Abstract

Using data from 17 countries that have suffered a currency crisis, this paper studies firm-level leverage and performance measures before and after a crisis has occurred. We show that in the years preceding a currency crisis, companies that are expected to benefit from currency depreciations increase their leverage more than companies that are expected to be harmed by currency depreciations. The evidence regarding the profitability and financial fragility ratios is consistent with the leverage results, since companies that are expected to benefit from depreciations fare worse than other companies before a crisis. We also provide evidence that the Asian crisis is different from the previous European and Latin American ones: in Asia all firms become more fragile after the crisis and their profitability declines and leverage increases further, whereas in Europe and Latin America there are clear signs of recovery after a crisis has occurred, especially for firms that are ex-ante expected to benefit from depreciations.

KEYWORDS: currency crisis, currency depreciation, corporate leverage, capital structure, profitability, financial fragility, exchange rates.

JEL classification: F3, F4, G3

Are currency crises caused by irresponsible macroeconomic policies? The answer used to be an unqualified yes: a currency crisis was a just retribution for government mismanagement. However, the 1997 crises in Asia have led many observers to question this view. Most of the afflicted economies had budget surpluses and healthy foreign exchange reserves. While current account deficits were large in some countries (Thailand and Malaysia), they were very modest in others (South Korea and Indonesia). Thus it is difficult to argue that currency depreciations were needed because of macroeconomic reasons.

Recently, a literature that places the corporate sector and its leverage as the central issue in currency crises has started to emerge. Most influential among those papers have been models by Aghion et al. (2001) and Krugman (1999). In those papers, firms' output prices are sticky and firms finance their operations at least partially with debt denominated in a foreign currency. When shocks or loss of confidence cause an initial currency depreciation, then declining profitability and financial distress problems for corporations lead to further depreciations. Hence, in these models a currency depreciation causes financial distress problems. The opposite view of currency depreciations is given by Bris and Koskinen (2002). In their model, exporting companies face a financial distress problem, which is solved through a currency depreciation. A currency depreciation helps to solve financial distress problems even when firms have borrowed in a foreign currency, if firms' cashflows are denominated in a foreign currency and costs at least partially in a domestic currency. A currency depreciation is not, however, costless, since it leads to excessive leverage and risky investments prior to a depreciation. Schneider and Tornell (2001) have a model that allows for asymmetric firm level developments both before and after a crisis. In their model, firms operate either in the tradable or in the non-tradable sector. The banking sector has been given a bailout guarantee and at the same time financial contracts suffer from imperfect enforceability. The existence of these two distortions give rise to the willingness to extend credit denominated in a foreign currency to the firms in the non-tradable sector and to firms being credit constrained by the extent of their net wealth. As a result, firms in the non-tradable sector are able to grow faster and more profitably than firms in the tradable sector with an

appreciating real exchange rate before a crisis and suffer more when the exchange rate collapses after a crisis.

To what extent corporate financial policies are related to currency depreciations is still an open question empirically. A currency depreciation may harm corporations that are financed with foreign debt, as Aghion et al. (2001) and Krugman (1999) note, and deepening financial distress will be a consequence of the currency crisis. If instead corporations see a potential currency depreciation as a means of resolving corporate distress problems, two main empirical predictions ensue: financial distress precedes a currency crises, followed by improving financial health; and only those firms that benefit from the currency depreciation should display excessive leverage prior to a crisis, as emphasized by Bris and Koskinen (2002). In general, firms' leverage and profitability could develop asymmetrically before and after a crisis has occurred, as implied by the model of Schneider and Tornell (2001): firms in the tradable sector showing higher leverage, lower profitability and growth preceding a crisis compared to the firms in the non-tradable sector and a reversal of roles after a crisis has occurred.

This paper contributes to this growing literature of corporate leverage and currency crises by providing empirical evidence of corporations' financial policies and performance around currency depreciations. We analyze micro level data from 20 countries from Asia, Europe and Latin America. Seventeen countries in our sample (the crisis sample) have experienced currency devaluations over the past decade¹. The remaining three countries (Argentina, Hong Kong and Japan), which did not experience a currency crisis even though their currencies faced some pressure, form our control sample (no crisis sample). In the no crisis sample, we identify the date where the currency suffered speculative attacks, that lead to somehow severe exchange rate depreciations. This date determines the event date around which we analyze financial policies and profitability.

We first document a median 1.91% increase in corporate debt-to-value ratios during the last three years prior to a currency crisis² for all countries. Such an increase in leverage is particularly large for European

and Latin American firms. In Asia, the evidence is not that clear. In the years following a currency depreciation, we find significant increases in leverage in all countries in Asia except Hong Kong and Japan. In Europe and Latin America, the post-crisis evidence is mixed. However, we find significant differences in corporate financial policies in countries that experienced a currency crisis relative to countries that did not. Debt ratios increase by 4.43% in the first group of countries prior to the crises, but they do not change in the second group. Besides, there is an 8.35% increase in leverage after the crisis in the crisis sample countries, against a 0.72% increase (only significant at the 10% level) in the no crisis sample.

Several theoretical explanations outlined above are consistent with these findings. It is also possible that the results are mere accounting artifacts: since we also document that firm profitability declines prior to a currency crisis, a reduction in earnings could automatically increase the debt-to-value ratios. Finally, leverage increases could be completely unrelated to currency crises, only a result of the preference for debt over equity during the 1990's.

We try to provide some more evidence for and against the previous theoretical arguments. In the papers by Aghion et al. (2001), Krugman (1999), and Bris and Koskinen (2002), firms either suffer or benefit from a currency depreciation depending on their exchange rate exposure. The asymmetric reaction to a currency depreciation is even more explicit in Schneider and Tornell (2001). Therefore, we first sort companies within a country into two groups using individual companies' stock market returns. In the first group we have companies whose stock returns decrease when the domestic currency appreciates with respect to the U.S. dollar (negative exposure companies), and in the second group we place those companies whose stock returns increase (positive exposure companies). The first group includes exporting firms and firms in the tradable sector in general, while the second group includes importing firms, firms financed with large amounts of foreign debt and firms in the non-tradable sector.

After sorting the companies into these two groups, we show that the companies with negative exposure have higher leverage than the companies with positive exposure, and, moreover, the negative exposure

companies increase their leverage more than positive exposure companies prior to a currency depreciation. Importantly, this is only true for countries in the crisis sample. In addition, we analyze companies profitability and financial fragility using several standard ratios, and show that negative exposure companies in particular become more fragile financially before a currency depreciation. We also find that profitability decreases for all companies before a currency crisis, but the effect is more pronounced for the negative exposure companies. This decline in profitability could explain why leverage increases. However, we show that profitability does not explain debt ratios at the time of the currency crisis in our cross-sectional regression. In this multivariate regression framework, controlling for firm and country characteristics, we report that companies that benefit from a currency depreciation have higher leverage than companies that are harmed by the depreciation. Interestingly, the results are the opposite for the no crisis sample in almost all respects: in general, positive exposure companies fare worse than negative exposure companies in these countries. Besides, after controlling for our measure of exchange rate exposure, we find the usual proxies for corporate governance quality to be either insignificant, or with unexpected signs, when used as a explanatory variables of firm leverage.

The finding that firms that benefit from a currency depreciation increased their leverage prior to the corresponding currency crisis supports the view in Bris and Koskinen (2002). The result that firms were less profitable and are more fragile even after a currency depreciation, is consistent with the arguments posed by Aghion et al.(2001) and Krugman (1999). We conclude that the evidence seems to support the arguments of Bris and Koskinen (2002) in Europe, whereas the Asian crisis is more in line with Aghion et al. (2001) and Krugman (1999). In general, the empirical evidence is consistent with Schneider and Tornell's (2001) argument of asymmetric performance for firms depending on whether the firms benefit or a harmed by currency depreciations.

In addition to these models our empirical evidence is in some respects consistent with the paper by Aghion et al. (2000), although their model does not explicitly deal with currency crises. In that model,

the liberalization of a country's capital account leads to a relaxation of credit constraints for the firms in that country. This leads to initial increased investments and profitability for the firms in the tradable sector. Further investments lead to decreased profitability because of raising costs. This might lead to capital flight and to a currency crisis. Empirically, the implications of Aghion et al. (2000) are similar to Bris and Koskinen (2002), although the economic mechanisms behind the results are different.

There is also a growing body of literature that emphasizes corporate governance issues in currency crises. Johnson et al. (2000) show that lack of outside investor protection is positively related to the amount of depreciation in emerging markets. Mitton (2002) provides evidence that during the Asian crisis firms that had higher disclosure quality and higher outside ownership concentration, had also better stock market performance. In addition, Lemmon and Lins (2001) show that a greater likelihood of outside shareholder expropriation led to lower stock market valuation during the Asian crisis. The approaches emphasizing corporate leverage and corporate governance can be viewed as complements. For example, to the extent that corporate governance problems lead to more reliance on debt financing at the expense of equity financing, then the two approaches are consistent. However, in our cross-sectional regression, we also control for corporate governance characteristics on the country level and find that our measure of exchange rate exposure still helps to explain company level leverage, while the corporate governance variables give inconsistent results.

The next section of the paper describes the data and its sources. In Section II we explain our approach to estimating exchange rate exposure. In Section III we study firm leverage and the relationship between leverage and exchange rate exposure. In Section IV we relate exchange rate exposure to several different measures of profitability. In Section V we provide cross-sectional evidence on the determinants of capital structure. Section VI concludes the paper.

I Data and sample description

Throughout the paper, we define a currency crisis as the event in which either a government or a central bank decides to let its currency float or administratively devalues it. We obtain information about currency crises that have occurred in the period 1985-2000. These are partly compiled in Kaminsky and Reinhart (1996). Additionally, Italy, the United Kingdom and the countries that experienced the Asian crisis of 1997 are also included in the sample. When a country has suffered several crises in the period 1985-2000 (this is the case, for instance, for Brazil, Spain and Turkey), exclusively the last one is considered. The final sample of crises includes seventeen countries, and its description is in Table I. There have been other major currency depreciations that are not included in the final sample for a variety of reasons. For example we do not include the Russian crisis of 1998 because of a lack of data on Russian firms. We also eliminate Bolivia, Chile, Colombia, Israel, Peru and Uruguay, because we lack stock price data before the crises. For some countries the most recent crisis has not been considered due to the unavailability of data after the crisis³. Brazil, for instance, suffered its last crisis in 1999. In addition, we include three countries that did not suffer what we define as a currency crisis. However, these countries – Argentina, Hong Kong and Japan – either suffered severe attacks on their currencies or even experienced a modest currency depreciation initially. Argentina⁴ and Hong Kong⁵ had a currency board and both countries experienced attacks on its currency, but neither country changed its exchange rate policy. Japan’s exchange rate initially depreciated against the U.S. dollar⁶, but later fully recovered. We will refer to these three countries as the no crisis sample.

For each country in our total sample, Datastream provides a Global Market Index, that includes a varying number of firms per country⁷. Datastream also provides accounting information regarding all the available firms in the corresponding market, for a window of five years around the year of the currency crisis.

We are able to find information in Datastream for 6,781 firms from the 20 countries we consider, 4,662 firms in our crisis sample and 2,119 firms in our control sample. Among those, 4,376 firms are from

Asia⁸, 2,255 from Europe, and 150 firms from Latin America. We compare the number of firms in our sample with the total number of firms in the stock exchange in the corresponding country as of December of the respective crisis year, as reported by the International Federation of Stock Exchanges. On average, our sample contains 65.20% of all the firms listed in a country's main stock exchange. This percentage is lower for Latin American countries, where currency depreciations happened earlier and hence the lack of data is a more severe problem.

[INSERT TABLE I]

In Table I, we calculate the domestic stock market return during the month of the currency depreciation. On average stock prices decline 3.39% during the crisis month. We also calculate the currency depreciation relative to the U.S. dollar⁹, both during the crisis and month and the following year. The average currency depreciation in our sample amounts to 16.60% during the crisis month and to 23.52% during the year (including the crisis month). The largest initial depreciation happened in Turkey (55.05%), the lowest in Italy (3.24%) for the crisis sample. Indonesia suffered the biggest depreciation (79.48%) in the 12 months following the crisis. Countries in the no crisis sample had very stable currencies, especially if measured on a yearly basis. The median debt-to-value ratio (book values) for the total sample is 35.89%, with Korea having the highest ratio (55.22%), and Sweden the lowest (15.77%). By regions, Asian countries display the highest debt levels, with a median leverage of 39.35%. European countries have a 28.57% debt ratio and the median for Latin America is 23.99%.

Table II describes the exchange rate regimes for the countries in our sample. Strictly speaking, only Brazil, Mexico, and the Philippines had fixed exchange rates prior to their currency devaluations. In addition to the member countries in the European Union, Finland, Norway and Sweden maintained their exchange rates within a band with respect to the European Currency Unit (ECU). Other countries (South Korea, Indonesia, Singapore, and Taiwan) fixed their real exchange rates with respect to either the U.S.

dollar or a basket of currencies. Malaysia and Venezuela allowed for fluctuations with respect to the dollar. Figure 1 shows that, although pegged to the dollar, Latin American currencies were the ones that fluctuated the most before the crises. Brazil pegged the real only six months before its last devaluation, and Mexico suffered several crises before the ones we consider in this paper. Asian exchange rates are the least volatile in the last six years before a crisis (the standard deviation of the monthly change in exchange rates is 0.84% in Asia, 1.54% in Europe, and 5.52% in Latin America).

[INSERT TABLE II]

[INSERT FIGURE 1]

In the next section we survey the literature on exchange rate exposure and propose a new methodology that allows us to differentiate firms depending on whether they benefit from or are harmed by currency depreciations. We regress the stock return of every firm on exchange rate changes and the component of the domestic market return that is orthogonal to the changes in the exchange rate.

II Exchange rate exposure

For the past twenty years, financial researchers have paid a great deal of attention to how to measure a firm's exposure to exchange rate movements. The basic models can be grouped into two categories: accounting based exposure and stock price based exposure. For our purposes, the accounting-based approach poses at least three problems. First of all, lack of data. The number of firms for which data on exports is available is quite limited in emerging markets¹⁰. Secondly, foreign sales may not be an accurate proxy for exchange rate exposure, because of hedging and debt denominated in foreign currencies. Finally, it is possible that a firm that only operates in the domestic market is nonetheless exposed to exchange rate risk, if competitors are foreign firms that sell to the country where the domestic firm operates¹¹. Therefore, movements in the exchange rate affect the competitiveness of the domestic firm and therefore its profits. Hence, in this

paper we use a stock market based measure of exchange rate exposure.

Among the studies that focus on stock price - based exposure, Jorion (1990, 1991), Bodnar and Gentry (1993) and Amihud (1994) regress a company's stock return on exchange rate changes and additional control variables such as a market portfolio return¹². Jorion (1991) uses a two-factor model, with the value-weighted stock market return as the first factor and the orthogonal component of innovations in a trade-weighted exchange rate as the second factor. The orthogonalization eliminates spurious pricing of the exchange rate factor because of a possible correlation between exchange rate and market return.

Finally, Bodnar and Wong (2000) suggest that the inclusion of a market portfolio increases the precision of the residual exposure estimates. However, if the market portfolio has a non-zero exposure, including a market portfolio as a regressor shifts the distribution of the residual exposure estimates with respect to the total exposure counterparts. Therefore residual exposure estimates reflect the deviation of the firm's exposure from the market's portfolio exposure. As most studies use a value-weighted portfolio, dominated by large firms with a more negative exposure to exchange rate movements, the residual exposure estimates suffer from a positive shift. The solution the authors suggest is the use of an equal-weight market portfolio to correct for the correlation between firm size and the sign of the exchange rate exposure.

A An alternative approach

Our calculation of the exchange rate exposure is inspired by Jorion (1991). However, our procedure is exactly the opposite of Jorion's: in explaining individual companies' stock returns, we use as regressors the change in exchange rate and the component of market return that is orthogonal to the change in exchange rate. This methodology circumvents the critique made by Bodnar and Wong (2000). We measure exchange rate exposure in absolute sense, not relative to the market as a whole. In order to avoid non-synchronous movements in exchange rates and stock returns, we use monthly data.

First we estimate the following regression for each country in our sample:

$$R_{mt}^j = \gamma_o^j + \gamma_1^j R_{xt}^j + \nu_{st}^j \quad \forall j = 1, \dots, 20 \quad (1)$$

where R_{mt}^j is the market return, and R_{xt}^j is the change in the exchange rate in country j . We estimate the γ coefficients using monthly data from month $t = -72$ to month $t = -37$ relative to the currency depreciation month¹³. Next, we calculate $F_{mt}^j = R_{mt}^j - (\hat{\gamma}_o^j + \hat{\gamma}_1^j R_{xt}^j)$ from the previous regression, and use the estimated orthogonal component of market return in the regression:

$$R_{ijt} = \delta_i + \beta_i^x R_{xt}^j + \beta_i^m F_{mt}^j + \epsilon_{ijt} \quad (2)$$

where R_{ijt} is the stock return of firm i in country j , R_x^j is the monthly change in the exchange rate in country j , and F_m^j is the estimated orthogonal component for market j . Note that, if the $\hat{\gamma}_1$ coefficients are not significantly different from zero, the orthogonalization induces an error in variables problem, and the variance of $\hat{\beta}_i^x$ will be inflated. Therefore we calculate F_{mt} with $\hat{\gamma}_1 = 0$ when its significance level¹⁴ is higher than 10%. The estimated β_i^x are, as stated, measures of firm i 's exposure to exchange rate risk (the exchange rate beta or ERB).¹⁵

Exchange rate exposure can be also affected by changes in leverage. If a firm borrows in a foreign currency it is more likely to display a positive ERB. Thus the ERB becomes endogenous. To avoid this problem, the estimation window for the ERB coefficients ends three years prior to the corresponding currency crisis. The changes in leverage we analyze in the paper, ranging from year $t = -3$ to year $t = +2$ relative to the crisis year, are therefore exogenous to past currency exposures.

Some of the countries where we calculate exchange rate exposures had fixed exchange rate regimes during the estimation period. Intuitively one expects exchange rate betas to be insignificant because of the invariability of exchange rates. However it is worth noting that, as Figure 1 shows, the nominal exchange rates in these countries fluctuated considerably. In Europe currencies were allowed to fluctuate within a band. In Asia, some of the pegs were real, in other countries the currency was pegged to the yen, and not

to the dollar. Finally, in other countries like Taiwan the currency fluctuated also within a band. This is clear evidence that the exchange rate regimes did not eliminate firms' currency risk.

In Table III we show for each country the average and median exchange rate betas and the market betas¹⁶, as well as each individual market exposure coefficient to exchange rate movements, following the methodology outlined above. The average exchange rate beta is the size-weighted average of the exchange rate betas calculated for the firms in a particular country. The market exposure is, for every country, the estimate of γ_1 in regression (1).

Only in eight countries the country exposure (the γ_1 coefficient) is significant at the 10% level of better. All European countries, except Turkey, have a negative value for γ_1 , whereas in Asia, countries have both negative and positive exposures. In Thailand, for instance, the country exposure is -5.659 (significant at the 5% level). Indonesia, in the other extreme, displays a country exposure of 6.029 (also significant at the 5% level). In our control sample, Argentina has a negative country exposure of -0.760 (significant at the 5% level).

[INSERT TABLE III]

We expect exporting firms to display a negative exchange rate beta, while domestic firms should have a positive exposure. Seoul Foods, for instance, a South Korean firm that manufactures bread and snack foods (arguably a non-exporting firm) has a beta of 1.783 . An exporting firm such as Shin Corporation¹⁷, from Taiwan, has a beta of -4.241 . The results for the average market betas are consistent with Bodnar and Wong (2000), since we find markets to be exposed to currency movements.

Therefore, and in the absence of data on the structure of the balance sheet for each firm, we are able to classify every firm in the sample into two categories depending on its exposure to exchange rate movements: firms that benefit from currency depreciations and firms that suffer from depreciations. It is worth noting that exporting firms may have an insignificant exchange rate beta if they hedge their currency exposure

or if they have borrowed in foreign currencies¹⁸.

We rank firms in a particular country by their exchange rate beta. Firms are not comparable in terms of exchange rate exposure across countries. Therefore we rank each firm with respect to the other companies in the same country by splitting the sample between firms with negative and positive exchange rate beta.

In the next section, we analyze the different effects of the currency depreciation on firms depending on whether the firm has negative or positive exposure to currency movements.

III Firm leverage

In this section we report debt-to-value ratios, as a measure of leverage, for all the firms in our sample.¹⁹ The debt-to-value ratio is analyzed for the last three years preceding the currency devaluation, as well as for two years after the devaluation. For each firm, we gather data on its total debt-to-value ratio as well as on the percentage of short-term debt to total debt from Datastream. Both ratios are in book values. We use book values primarily because using market values would yield spurious results. For example, a decline in stock prices before a currency depreciation would imply an increase in debt-to-value ratios without any increase in the amount of debt, if market values were to be used.

[INSERT TABLE IV]

First we report firm level debt-to-value-ratios country by country and on a regional level. The results are shown in table IV. For the overall sample, the median increase in leverage is 1.91% in the two years preceding a crisis (significant at the 1% level). The increase is 12.78% in Europe (significant at the 1% level), 0.42% in Asia (also significant at the 1% level) and 7.16% in Latin America (significant at the 10% level). For the countries with currency crises, the increase is a significant 4.43%, but for the control sample there is no increase in leverage prior to the currency attack. In levels, Asia as a region has the highest leverage throughout. On a country level, at the year of a crisis, we document high leverage in Europe for

Finland, Italy and Norway (all above 40%), in Asia for Indonesia, Japan, Korea and Thailand (ranging from 40% to over 51%) and in Latin America for Mexico (40%).

In the two years after a crisis, the debt ratio increases by 3.73% for the overall sample (significant at the 1% level). For the crisis sample, the increase is 8.35% (significant at the 1% level), but for the control sample the increase is only 0.72% (significant at the 10% level). In the post-crisis period we document markedly different developments depending on the region. In Europe, there is not much change in the leverage level after the crisis. Asia and Latin America both exhibit a significant increase in debt-to-value ratios. For Asia, the increase in leverage is consistent throughout all the countries, except for Hong Kong and Japan, which both belong to our control sample. Based on changes in leverage, the crises in Europe and Asia are different: increases in leverage before the crises for both regions, but continuing increases in Asia even after the crisis, while in Europe there is no change for the post-crisis period. If we group all the non-Asian countries together, there is even a significant decline in leverage after the crises (-1.19%).

After studying the changes in leverage on a firm level, we sort firms into two groups based on their exchange rate exposure. Since in Aghion et al.(2001) and Bris and Koskinen (2002) the effect of depreciation on firms' financial distress problems is the opposite, and Schneider and Tornell (2001) predict different patterns for firms in the tradable and non-tradable sectors, it is important to establish what kind of firms increase their leverage prior to a currency crisis and what happens to different firms and their leverage after a crisis.

[INSERT TABLE V]

The results are shown in table V on a regional level for companies sorted into two groups based on their exchange rate exposure. For our crisis sample, we find that firms that benefit from a currency depreciation (those with negative exchange rate beta) increase their debt-to-value ratios 7.35% in median (significant at the 1% level) in the two-year period that precedes a devaluation, while firms that suffer from

a depreciation increase leverage by 1.59% (significant at the one percent level). The difference between negative and positive exposure firms is also significant at the one percent level. Negative exchange rate beta firms increase their leverage while the positive exchange rate beta firms decrease their leverage in Europe (median increase 13.66%, significant at the 10% level, compared to a insignificant decrease of 1.86%) and in Asia (5.69% median increase versus a decrease of 3.92%, significantly different at 1% level). In Latin America both types of firms increase their leverage (13.46% and 8.75% median increases). The results are reversed for the control sample, where negative exchange rate beta firms decrease their leverage by an insignificant 0.71% and positive exchange rate beta firms increase by 0.62% percent (significant at the 5% level). Hence, firms behave differently in the crisis sample and in the no crisis sample depending on their exchange rate exposure. In general, in the crisis sample, the firms that have negative exposure increase their leverage more than positive exposure firms. For the control sample, the the opposite holds. Asia as whole (the crisis sub-sample from Asia plus Hong Kong and Japan) does not exhibit large increases in leverage.

In the two years that follow the currency depreciation, the patterns are reversed. In the crisis sample, positive exchange rate beta firms increase their leverage significantly more than negative exchange rate beta firms (2.87% for negative exposure firms and 14.97% for positive exposure firms, significantly different at the 10% level). In the control sample, there is no change in leverage after the crisis.

On the regional level, we can observe clear differences. In Asia and Latin America, leverage increases for both types of firms after the crisis. In Asia, the positive exposure firms increase their leverage by 25.00% (significant at the 1% level) and negative exposure firms by 6.13% (also significant at the 1% level, and the difference is also significant at the 1% level). Based on this evidence of increasing leverage, currency depreciations did not help to alleviate financial distress problems especially in Asia. The situation is markedly different in Europe for the two years after the crisis has occurred. Negative exposure firms show declining leverage in Europe in the two years following the crisis. The median decrease is 3.96%

(significant at the 1% level). Moreover, debt-to-value ratios remain clearly on a higher level in Asia than in Europe or Latin America throughout the pre- and post-crisis periods. The Asian and non-Asian samples both exhibit big leverage increases for the positive ERB firms.

[INSERT TABLE VI]

We also analyze the changes in short-term debt ratios to total debt, where short-term is defined as a maturity of less than one year. Results are in table VI. For the overall crisis sample and for Europe and Latin America, the median short-term debt to total debt ratio actually declines both in the two years before a crisis and after a crisis. This holds for both negative and positive exchange rate beta firms. The Asian crisis sub-sample shows somewhat different results, since there is a significant increase for the negative exposure firms in the two years preceding a crisis (an increase of 1.16%, significant at the 1% level). Moreover, if we just limit the attention on the crisis year, Asian firms clearly resort to more short term financing. Interestingly, the no crisis sample also exhibits increasing use of short-term debt prior to a crisis.

Our results concerning the increase in leverage are consistent with Pomerleano (1998) and Harvey and Roper (1999). These authors also document significant increases in short-term debt. Pomerleano (1998) documents the rapidly increasing debt ratios in Asia, specially short-term, from 1992 to 1996. Harvey and Roper (1999) report that the median leverage ratio across the 261 firms in their sample was 68.6 percent in 1992, and 114 percent in 1996. The leverage increase was mostly short-term again. We also document increases in short-term debt, especially for the negative exposure firms, but the magnitude of increase in our sample is rather modest. However, during the crisis year Asian firms clearly exhibit a jump in the amount of short-term borrowing..

In Claessens et al. (1998), Asian firms also display increasing debt ratios, and their data suggest that the ratio of short term debt to total debt in the Asian economies was significantly larger than in the U.S.

or Germany (the median short-term debt share increases from 47.26 percent in 1988 to 60.43 percent in 1996; this ratio is 25.9 percent in 1996 in the U.S., 45.3 percent in Germany). Our evidence is consistent with Claessens et al.(1998), since we also document that in Asia the percentage of short term debt relative to total debt was clearly higher than in other regions.

In general, these results show that economies display increasing corporate leverage prior to a currency depreciation, particularly among companies that benefit from currency depreciations. The increase in leverage is not due to relatively higher increase in short-term borrowing for European and Latin American companies. In addition, the no crisis sample demonstrates no increases in over all leverage prior to the date of the currency attack, while there is an increase in the amount of short-term debt used. So what differentiates crisis and no crisis countries is not the changes in the amount of short-term debt, but the changes in the overall level of leverage.

The increase in leverage for negative exposure companies prior to a currency depreciation is consistent with Bris and Koskinen (2002), whereas the increase in leverage after a currency depreciation, especially among the positive exposure firms, is consistent with Aghion et al. (2001). All in all, the results clearly show that firms in different sectors of the economy show distinct patterns before and after a crisis has occurred. These patterns are consistent with Schneider and Tornell (2001), to the extent that our classification of firms based on their ERBs corresponds to the classification of traded and non-traded sectors used by Schneider and Tornell (2001).

In the next section we analyze alternative measures of performance, profitability and investment.

IV Other variables

A Profitability

Harvey and Roper (1999), Claessens et al. (1998), and Pomerleano (1998) report a significant decline in profitability in Asian economies prior to the 1997 crisis (decreasing Return on Assets in Claessens et al., 1998; declining Return on Equity in Harvey and Roper, 1999; and decreasing Return on Equity and Return on Capital Employed in Pomerleano, 1998). We want to examine whether this result extends to other regions and whether it is uniform across firms with different exposure to exchange rate movements.

[INSERT TABLE VII]

We obtain data on two measures of profitability (Earnings Before Interest and Taxes over Total Revenues, and Return on Capital Employed). Results are in Tables VII and VIII. We do find significant declines in profitability under both measures and in the three regions under consideration for our crisis sample in the two years preceding the crisis. For the overall crisis sample, the EBIT to revenues ratio decreases for both negative and positive exposure companies the two years prior to a currency depreciation. The median decline is more severe for negative exposure firms (-30.05% for the negative exposure firms compared to -8.45% for the positive exposure firms, significantly different at the 1% level). This result carries over to Europe and Asia, where the firms that have negative exchange rate betas have a bigger decrease in median profitability (the difference is significant at least at the 5% level). In the control sample and for the Latin American crisis sample, it is the positive exposure firms that show larger declines in EBIT to revenues ratio in the two years prior to a crisis.

After the currency depreciation, profitability decreases only for the positive exposure firms in Europe and Latin America. Interestingly, this result does not hold for Asia, where EBIT to revenues ratio declines both for negative and positive exposure firms. The same results holds for our control sample. Based on changes in EBIT to revenues ratios, Asia is again different from other crisis regions: in Asia, all firms suffer

from declining profitability, whereas elsewhere only the positive ERB firms show further decreases.

[INSERT TABLE VIII]

The other measure of profitability we use, the Return on Capital Employed (ROCE), confirms that profitability decreases in the two years before a currency depreciation. In the overall crisis sample, both negative and positive exposure companies exhibit declining profitability, but again it is the negative exposure firms that suffer more (decreases of 3.26% and 2.64%, respectively). Interestingly, now the control sample tells the opposite story: increase in ROCE for negative exposure firms and no decline in ROCE for positive exposure firms in the two years prior to a crisis. Asian firms, both in the crisis sample alone and grouped together with Hong Kong and Japan, clearly have lower profitability compared to European and Latin American firms both before and after the crises.

After currency depreciations, we cannot observe any improvement in ROCE for the overall crisis sample. This result is, however, due to adverse development in Asia after the crisis, and is consistent with the previous result using EBIT to revenues ratio as a measure of profitability. After a currency depreciation, the profitability of all firms in Asia declines no matter what the measure. The same is true for the control sample. In Europe and Latin America, there is no significant change in ROCE after the currency depreciations. These results confirm that the Asian crisis is different from the European and Latin American ones. Further declines in Asia for all firms, but in Europe and Latin America only the positive ERBs firms have declining profitability if EBIT to revenues is used as the measure. If ROCE is used as a measure of profitability, then neither negative nor positive exposure firms in Europe and Latin America show further decreases in profitability.

B Financial fragility

Radelet and Sachs (1998) blame financial panic as a cause of the East Asia crises of 1997. They identify the ratio of short-term debt to foreign exchange reserves as an indicator of a country's risk. Radelet and Sachs (1998) report that this ratio was above one for Indonesia, Thailand and South Korea prior to 1997. However, it was also below one for some other countries affected by the crises, such as Taiwan and the Philippines.

We study financial fragility in a similar fashion to Radelet and Sachs (1998), except that we use firm level data. In our analysis, the current ratio measures the ability of a creditor to pay off its short-term debts. The current ratio is calculated as current assets to current liabilities, and it reflects the current liquidity of the firm. Pomerleano (1998) argues that this would be a good measure of a firm's financial fragility, although the ratio is not reported in his study.

[INSERT TABLE IX]

We report in Table IX the current ratio for 2,994 firms in our crisis sample and for 1,304 firms in our control sample. The evolution of the current ratio differs across firms depending on their currency exposure. While negative exposure firms decrease their current ratio by 5.00% (significant at the 1% level), the change for positive exposure is insignificant for the overall crisis sample. The evidence differs somewhat depending on the crisis region: for all the regions, negative exposure companies have a significant decline in current ratio, but for positive exposure firms the evidence is divergent. In Europe, the positive ERB firms exhibit even greater decline in current ratio than the the negative ones, whereas in Latin America the positive exposure firms become less fragile. For the control sample, the decline in the current ratio is about the same for all firms. It is interesting to note that for the U.S. the current ratio for the total sample of Compustat firms (5,108 firms with data available) in the years 1995 through 1998 is respectively 3.29, 3.70, 4.04 and 3.34, considerably higher than either in our crisis or control samples.

Interestingly, for two years after the crisis, the current ratio still declines for Asian firms (a decline of 12.00% for the negative exposure firms and 23.00% for the positive exposure firms, both significant at the 1% level), whereas in Europe the positive ERB firms show increasing current ratio and in Latin America only the negative exposure firms decrease their current ratios. This is further evidence that the Asian firms have been slower in their recovery compared to European and Latin American firms.

[INSERT TABLE X]

Table X complements the previous result. We display the interest coverage ratios for the firms in the sample, and find a clear deterioration in solvency for both negative and positive exposure firms prior to the onset of the corresponding crisis. The interest coverage ratio is calculated as EBITDA divided by Interest Expense, where EBITDA are the company's earnings before total interest expense, depreciation, amortization and provisions. For the overall crisis sample, negative exchange rate beta firms experience a decrease of 40.25% in their interest coverage ratio, while firms with a positive exchange rate beta decrease their interest coverage ratio by 30.79%, both coefficients significantly different from zero at 1% level. For European firms, the change in interest coverage ratio declines for both types of firms (−50.47% change for negative exposure firms and −44.42% change for the positive exposure firms, both significant at the 1% level). For Asian firms, the negative exposure firms show a significant decline in interest coverage (a decrease of 7.09%, significant at the 1% level). It is especially interesting to observe that the level of interest coverage is very low for Asian firms already several years before the onset of the crisis, especially for the negative ERB firms. Also noteworthy is the observation that in our control sample positive exposure firms significantly increase their interest coverage ratios prior to the attacks (an increase of 11.18% for positive exposure firms, significant at the 1% level).

For European firms, the interest coverage ratio increases significantly (an increase of 8.56% for the negative ERB firms) during the two years following the currency crisis, while for the Asian firms, the

interest coverage ratio declines even further (a decline of 35.80% for negative exposure firms and 45.07% for the positive exposure firms, both significant at the 1% level). Analysis of the interest coverage ratio thus further confirms the special characteristics of the Asian crisis with respect to the turbulences in Europe and Latin America. Moreover, interest coverage is markedly lower in Asia during the six years that we study compared to Europe and Latin America. After two years of the onset of the crisis, interest coverage is below one for negative ERB firms in Asia. This implies that Asian companies did not earn enough revenues to cover their interest expenses.

C Investments

We analyze the investment policies in our sample of firms from three different regions by obtaining data on changes in total assets. We define net investments as the ratio of changes in total assets relative to total assets in the previous period. In Table XI we summarize changes in net investments for a period of six years.

[INSERT TABLE XI]

Overall in our crisis sample, negative ERBs companies invest less than they did before the onset of a currency crisis. (a decline of 7.10%, significant at the 1% level), whereas there is no change for the positive ERB companies. In our control sample, both negative and positive exposure firms increase their investments. Among the regions in our crisis sample Asia stands out once more: both types of firms increase their investments in the two years before the crisis (increases of 4.88% and 2.25% for negative and positive exposure firms, respectively). Moreover, the investment levels for Asian firms are high until the crisis. In this respect, Asia is different from Europe and Latin America. Claessens et al. (1998) report, in line with our results, relatively higher investment rates (measured as new dollar investments as a share of existing fixed assets) in Asian firms than in U.S. and German firms. Consistent with Schneider and

Tornell's (2001) model, the positive exposure firms grow more in the years preceding a currency crisis in all the regions.

Asian investment patterns differ from those of Europe and Latin America also after the currency depreciations. Both negative and positive ERB firms in Asia show decreases in the investment rate after the crisis. Two years after the crisis the negative exposure firms in Asia are actually downsizing, not just growing at a slower rate. In Europe and Latin America the negative ERB firms increase their investment rates.

D Summary of the findings

Our analysis suggests that firms in countries that have suffered dramatic exchange rate depreciations in the last decade follow a similar pattern of financial policies prior to a currency crisis. We have documented significant increases in leverage in the two years preceding a currency depreciation. These increases in leverage are greater for negative exposure firms in our crisis sample, whereas for the control sample the opposite holds. We also show a decline in profitability in the corporate sector. The decline is more accentuated for the firms with negative exposure to exchange rate movements. Again, the evidence for the control sample is very different. The major difference between Asian companies and other companies in the pre-crisis period is that Asian companies keep on investing a lot.

We are able to document significant differences across regions in the years following a currency depreciation. In Europe and Latin America the performance of negative ERB firms improves or at least does not get any worse, while in Asia the performance of all firms gets worse after the onset of the crisis. The evidence in Europe fits quite well with the predictions of Bris and Koskinen (2002), whereas the implications of Aghion et al. (2001) are more consistent with the Asian evidence. Overall, the evidence gives support to the Schneider and Tornell (2001) model to the extent that firms with negative and positive exchange rate exposures correspond to firms in tradable and non-tradable sectors.

Next we study cross-sectionally the determinants of a firm leverage prior to the currency crises.

V Cross-sectional analysis on firm leverage

We complete the analysis by testing whether firms' leverage prior to a currency depreciation can be explained partially by their exposure to currency movements. If financial distress is likely to induce a government to let the currency depreciate as a way of bailing out companies, as postulated by Bris and Koskinen (2002), then we should expect firms that benefit the most from a currency depreciation to have a higher leverage than companies that suffer from depreciation prior to a currency crisis. So far we have showed in a simple time-series framework, that negative exposure companies increase their leverage more than positive exposure companies do. At the same time, we also know that negative exposure firms profitability declines more than positive exposure firms profitability during the pre-crisis period. Hence, the increasing leverage for negative exposure firms could be just an accounting artifact resulting from accumulating losses. Studying leverage in a cross-sectional regression allows us to control for profitability and other firm specific characteristics and as a result we can get a more reliable evidence about the role of currency exposure in determining the leverage choices of the firms.

We perform cross-sectional regression analyses at the firm level where the dependent variable is the firm's debt-to-value ratio (book values) as of December prior to the corresponding currency crisis. The set of explanatory variables includes the firm's exchange rate beta, calculated over a window of $t = -60$ to $t = -24$ months relative to the event month. We construct a dummy variable I_i that takes value 1 if the corresponding firm i belongs to the crisis sample, and zero if it belongs to the control sample. We then decompose the effect of the exchange rate beta into two groups, depending on the dummy variable. The first component equals $I_i\beta_i^x$, that is described in Table XII as 'Exchange Rate Beta – Crisis Sample'. The second component equals $(1 - I_i)\beta_i^x$, described as 'Exchange Rate Beta – No Crisis Sample'. The procedure allows us to disentangle the effect of the exchange rate regime in a joint estimation.

La Porta et al. (1998) argue that laws affecting investor protection have consequences for corporate finance. We therefore control in our analysis for differences in efficiency of the judicial system, rule of law, corruption, and risk of expropriation across countries. The variables reported in La Porta et al. (1998) are averages calculated over different time horizons, so their interpretation must be taken with caution. For instance, the efficiency of the judiciary system is calculated by La Porta et al.(1998) as the average between 1980 and 1993, while the start of currency crises we consider dates from 1992. In our regressions, we therefore employ the complete time series of data that La Porta et al. use in their paper²⁰, and calculate when possible the five year average prior to the corresponding currency crisis date. Comparing the mean values of the variables in our sample with all the countries considered by La Porta et al. (1998) we do not observe dramatic differences (the mean values for the variables ‘Efficiency of the Judicial System’, ‘Rule of Law’, ‘Corruption’, and ‘Risk of Expropriation’ are 7.10, 6.78, 6.59, and 7.96 for our sample, and 7.67, 6.85, 6.9, and 8.05, for a total sample of 49 countries in La Porta et al.).

Rajan and Zingales (1995) argue that highly levered companies are more likely to give up profitable investment opportunities. Hence, growth opportunities (using the market value of assets divided by the book value of assets as a proxy) should be negatively related to debt-to-equity ratios. We calculate the average market to book ratio in the three years preceding the currency crises for 3,211 firms in our sample. In Rajan and Zingales (1995) size is measured by the logarithm of sales. They obtain a positive coefficient in their regressions, although, in their view, a negative relationship between size and debt levels is sensible if size is also a proxy for the information outside investors have. Our measure of size is a three-year average of a firm’s sales before the relevant currency depreciation. Additionally, Rajan and Zingales (1995) find a negative relationship between earnings (earnings before interest, taxes and depreciation normalized by the book value of assets) and book debt-to-value ratios. Our measure of profitability is EBIT normalized by total assets. We further control for the log of the GDP per capita in dollars. In addition, in model I we also employ firm-level fixed effects.

[INSERT TABLE XII]

The results from the regression are reported in Table XII. For the total sample, we find results consistent with Rajan and Zingales (1995), since profitability and size have respectively negative and positive coefficients in general. Contrary to Rajan and Zingales (1995), market to book ratio is never significant in our cross-sectional regressions. Focusing on the coefficient for the exchange rate beta, we consistently find a negative relationship between a firm's exposure to exchange rate movements and book leverage for the firms in our crisis sample. The opposite holds for the firms in the control sample. This means that negative exposure firms have higher leverage than positive exposure firms for our crisis sample, even when we control for the relevant firm characteristics. This finding is consistent with the arguments in Bris and Koskinen (2002). We also find that some corporate governance variables help to explain leverage, albeit sometimes the coefficients are not significant. Corruption index and risk of expropriation get negative coefficients, which are to be expected: high corruption and high risk of expropriation lead to increasing leverage.

VI Conclusions

This paper uses company level data from seventeen countries that have experienced a currency crisis during the past decade. We also include data from three control countries, whose currencies were under attack, but remained quite stable. First we study leverage on company level before and after the currency crises. We document increasing leverage before the onset of the crises for Europe, Asia and Latin America. After the respective crises, we show that leverage further increases in Asia and Latin America, but not in Europe. Furthermore, the increasing leverage during the pre- and post-crisis periods is confined to the countries that were forced to devalue their currencies during the crisis.

Next we sort companies into two groups depending on whether they benefit from or are harmed by

currency appreciations. The sorting is done using companies individual stock returns that are regressed on their home currency's movement against the U.S. dollar and on the part of market return that is orthogonal to the currency movement. Using this grouping we are able to show that there are differences in companies' leverage and profitability depending on their exchange rate exposure in our crisis sample. While leverage increases and profitability declines for all companies, these effects are more pronounced for negative exchange rate exposure companies. We find the opposite for our control sample. Moreover, there are clear differences between the regions. For the European firms that have negative exchange rate exposure, we document that leverage increases and profitability decreases before the crisis, but the financial health of these companies improves after the crisis. Thus there is evidence that currency depreciations have helped the European negative exposure companies. For Asian firms, leverage increases and profitability decreases both before and after the currency depreciations, albeit the negative exposure companies suffer more during the pre-crisis period and less during the post-crisis period. We can conclude that currency depreciations did not help to improve the financial health of Asian companies. The evidence for Latin America is mixed and the Latin American situation lays somewhere between the European and Asian ones. Regarding financial fragility, we find that all firms in our crisis sample become more fragile before the onset of the crisis. Interestingly, there is evidence that again the Asian crisis differs from crises in Europe and Latin America: firms in Asia become even more fragile after the crises, when especially the negative exposure firms in Europe and Latin America start to recover. In addition, net investments also confirm that the Asian crisis is different. In Asia, investments increase prior to the crisis and decline afterwards, while the patterns are the opposite for Europe and Latin America.

The time-series evidence documented could be partially a result of accounting identities resulting from low or even negative profitability. Hence the time-series evidence does not prove any kind of strategic behavior on the part of the negative exchange rate exposure firms. We address this problem in a cross-sectional regression controlling for firm characteristics, including profitability. We find that the firms

with negative exchange rate exposures have higher leverage prior to a crisis than firms that have positive exchange rate betas. The results of higher leverage, higher financial fragility and lower profitability for negative exposure companies are consistent with the arguments in Bris and Koskinen (2002), whereas the evidence that all kinds of firms suffer from these problems is consistent with Aghion et al. (2001). The results of recovery among negative exposure firms especially in Europe show that currency depreciations have helped to solve balance sheet problems, as argued by Bris and Koskinen (2002). We also provide evidence from Asia that is consistent with Aghion et al. (2001): all firms in Asia have lower profitability and are more fragile even after a currency depreciation. In all the crisis regions we establish that prior to the crises, the positive exposure firms fare better than the negative exposure firms and the roles are reversed after the crises. This asymmetrical pattern is consistent with Schneider and Tornell (2001), if our classification of firms to negative and positive exposure firms correspond to the firms belonging to the tradable and non-tradable sectors. Also the observation that positive exposure companies grow faster than negative exposure companies is in accordance with Schneider and Tornell (2001).

The evidence that negative exposure firms suffer more prior to currency crises is also consistent with Aghion et al. (2000). In that paper the declining profits for firms that produce a tradable good is due to increasing costs, not due to firm-level strategic behavior, as in Bris and Koskinen (2002). However, the evidence that negative exposure firms increase their leverage more than declining profits would dictate hints at strategic behavior by the firms.

The results provided in this paper could also be consistent with the corporate governance explanations explored by Johnson et al. (2000), Lemmon and Lins (2001) and Mitton (2002). These papers show, either providing country- or firm-level evidence, that the magnitude of the crisis was negatively related to corporate governance measures in Asia. While these papers concentrate on economic development on a country- or firm-level during the crisis, they do not provide adequate explanation on what caused the crisis. One feasible way for deficiencies in corporate governance to propagate a currency crisis is through

increased leverage. We try to examine this issue in our cross-sectional regression using country-level variables of corporate governance. The results give some support to the view that corporate governance has an independent role in increasing corporate leverage. However, a word of caution is needed: in order to properly study the effects of corporate governance, firm level variables should be used. While we can see the merit of this approach, this is beyond the scope of this paper.

Whether the corporate sector's choice between foreign and domestic debt affects the probability and the severity of currency crises is still an open question. The measure of leverage that we report in this paper does not distinguish among different sources of debt financing. However, by estimating measures of exchange rate exposure on a firm level, we can at least partially deal with this problem. Disaggregated data on debt financing for emerging and developing economies such as the ones that we consider is not easily available, so indirect measures are necessary. The analysis, however, would have interesting implications, and deserves further research.

Notes

¹Out of the 17 countries in our depreciation sample, four countries had strictly fixed exchange rates, eleven countries had fixed rates within a band and two countries had real exchange rate target.

²Referring to a currency crisis for the no crisis sample is obviously a misnomer. For expositional purposes, and for Argentina, Hong Kong, and Japan, *before the crisis* and *after the crisis* mean before and after the speculative attacks to their currencies, respectively.

³We require six years of past information, and two years of post-crisis data, on stock prices for the firms available in the sample in order to perform the estimation.

⁴Following the Mexican devaluation of December 1994, the Buenos Aires stock market witnessed the Merval blue-chip index sliding 17% in January 1995. At the same time, bonds fell sharply, while short-term interest rates nearly tripled. The conversion rate peso-dollar was permitted to fall to 0.998. Although Argentina had a currency board, the Central Bank was forced to take measures to increase the confidence in the peso and inject liquidity into the financial system: the Central Bank started converting pesos into dollars, at par. Banks' reserve requirements on deposits were allowed in the currency of choice, eliminating Central Bank regulation of the denomination of reserves. Reserve requirements on dollar and peso deposit accounts were unified. The measures were well received by the Buenos Aires stock market. The blue-chip index closed up 10.34 per cent the day after the announcement.

⁵In October 1997, speculators pounded the Hong Kong dollar, hoping that the authorities would follow other Southeast Asian countries in allowing the currency to depreciate. The stock market lost \$ 50 billion in a period of three days. Hong Kong overnight interest rates increased 300 percent on October 23. Speculators were shorting the Hong Kong dollar during this period.

⁶The yen depreciated 7.37% in November 1997, and it was at its five-year low in November 25. The Yamaichi Bank had collapsed in November 22.

⁷There are 50 stocks from Brazil, 50 from Venezuela, 90 from Mexico, 50 from Finland, 50 from Norway, 120 from Spain, 70 from Sweden, 50 from Turkey, 550 from the UK, 160 from Italy, 50 from Indonesia, 100 from South Korea, 90 from Malaysia, 50 from the Phillipines, 100 from Singapore, 70 from Taiwan, 50 from Thailand, included in each market index.

⁸Pomerleano (1998), with a sample of firms that include Japan and Hong Kong, employs data from 734 companies.

⁹Throughout the paper, exchange rates are calculated as units of dollars per domestic currency.

¹⁰In their paper on the Asian crises of 1997, Allayannis et al. (2000) are able to find data on exports only for the largest 50 companies in each country.

¹¹For example, shipbuilders in China argued for a devaluation of the renminbi in 1998, since Japanese and South Korean shipbuilders became more competitive as a result of the 1997 crises (Financial Times, July 6, 1998).

¹²In the early studies of Dumas (1978), Adler and Dumas (1984) and Hodder (1982), exposure was measured by the regression coefficient of the real value of the firm on the exchange rate. Although these models are easy to implement, they find the percentage of firms with a significant exposure to exchange rate movements to be low.

¹³Calculating market-based exchange rate exposure can be problematic for countries with currency boards. Argentina, for instance, has a currency board since 1991. We use data on Argentinian companies from 1989 to 1992 to calculate exchange rate exposures (Argentina crises happened in 1995), so firm sensitivities are calculated with pre-currency board data. Hong Kong pegged its currency to the US dollar in 1983. However, the parity has been changing constantly since then.

¹⁴The results in the paper are insensitive to the choice of the minimum significance level. In fact when we limit ourselves to significance levels of 1% or better, our ERB estimates arise from regressing stock returns on exchange rate changes directly (see Table III).

¹⁵In this paper, we only report the results we get using all of our observations. As a robustness check, we have also calculated all the results using only the observations, whose estimates of the exchange rate exposure are significant at the 10% level or lower. None of the qualitative results change. These results are available upon request.

¹⁶If the estimates for country exposure $\hat{\gamma}_1$ are significant, then we report the orthogonalized market betas. Otherwise ordinary market betas are reported.

¹⁷Shiang Shin Corporation, located in Taiwan, is engaged in the manufacturing and exporting of Nitrile Gloves, Latex Surgical Gloves, Latex Examination Gloves, Vinyl Examination Gloves and other Disposable Medical Products. Its main markets are in the U.S.A., Europe, Australia, Japan, Central & South America.

¹⁸Allayannis and Ihrig (2001) and Dominguez and Tesar (2001) provide evidence, that estimates of exchange rate exposure are time-varying and often change signs. In our context, classification of a firm to a wrong exchange rate exposure group would be a conservative mistake.

¹⁹Throughout the paper, we consider the debt-to-value ratio as the object of study. The results do not change qualitatively when we use the debt-to-equity ratio instead.

²⁰We are grateful to Florencio López de Silanes for providing us with this unpublished data.

Table I. Sample Description.

This table displays the number of firms in the sample, number of firms in the corresponding exchange, market return in the devaluation month, and currency depreciation in the crisis month and around the crisis month (attack month for the non crisis sample); and median leverage at the time of the currency crises (currency attack for the no crisis sample). The sample includes all firms with available information in Datastream for seventeen countries that have suffered a currency crises in the period 1985-2000, plus Argentina, Hong Kong, and Japan. Stock returns, Exchange rates, Market Returns and accounting variables are from Datastream. The number of firms in the main exchange is as of December of the corresponding crisis year, and it is obtained from the International Federation of Stock Exchanges' web page, at www.fibv.com/stats/ta11.xls.

Argentina	Fixed peso-dollar exchange rate
Brazil	Fixed against the dollar six months before the crisis.
Spain	The exchange rate is maintained within a margin of ± 15 percent around the bilateral central rates against other participating currencies, with the exception of Germany and the Netherlands, in which case the exchange rate is maintained within a margin of ± 2.25 percent.
Finland	Unilaterally pegged to Ecu.
Hong Kong	Currency Board since 1989
Japan	Flexible Exchange rates
Indonesia	Explicit real exchange rate targeting with the nominal rate falling from 1900 rupiah to the US \$ in 1990 to 2400 by the beginning of 1997
South Korea	The Korean won followed periods of fixity to the US \$ but had a more flexible exchange rate regime. The Won depreciated in nominal terms from 1990 until the beginning of 1993 (from 700 to almost 800 won per dollar). Next, it traded in a very narrow range of 800 to 770 won/\$ between the beginning of 1993 and the middle of 1996. Then, it started to depreciate by about 10% reaching a rate of 884 at the end of 1996
Mexico	Fixed peso-dollar exchange rate
Malaysia	A 10% range of 2.7 to 2.5 ringitt to the US\$ for most of the years between 1990 and the beginning of 1997
Norway	The krone was first pegged to the Ecu on October 19, 1990, within a margin of ± 2.25 per cent from a fixed rate of Nkr7.9940 per Ecu.
Philippines	The Peso fluctuated in a 15% range of 28 to 24 between 1990 and the beginning of 1995 but was practically fixed at a 26.2 rate to the US dollar from the spring of 1995 until the beginning of 1997
Sweden	Behaved as an ERM country, although not officially in the system.
Singapore	The currency actually appreciated in nominal terms throughout the 1990s going from a rate of 1.7 in 1990 to a rate of 1.4 by the end of 1996.
Italy	The exchange rate is maintained within a margin of ± 15 percent around the bilateral central rates against other participating currencies, with the exception of Germany and the Netherlands, in which case the exchange rate is maintained within a margin of ± 2.25 percent.
Taiwan	Real exchange rate targeting allowing its currency to fall from a rate of 24 New Taiwan dollars per US\$ in 1990 to a rate of 27.8 by the end of 1996.
Thailand	The Thai Bath was effectively fixed in a narrow 25.2 to 25.6 to the US\$ from 1990 until 1997
Turkey	Managed floating exchange rate.
United Kingdom	The exchange rate is maintained within a margin of ± 15 percent around the bilateral central rates against other participating currencies, with the exception of Germany and the Netherlands, in which case the exchange rate is maintained within a margin of ± 2.25 percent.
Venezuela	The exchange rate is maintained within margins of ± 7.5 percent.

Table II

Exchange Rate Regimes in countries that have suffered Currency Crises

The Table describes the Exchange Rate Regimes of seventeen countries that have suffered currency crises since 1990, and three countries that have suffered severe currency attacks during the same period. The description corresponds to the regime prevailing one month prior to the last currency depreciation considered in Table 1.

* and ** indicate that the coefficient is significantly different from zero at the 0.1 and 0.05 levels or better, respectively.

Table III. Exchange rate beta.

Number of firms in the sample per country, size-weighted average firm exchange rate beta, and average firm market beta. Size is as of the year of the currency crisis. ‘Country Exposure’ is the coefficient of a regression of the country’s market return on exchange rate changes. Stock returns, Exchange rates, Market Returns and accounting variables are from Datastream. Exchange rate betas are significant when their p-value is lower than 0.05.

Table IV. Debt to Value Ratio.

This table displays the median Debt to Value Ratio by country. The debt-to-value ratio is calculated dividing total debt by the sum of total debt plus the book value of equity. In the last panel, we report the p-values corresponding to a two-tailed Wilcoxon test of difference in medians. Stock returns, Exchange rates, Market Returns and accounting variables are from Datastream.

Table V. Debt to Value Ratio at the Region Level, by Exchange Rate Beta.

Median Debt to Value Ratio, by country and exchange rate beta. The debt-to-value ratio is calculated dividing total debt by the sum of total debt plus the book value of equity. Tests of significance are based on a Wilcoxon signed rank test. The third row in every panel is the p-value for a two-tailed test of equal medians in negative and positive exchange rate beta firms. We also report the p-value for a test of equality of medians crisis vs. no crisis sample, as well as Asian vs. non Asian countries.

Table XII. Firm Leverage and Currency Exposure.

This table reports the results of the regression of a firm's debt-to-value ratio on the variables listed under the variables column for countries that have suffered a currency crises in the period 1985-2000. The debt-to-value ratio is calculated dividing total debt by the sum of total debt plus the book value of equity. The variables "Exchange Rate Beta – Crisis Sample" and "Exchange Rate Beta – No Crisis Sample" are dummy variables that equal the Exchange Rate Beta of the firm in question or zero, depending on whether the firm belongs to a country in crisis or the non-crisis sample, respectively. Exchange rates and accounting variables are from Datastream. The corporate governance variables are from La Porta et al. (1998). P-values have been corrected for heteroskedasticity following the approach in White (1980). All R-squares are adjusted. Model I is estimated with country-fixed effects.

Latin America

Europe

Asia

No Crisis Sample

Figure I. Exchange Rate Changes before Currency Crises

The graph shows the average appreciation / depreciation of the nominal exchange rate US dollar / domestic currency in the 72 months preceding the currency crises in Latin America (Brazil, Mexico, and Venezuela), Europe (Finland, Italy, Norway, Spain, Sweden, Turkey, and the United Kingdom), Asia (Indonesia, Malaysia, Philippines, Singapore, South Korea, Taiwan, and Thailand), and the no crisis sample of countries with either floating rates or currency boards (Argentina, Hong Kong, and Japan) considered in the paper.
