$$tb = nx_1/y_1 = (1/2) - (1/2) (y_2/y_1)^{1-\alpha} = (1/2) [1 - (y_2/y_1)^{1-\alpha}].$$

Thus, for  $\sigma=1/\alpha < 1$ , the correlation between  $p$  and  $tb$  is  $-1$ , and for  $\sigma > 1$  the correlation is  $+1$ . For  $\alpha=1$ , the trade balance is zero in both states and the correlation is not defined. Note that the persistence parameter,  $\rho$ , has no bearing on this correlation. The cross-correlation function for the trade balance and the terms of trade has the form

$$\text{corr}(tb_t, p_{t+k}) = \text{sign}(\sigma-1) \rho^{|k|},$$

where  $\sigma=1/\alpha$ . As noted earlier, this function is symmetric in  $k$ .

Case 2: preference for home goods ( $\omega > 1$ ). To make this concrete, let  $\varepsilon=0.05$ ,  $\omega=2$ , and  $\gamma=2$ . With  $\alpha=5$ , the standard deviation of the logarithm of the terms of trade is 0.497, slightly smaller than in the case of identical preferences. There is a critical value  $\sigma^*=0.885 < 1$  of the elasticity of substitution such that for  $\sigma > \sigma^*$ , the trade balance and the terms of trade are positively correlated, and for  $\sigma < \sigma^*$  they are negatively correlated. The cross-correlation function is

$$\text{corr}(tb_t, p_{t+k}) = \text{sign}(\sigma^*-1) \rho^{|k|},$$

which remains symmetric.

## 5 The Marshall-Lerner Condition and the Harberger-Laursen-Metzler Effect

The theory of the last two sections and its relation to time series data are relatively straightforward. We have found, however, that this theory gives us a much different understanding of the relation between trade and relative prices than that underlying either the widely cited Marshall-Lerner condition or the 1980s literature on the Harberger-Laursen-Metzler effect. In this section, we contrast our work with these other approaches.

The elasticity condition of Proposition 1 is an example of a common result in price theory, that the sign of something depends on whether utility is more or less concave than the log ( $\sigma=1$ ). In that sense, there is nothing surprising about it. What we find interesting in the present setting is the difference between this condition and the Marshall-Lerner condition, often cited as the determining factor in the sign of the relation between the trade balance and the terms of trade. The Marshall-Lerner condition is the centerpiece of textbook treatments of this issue; among many other examples, see Dornbusch (1980, p. 59), Ethier (1988, pp. 402-7), and Krugman and Obstfeld (1991, p. 423).

The Marshall-Lerner condition applies to a static economy, but we can review its logic in a one-period version of our two-country world. Our treatment follows Kemp (1987). We start by deriving conditions on static import demand functions that allow us to express the balance of trade as an increasing function of the terms of trade. Among the conditions for equilibrium in the static economy are the resource constraint for the home good,

$$a_1 + a_2 = y_1,$$

and the first agent's budget constraint,

$$a_1 + pb_1 = y_1.$$

These conditions together imply balanced trade:

$$nx_1 = a_2 - pb_1 = 0.$$

Utility maximization by both agents, subject to their respective budget constraints, results in import demand functions, say  $a_2(p)$  and  $b_1(p)$ . These functions define net exports as a function of the terms of trade:

$$nx_1(p) = a_2(p) - pb_1(p).$$

This function is increasing in  $p$  if

$$\varepsilon + \varepsilon^* > 1,$$

where

$$\varepsilon = -(\partial b_1 / \partial p)(p / b_1)$$

and

$$\varepsilon^* = (\partial a_2 / \partial p)(p / a_2)$$

are the domestic and foreign import elasticities. The inequality is the well-known Marshall-Lerner condition.

We now apply this analysis to our economy. The relevant import demand functions are

$$b_1(p) = y_1 / (p + p^\sigma)$$

$$a_2(p) = y_2 p^{\sigma+1} / (p + p^\sigma),$$

where, as before,  $\sigma = 1/\alpha$  is the elasticity of substitution between foreign and domestic goods. The import elasticities are therefore

$$\varepsilon = (1 + \sigma p^{\sigma-1}) / (p + p^\sigma),$$

$$\epsilon^* = p^\sigma (\sigma + p^{\sigma-1}) / (p + p^\sigma).$$

Adding these two expressions, we find that for all positive  $p$  and  $\sigma$ ,

$$\epsilon + \epsilon^* > 1.$$

In other words, the Marshall-Lerner condition is always satisfied in this economy, regardless of the value of the elasticity of substitution between foreign and domestic goods. This example illustrates a more general result, cited by Ethier (1988, section A.3): The Marshall-Lerner condition is always satisfied when consumers in the two countries have identical homothetic preferences.

Clearly, the Marshall-Lerner condition has no connection with the elasticity condition of Proposition 1 and therefore has no bearing on the correlation between the trade balance and the terms of trade for time series data generated by economies like ours. The difference in results stems, we think, from the difference between dynamic modeling and the static analysis that underlies the Marshall-Lerner condition. Despite the intuitive appeal of the latter, we find that when the dynamics are worked out explicitly, we get a different interpretation of this property of the data.

The theoretical state of the art regarding the relation between the trade balance and the terms of trade, however, is not the Marshall-Lerner condition but the 1980s revival of the Harberger-Laursen-Metzler effect initiated by Obstfeld (1982) and Svensson and Razin (1983). These papers, and others that followed, start with the central insight of the absorption approach: that trade imbalances reflect differences between saving and investment. The theoretical economies of these two papers are deterministic but share with ours the feature that dynamics are explicit. They come, however, to much different conclusions regarding the factors that lead to a positive association between the trade balance and the terms of trade. These papers suggest that two factors are critical in determining the pattern of

comovements: the persistence of the shock and the form of dependence of the discount factor, or rate of time preference, on future utility. Transitory shocks typically lead, in their analysis, to movements in the terms of trade and the trade balance of opposite sign. We find, in contrast, that the relation between the trade balance and the terms of trade is independent of the dynamics of prices.

The aforementioned papers also find that the effect of permanent shocks depends on the behavior of the discount factor. As Svensson and Razin (1983, p. 100) put it: "A permanent terms-of-trade deterioration ... causes a deterioration or improvement in the real trade balance, depending on whether ... the rate of time preference decreases or increases, respectively, with the level of welfare." Obstfeld (1982) assumes that the rate of time preference is increasing in utility and therefore predicts a decline in the trade balance. In his words (1982, p. 251), "...an economy specialized in production must experience a fall in aggregate spending and a current [account] surplus as a result of an unanticipated, permanent worsening in its terms of trade." In both papers there is no effect of a permanent change in price on the trade balance if the rate of time preference is constant. In our economies, the rate of time preference is constant, fixed by the discount factor  $\beta$ . The conclusion should then be that permanent movements in the terms of trade have no effect on the trade balance. We find, instead, that the relation between the trade balance and the terms of trade is determined by the elasticity of substitution, regardless of the persistence of shocks.

As in our analysis of the Marshall-Lerner condition, the difference between our approach and that of the Harberger-Laursen-Metzler literature stems, in part, from our definition of the issue. In our analysis, the relation between the trade balance and the terms of trade pertains to the correlation between these two variables for a single time series realization,

like the quarterly series for Japan, the United Kingdom, and the United States described in table 4.1. This corresponds, in our theoretical economies, to the correlation between the two variables along an equilibrium path. In the analysis of Obstfeld (1982) and Svensson and Razin (1983), however, the Harberger-Laursen-Metzler effect pertains to a comparison between two different deterministic equilibria: one in which the terms of trade is high, and one in which it is low. Apparently these two thought experiments emphasize much different features of the theory. We would argue that our thought experiment is closer to what we have in mind when we compare theory and data. A closer look also suggests, as brought out in Backus (1992) and Stockman and Svensson (1987), that the theory requires explicit treatment of the stochastic structure of the economy, something that deterministic analysis obviously cannot provide.

One way in which these two points of view might be reconciled is to consider economies in which agents have more limited ability to hedge risk than they do in the complete market economies of sections 3 and 4. In the 1980s analysis of the Harberger-Laursen-Metzler effect, income effects play a central role. In our economies, however, there are no income effects along an equilibrium path. With complete markets, each agent has a single, date-0 budget constraint. As a result, each has a state-invariant marginal utility of income, reflected in the constant welfare weights of our optimum problem. Backus (1992), Kehoe and Richardson (1985), and Mendoza (1992) suggest that some of the flavor of the Harberger-Laursen-Metzler literature may carry over to dynamic stochastic settings with some types of market incompleteness.

In short, we find that explicit dynamic stochastic analysis of trade and relative prices leads to much different views of the factors determining their comovements. Even the role of that textbook standard, the Marshall-Lerner condition, may need to be reconsidered.

## 6 Government Spending

The theory thus far has focused on fluctuations in trade and prices arising from movements in endowments. Here we consider an extension to the exchange economy of section 3 in which we have, in addition, exogenous shocks to government spending. Related analyses have been provided by Baxter (1992), Buiter (1989), Hodrick (1988), Macklem (1990), Obstfeld (1989), Reynolds (1991), and Yi (1991). We find this extension both interesting in its own right and a useful step toward introducing a wide range of impulses into dynamic general equilibrium models of trade: shocks, for example, to taxes, tariffs, and possibly even monetary policies. To keep the analysis simple, we restrict ourselves to the case of symmetric preferences ( $\omega=1$  in the Armington aggregator  $G$ ).

In this new economy, the government is an additional consumer of goods. Let us say that in state  $z^t$  the government of country  $i$  consumes the quantity  $g_i(z^t)$  of its home good. This spending is financed with lump-sum taxes, say  $\tau_i(z^t)$ . An equilibrium then consists of quantities ( $a_i$  and  $b_i$ ), prices ( $q_i$ ), and government policies ( $g_i, \tau_i$ ) such that (i) agents maximize utility given prices and budget constraints, (ii) quantities satisfy the resource constraints,

$$\begin{aligned} y_1(z^t) - g_1(z^t) &= a_1(z^t) + a_2(z^t), \\ y_2(z^t) - g_2(z^t) &= b_1(z^t) + b_2(z^t), \end{aligned}$$

and (iii) policies satisfy governments' budget constraints.

With this structure, the economy is equivalent to one with "net endowments"  $y_i - g_i$ , rather than  $y_i$ , and we can apply most of the results of section 3 with little change. The equilibrium allocation includes

$$a_i(z^t) = s_i [y_1(z^t) - g_1(z^t)],$$

$$b_i(z^t) = s_i [y_2(z^t) - g_2(z^t)],$$

for  $i=1,2$ , with consumption shares  $s_i = \lambda_i^{1/\gamma} / \sum_j \lambda_j^{1/\gamma}$  for some choice of welfare weights  $\lambda_i$ . The equilibrium terms of trade is

$$p(z^t) = \{[y_2(z^t) - g_2(z^t)] / [y_1(z^t) - g_1(z^t)]\}^{-\alpha}.$$

The variability of the terms of trade is governed, then, by the variability of the net endowment ratio and the elasticity of substitution,  $\sigma=1/\alpha$ . In practice, the addition of government purchases has little influence on the variance of  $p$ , since  $g$  is only a fraction of output and is generally less variable. The same reasoning applies to persistence: Introducing government purchases of goods and services does little to change our prediction that relative prices retain the persistence of output ratios.

The most interesting consequences of government purchases concern trade. If  $w_i = y_i - g_i$  is the endowment net of government purchases, net exports in country 1 are

$$\begin{aligned} nx_1(z^t) &= (1-s_1)w_1(z^t) - [w_2(z^t)/w_1(z^t)]^{-\alpha} s_1 w_2(z^t) \\ &= w_1(z^t) \{ (1-s_1) - s_1 [w_2(z^t)/w_1(z^t)]^{1-\alpha} \}. \end{aligned}$$

The ratio of net exports to output is

$$nx_1(z^t)/y_1(z^t) = \{ (1-s_1) - s_1 [w_2(z^t)/w_1(z^t)]^{1-\alpha} \} w_1(z^t)/y_1(z^t).$$

In our earlier analysis,  $g_1$  was zero and the last term was, therefore, one. As a result, the effect of the endowment ratio on the trade balance, and the association between movements in the trade balance,  $nx_1/y_1$ , and the terms of trade,  $p$ , depended only on the value of  $\sigma=1/\alpha$ . For  $\sigma < 1$  the association was positive; for  $\sigma > 1$  the reverse. Here we find an additional factor, the ratio of the net endowment,  $w_1$ , to total output,  $y_1$ .

We can get some idea of the contributions of output and government spending shocks on trade and price fluctuations by considering special cases. Consider, first, the case in which  $g_1$  is proportional to  $y_1$ . Then  $w_1/y_1$  is constant, and the relation between the trade balance and the terms of trade is determined by  $\sigma$ , as it was in Proposition 1. With  $\sigma > 1$  (or  $\alpha < 1$ ), the trade balance and the terms of trade are positively related along an equilibrium path; with  $\sigma < 1$ , they are negatively related. Alternatively, suppose outputs  $y_1$  are constant and  $g_1$  is the only shock. Then the trade balance and the terms of trade are positively associated, regardless of the value of  $\sigma$ . This example is like many others in economics in which the comovement between two endogenous variables depends on the source of their fluctuations.

This analysis suggests a second look at trade and price data, with special attention paid to government purchases. As we see in table 4.2, there has been little regularity across countries in either the variability of government purchases relative to that of real output, or in the correlation between these two variables. The same statement applies to the correlations of government purchases with the trade balance and the terms of trade. That is not to say that government purchases have not played a role in trade and price behavior, but that this role is not simple enough to show up in summary statistics of this form. Froot and Rogoff (1991) document somewhat stronger indications of a relation between government spending and real exchange rates using different methods.

## 7 Trade and Capital Formation

In the exchange economies of sections 3 and 4, we compared properties of the data with analogous properties of trade and relative prices in simple theoretical economies. This analysis brought up two questions that deserve a closer look. We found, for one thing, that the variability of the terms of

trade is governed by the variability of the output ratio and the elasticity of substitution between foreign and domestic goods. By choosing a small enough elasticity, the theory can generate literally any amount of relative price variability. The question, in this case, is whether price variability in the theory and the data are close for reasonable values of this elasticity. In another respect, we found that the exchange economy could not, for any choice of parameter values, mimic the data: the cross-correlation function for the trade balance and the terms of trade. In the data this function is generally asymmetric, a feature we document in figure 4.1 and label the S-curve. In the exchange economy, however, the function is symmetric by construction, since both the trade balance and the terms of trade are functions of the same state variable. The question here is whether this property changes when we introduce physical capital formation.

The introduction of capital formation brings us closer to the theme of the absorption approach to the balance of payments: that fluctuations in trade reflect differences between saving and investment. As a matter of pure accounting, this connection is undeniable, but it also shifts one's attention away from within-period relative prices to the intertemporal decisions to save and invest. Thus, Sachs (1981) argues that trade deficits often reflect investment booms and Stockman and Svensson (1987) tie both trade and relative prices to fluctuations in, among other things, fixed capital formation. We continue this tradition by introducing capital formation to an economy that is otherwise like our earlier ones. The structure is adapted from Backus, Kehoe, and Kydland (1992b). The emphasis, as in earlier sections, is on the dynamics of the trade balance and the terms of trade.

The theoretical economy has the following elements. There are, as before, two countries that specialize in different goods. Preferences of the representative consumer in each country  $i$  are characterized by an expected

utility function of the form

$$u_i = E_0 \sum_{t=0}^{\infty} \beta^t U(c_{it}, 1-n_{it}),$$

where  $c_{it}$  and  $n_{it}$  are consumption and hours worked in country  $i$ ,  $U(c, 1-n) = [c^\mu (1-n)^{1-\mu}]^{1-\gamma} / (1-\gamma)$ , and  $\gamma \geq 0$ . The primary difference in preferences from the economy of section 3 is the appearance of leisure in agents' utility functions.

Goods in the two countries, labeled  $a$  for country 1 and  $b$  for country 2, are produced using capital,  $k$ , and labor,  $n$ , with linear homogeneous production functions of the same form,  $F(k, n) = k^\theta n^{1-\theta}$ . This gives rise to the date- $t$  resource constraints,

$$\begin{aligned} a_{1t} + a_{2t} &= y_{1t} = z_{1t} F(k_{1t}, n_{1t}), \\ b_{1t} + b_{2t} &= y_{2t} = z_{2t} F(k_{2t}, n_{2t}), \end{aligned}$$

in countries 1 and 2, respectively. The quantity  $y_{it}$  denotes GDP in country  $i$ , measured in units of the local good, and  $a_{it}$  and  $b_{it}$  denote uses of the two goods in country  $i$ . If  $k$  and  $n$  are constant, this reduces to the pure exchange setting of section 3, with productivity shocks giving rise to proportionate output fluctuations. The vector  $z_t = (z_{1t}, z_{2t})$  is a stochastic shock to productivity whose properties will be described shortly.

Consumption, investment, and government spending in each country are composites of the foreign and domestic goods, with

$$\begin{aligned} c_{1t} + x_{1t} + g_{1t} &= G(a_{1t}, b_{1t}), \\ c_{2t} + x_{2t} + g_{2t} &= G(b_{2t}, a_{2t}), \end{aligned}$$

where, as before,  $G(a, b) = [\omega a^{1-\alpha} + b^{1-\alpha}]^{1/(1-\alpha)}$ . The parameters  $\alpha$  and  $\omega$  are both positive, and the elasticity of substitution between foreign and domestic goods is  $\sigma = 1/\alpha$ . As noted earlier, this structure is widely used in

static general equilibrium models of trade. Capital stocks evolve according to

$$k_{it+1} = (1-\delta)k_{it} + x_{it},$$

where  $\delta$  is the depreciation rate. Two differences between this economy and the exchange economy of sections 3-5 are the introduction of capital formation and the assumption here that government spending may have some foreign content.

Finally, the underlying shocks to our economy are independent bivariate autoregressions. The technology shocks follow

$$z_{t+1} = A z_t + \epsilon_{t+1}^z,$$

where  $\epsilon^z$  is distributed normally and independently over time with variance  $V_z$ . The correlation between the technology shocks,  $z_1$  and  $z_2$ , is determined by the off-diagonal elements of  $A$  and  $V_z$ . Similarly, shocks to government spending are governed by

$$g_{t+1} = B g_t + \epsilon_{t+1}^g,$$

where  $g_t = (g_{1t}, g_{2t})$  and  $\epsilon^g$  is distributed normally with variance  $V_g$ . Technology shocks,  $z$ , and government spending shocks,  $g$ , are independent.

With these elements, and the parameter values listed in table 4.3, we can approach the behavior of the terms of trade. The critical parameters, for our purposes, are the elasticity of substitution,  $\sigma$ , which we set equal to 1.5, and the steady-state ratio of imports to GDP, which we set equal to 0.15 by choosing  $\omega$  appropriately. In this benchmark version of the economy, foreign and domestic goods are better substitutes than they would be with Cobb-Douglas preferences ( $\sigma=1$ ) and imports are, on average, 85 percent of GDP. The choice of elasticity is in the range of estimates from a large number of studies, as documented by Whalley (1985, ch. 4). Estimates of the

elasticity are generally close to one, and often slightly larger. The import share is slightly larger than we see in the United States, Japan, or an aggregate of European countries (with intra-European trade netted out), but smaller than we see for most countries individually.

A number of properties of the theoretical economy with alternative parameter settings are reported in table 4.4. Consider, first, fluctuations in the terms of trade. The standard deviation of the terms of trade with our benchmark parameter values is 0.48 percent, which is a factor of six less than we see for the United States in table 4.1. With smaller values of  $\sigma$ , the theoretical economy generates greater variability of the terms of trade. As illustrated in figure 4.2, the standard deviation of  $p$  gets larger as we decrease  $\sigma$ , and for  $\sigma$  less than 0.03 the standard deviation exceeds 2. Thus, it appears that while the theory can produce as much variability in the terms of trade as we see in the data, it requires an elasticity of substitution much smaller than most existing estimates.

The value of  $\sigma$  required to match the variability of the terms of trade in US data is substantially smaller in this model (less than 0.03) than in our calculation in section 3 for the United States and Japan (for which we estimated that  $\sigma=0.73$  would be sufficient). Three factors account for most of this difference. The first is that the theoretical economy has, in the benchmark case, about 25 percent less variability in the output ratio than we calculated for Japan and the United States. Modifications of the theory that bring the magnitude of business cycles closer to the data will also bring the theory and data closer together with respect to price variability. The second factor is capital formation. If we eliminate capital (which we can do by setting  $\theta=0$  in the production function), the economy generates considerably greater price variability, despite less variability in the ratio of outputs. The final factor is the import share. If the import share is

raised from 0.15 to 0.25, the variability increases substantially at every value of  $\sigma$ . For  $\sigma=1.5$ , the benchmark value, the standard deviation of the relative price rises from 0.48 to 0.58.

A second property of the model is the contemporaneous correlation between net exports and the terms of trade. In the data, this correlation has been positive for the United States and negative for Japan and the United Kingdom (see table 4.1). In the theoretical economy we find, for the benchmark parameter values, that the correlation is  $-0.41$ . As we might expect from Propositions 1 and 2, this correlation is sensitive to the elasticity of substitution. We see in figure 4.3 that the correlation increases with  $\sigma$ , and is positive for elasticities greater than  $\sigma^*=2.76$ . This feature, too, is strongly influenced by capital formation. In the model without capital ( $\theta=0$ ), the economy is much like that described in Proposition 2, with a critical elasticity  $\sigma^*=0.94$ . For  $\sigma>\sigma^*$ , the trade balance and the terms of trade are positively correlated; for  $\sigma<\sigma^*$ , the reverse.

A third property of interest is the impact of government spending on the correlation between the trade balance and the terms of trade. We see in table 4.4 that with only shocks to government spending, the correlation between net exports and the terms of trade shifts from negative to positive. This mirrors a similar result in section 6. With shocks to both productivity,  $z$ , and government spending,  $g$ , we find that the former dominate, in the sense that the economy's properties are similar to those with shocks to productivity alone.

Finally, we look at the complete cross-correlation function for net exports and the terms of trade. As pictured in figure 4.4, this correlation has the same asymmetric shape we documented for the data in figure 4.1. Some intuition for this behavior is provided by figure 4.5, in which we graph the dynamic responses to a one-standard-deviation shock to domestic productivity.

Following this shock, output and the relative price of foreign goods both increase. Consumption also rises, but by less than output. Investment grows initially by much more than consumption, as resources are transferred to the home country to exploit its expected future productivity advantage. As capital accumulates, this resource transfer diminishes. The trade balance, which is the difference, at market prices, between output and the sum of consumption and investment, exhibits an initial period of deficit, followed by surplus. These dynamic responses give rise to the asymmetric cross-correlation function of figure 4.4.

In short, much of the intuition for this dynamic general equilibrium trade model is available from the exchange economy of sections 3-5. What the exchange economy misses completely are the dynamics of the relation between the trade balance and the terms of trade: the asymmetric cross-correlation function that we documented in the data and labeled the S-curve. The cross-correlation function between these two variables is symmetric in the exchange economy for all parameter values. In this section, we have seen that the dynamics of capital formation provide a plausible basis for an asymmetric pattern.

## **8 Final Thoughts**

We have argued that a dynamic general equilibrium approach to aggregate trade theory provides both a new level of understanding of the interrelations between trade and price movements and a framework in which these relations can be quantified. With regard to the former, we have seen that the relation between trade and price variables is much different from that suggested by the Marshall-Lerner condition cited in most textbooks. With regard to the latter, we suggest that the dynamic relation between trade and the relative price of foreign goods can be understood as a consequence of the dynamics of

capital formation. Thus, the dynamics of trade variables are inseparable from the dynamics of the rest of the economy.

Future work will undoubtedly focus, however, not on these contributions, but on dimensions in which the theory, in its current incarnation, provides a relatively poor approximation to the dynamics of actual economies. The most obvious example is the variability of the terms of trade. In the economy of section 7, and in Stockman and Tesar (1991) as well, the standard deviation of the terms of trade is substantially smaller than we estimate in the data. This discrepancy between theory and data helps to motivate theories in which monetary policy influences relative prices (Grilli and Roubini 1992, Schlagenhauf and Wrase 1992) and in which international market segmentation, possibly in conjunction with imperfect competition, also plays a part (Dumas 1992, Giovannini 1988, Lapham 1990). Ongoing research will likely tell us how important each of these features is, and how they modify the lessons of the theory outlined above.

**APPENDIX: Proof of Proposition 2**

The algebra behind Proposition 2 is straightforward but fairly tedious. We start by reducing the economy to two equations in two unknowns. The unknowns are the consumption shares of the first agent,  $s_1^a = a_1/y_1$  and  $s_1^b = b_1/y_2$ . The first-order conditions and resource constraints then imply

$$(A1) \quad s_1^a / (1-s_1^a) = \omega^v s_1^b / (1-s_1^b)$$

and

$$(A2) \quad [s_1^a / (1-s_1^a)]^\gamma (\lambda_2 / \omega \lambda_1) = [(\omega + m^{1-\alpha}) / (1 + \omega^{1+v} m^{1-\alpha})]^{(\alpha-\gamma)/(1-\alpha)},$$

where  $m = b_1/a_1 = x s_1^b / s_1^a > 0$  and  $v = 2/\alpha > 0$ . With these substitutions, the two equations determine  $s_1^a$  and  $s_1^b$  as functions of the endowment ratio  $x = y_2/y_1$ . Note that if either  $\omega = 1$  or  $\alpha = \gamma$ , the right side of (A2) is one and  $s_1^a$  is constant.

Preliminaries: (a) If we differentiate the first equation we get

$$d[s_1^a / (1-s_1^a)] = ds_1^a / (1-s_1^a)^2 = \omega^v ds_1^b / (1-s_1^b)^2$$

or

$$ds_1^b / s_1^b = (s_1^b / s_1^a) \omega^v ds_1^a / s_1^a.$$

Thus,  $s_1^a$  and  $s_1^b$  are positively related and we can use this relation to substitute out any  $ds_1^b$ 's we get.

(b) Differentiate the ratio  $(s_1^b / s_1^a)$ :

$$d(s_1^b / s_1^a) = (s_1^b / s_1^a) [(s_1^b / s_1^a) \omega^v - 1] ds_1^a / s_1^a.$$

(c) Differentiate m:

$$dm/m = dx/x + [(s_1^b / s_1^a) \omega^v - 1] ds_1^a / s_1^a.$$

(d) Inequalities. From (A1) and  $\omega > 1$ :

$$s_1^a > s_1^b,$$

$$(s_1^b / s_1^a) \omega^v - 1 = (s_1^a - s_1^b) / (1-s_1^a) > 0.$$

We now prove the claims in the text.

1. We show that  $s_1^a$  is increasing in  $x$  if  $\gamma > \alpha$ , and decreasing if  $\gamma < \alpha$ .

We differentiate (A2) and find, after rearrangement:

$$(A3) \quad \gamma (w+m)^{1-\alpha} (1+w)^{1+v} m^{1-\alpha} ds_1^a/s_1^a = (\alpha-\gamma) (1-w)^{2+v} (1-s_1^a) m^{1-\alpha} dm/m.$$

If we substitute the expression for  $dm/m$  [(c) above] we get an equation of the form

$$(A4) \quad A ds_1^a/s_1^a = B dx/x,$$

so that  $s_1^a$  is increasing in  $x$  if  $B/A > 0$ , and decreasing otherwise. The coefficient of  $dx/x$  is

$$B = (\alpha-\gamma) (1-\omega)^{2+v} (1-s_1^a) m^{1-\alpha}.$$

Since  $\omega > 1$ ,  $B$  has the same sign as  $\gamma - \alpha$ . The coefficient of  $ds_1^a/s_1^a$  is

$$A = \gamma (w+m)^{1-\alpha} (1+w)^{1+v} m^{1-\alpha} + (\gamma-\alpha) (1-\omega)^{2+v} (s_1^a - s_1^b) m^{1-\alpha}.$$

Clearly if  $\gamma < \alpha$ ,  $A$  is positive and  $ds_1^a/dx$  is negative. If  $\gamma > \alpha$ , then

$$A/\gamma = (w+m)^{1-\alpha} (1+w)^{1+v} m^{1-\alpha} + \theta (1-\omega)^{2+v} m^{1-\alpha},$$

where  $\theta = (s_1^a - s_1^b)(\gamma - \alpha)/\gamma < 1$ . Combining terms makes it clear that  $A$  is positive in this case, too. Thus, the sign of  $ds_1^a/dx$  is the same as the sign of  $\gamma - \alpha$ .

2. An immediate corollary is that  $c_2/c_1$  is increasing in  $x$ : The first-order conditions imply

$$[s_1^a/(1-s_1^a)]^\alpha = (\omega\lambda_2/\lambda_1) (c_2/c_1)^{\gamma-\alpha}.$$

The behavior of  $s_1^a$  with respect to  $x$  implies that the consumption ratio,  $c_2/c_1$ , is increasing in  $x$ , as claimed in the text.

3. We now show that  $b_1/a_1 = m$  is increasing in  $x$ . From (A3) we have

$$\begin{aligned} (\alpha-\gamma) (1-w)^{2+v} (1-s_1^a) m^{1-\alpha} dm/m &= \gamma (w+m)^{1-\alpha} (1+w)^{1+v} m^{1-\alpha} ds_1^a/s_1^a \\ &= \gamma (w+m)^{1-\alpha} (1+w)^{1+v} m^{1-\alpha} (B/A) dx/x. \end{aligned}$$

From the definition of B,

$$(A5) \quad A \, dm/m = \gamma (w+m)^{1-\alpha} (1+w^{1+v} m^{1-\alpha}) \, dx/x.$$

Since  $A > 0$ ,  $m$  is increasing in  $x$ .

4. We turn to the dependence of the trade balance on  $x$ . As in the text,

$$nx_1/y_1 = 1 - s_1^a [1 + \omega^{-1} m^{1-\alpha}].$$

Differentiating, we find

$$d(nx_1/y_1) = -ds_1^a [1 + \omega^{-1} m^{1-\alpha}] - (1-\alpha) s_1^a \omega^{-1} m^{1-\alpha} dm/m,$$

which is positive if

$$[1 + \omega^{-1} m^{1-\alpha}] ds_1^a / s_1^a + (1-\alpha) \omega^{-1} m^{1-\alpha} dm/m < 0.$$

From (A4) and (A5) we can show that this inequality holds for large enough  $\alpha$ .

Table 4.1

## Properties of the Trade Balance and the Terms of Trade

Country	Period	Standard Dev. (%)		Auto-correlation		Cross-Correlation	
		p	nx	p	nx	(p,nx)	(p,y)
Japan	1955-89	5.97	.97	.87	.77	-.46	-.09
	1955-70	2.17	.98	.73	.66	-.55	.41
	1971-89	7.76	.94	.87	.83	-.51	-.27
United Kingdom	1955-89	2.71	1.08	.76	.66	-.54	.20
	1955-70	1.51	.78	.38	.54	-.15	.56
	1971-89	3.38	1.21	.79	.65	-.60	.10
