Human activities and global warming: a cointegration analysis[☆]

Hui Liu, Gabriel Rodríguez*

Department of Economics, University of Ottawa, P.O. Box 450, Station A, Ottawa, ON, Canada K1N 6N5

Received 25 July 2003; received in revised form 22 February 2004; accepted 30 March 2004

Abstract

Using econometric tools for selecting I(1) and I(2) trends, we found the existence of static long-run steady-state and dynamic long-run steady-state relations between temperature and radiative forcing of solar irradiance and a set of three greenhouse gases series. Estimates of the adjustment coefficients indicate that temperature series is error correcting around 5–65% of the disequilibria each year, depending on the type of long-run relation. The estimates of the I(1) and I(2) trends indicate that they are driven by linear combinations of the three greenhouse gases and their loadings indicate strong impact on the temperature series. The equilibrium temperature change for a doubling of carbon dioxide is between 2.15 and 3.4 °C, which is in agreement with past literature and the report of the IPCC in 2001 using 15 different general circulation models.

1. Introduction

One of the main conclusions achieved by the Intergovernmental Panel on Climate Change (IPCC, 2001) is that temperature series is warming for the past 150 years. Furthermore, the same reference attributes the responsibility of the changes to human activities generated greenhouse gases. A basic argument in this diagnostic is that temperature series are higher compared to the pre-industrial periods; see also Santer et al. (1996). There are two sources for this evidence. They are the physically-based simulation models of climate and the statistical analysis of historical data, respectively. The simulation models of climate are based on physical motion equations trying to describe the principal issues governing the behavior of temperature. They also include the radiative forcing of greenhouse gases

and tropospheric sulfates. This kind of model are generally referred as general circulation models (GCMs).

On the other hand, the statistical analysis deals directly with the historical record of the temperature variables, solar irradiance and greenhouse gases. In some cases, this approach uses simple and standard statistical or econometric tools in identifying for the effects of human activities (greenhouse gases) on the temperature series. However, because all these time series exhibit strong trends, classical tools will indicate spurious positive relation among these variables. In consequence, it is important to identify clearly the time series properties of the data before starting any other kind of analysis between the series. In this aspect, the principal goal is the identification for the existence of unit roots in the data which means the existence of stochastic trends. It is the starting point of the research agenda of Stern and Kaufmann (1997, 1999, 2000) and Kaufmann and Stern (2002).¹ Using different statistical

¹ See next section for a brief but more complete survey of the literature.

tests for the identification of unit roots, they find that temperature series is an $I(1)$ process,² and that greenhouse gases contain two unit roots. After analyzing for causality between different set of time series, Stern and Kaufmann (1997) investigate the existence of long-run steady-state relations (i.e. cointegration between sets of variables) using multivariate techniques proposed by Johansen (1988, 1995b). They conclude that there exists a long-run relation between the set of variables and that temperature series is reacting to the disequilibria towards this steady-state relation in around 40–50% each year. However, the authors believe that this value is too high and it may be a consequence of the existence of $I(2)$ trends in the system. Kaufmann and Stern (2002) recognizes the necessity to take into account for $I(2)$ trends in an adequate statistical framework.

The statistical framework for $I(2)$ is proportionated by the approach suggested by Johansen (1992, 1995a); see also Paruolo (1996); Rahbek et al. (1999); Paruolo and Rahbek (1999). It is more complex but richer in terms of the long-run relations that we may find. In fact, there are the standard (static) long-run steady-state relations but there also exist the dynamic long-run steady-state relations which are given by the linear combinations between the levels of the variables and their first differences. It is also possible to find medium-run steady-state relations. In this paper, we follow this approach.

The empirical results show that global temperature and solar irradiance series are $I(1)$ processes, carbon dioxide is an $I(2)$ process, and methane and nitrous dioxide seem to contain explosive roots. According to this evidence, three different systems are proposed, estimated and analyzed. The results indicate that temperature series is error correcting around 10–50% of the disequilibria each year, depending of the type of steady-state relation that is considered. Regarding the equilibrium temperature change for a doubling of carbon dioxide, the results indicate that it is between 2.1 and 3.4 °C, depending of the steady-state used to calculate it. It is worth noting that these values are in agreement with other values found in the literature (see Kaufmann and Stern, 2002) and the average value calculated by the Intergovernmental Panel on Climate Change (IPCC, 2001).

The rest of this paper is organized as follows. Section 2 presents a brief review of the literature. Section 3 deals with the methodological issues while Section 4 presents the empirical results. Section 5 concludes.

2. A brief review of the literature

In order to place this work in the context of the literature on climate change, a brief summary of some of the relevant papers is provided below. When we observe pictures of global temperature series, greenhouse gas concentrations, and solar irradiance, all give us the information that they have increased in the last 150 years; see also Stern and Kaufmann (2000). Presence of strong trends implies that the use of standard statistical or econometric tools will indicate a significant and positive association between sets of variables analyzed. Unfortunately, the use of standard statistical or econometric tools is misleading in this context. Therefore, a careful analysis of the statistical properties of the time series appears as a necessary condition for an adequate empirical analysis. This is the starting point of the research applied by Stern and Kaufmann (1997, 1999, 2000), and Kaufmann and Stern (1997, 2002). Apart from them, there is little research that explicitly argued in favor of the use of econometric time series methods, such as Tol (1994), Tol and de Vos (1998), and Schönwiese (1994). Some other exceptions in the analysis of the time series properties of global temperature series are Bloomfield (1992), Bloomfield and Nychka (1992), Woodward and Gray (1993, 1995), Galbraith and Green (1993); Richards (1993); Fomby and Vogelsang (2002). Before them, most of the research analyzing the relationship between temperature and forcing variables have used simple regression models as in Lean et al. (1995), or frequency domain methods as in Kuo et al. (1990) and Thomson (1995, 1997).

The analysis of the time series properties of temperature, solar irradiance, greenhouse gases and other variables has been performed in Stern and Kaufmann (1997). One of the principal conclusions of their research is that global temperature series has a unit root or in other terms, this time series has a stochastic trend, which is denoted by $I(1)$. At the same time, greenhouse gases variables have been found to contain one or two unit roots. The econometric tools used were the well known unit root statistics proposed by Dickey and Fuller (1979), Said and Dickey (1984), Phillips and Perron (1988), and Schmidt and Phillips (1992). As a consequence of the size and power problems of these unit root statistics in detecting for more than one unit root,³ there is not a complete and clear picture regarding the degree of integration of the greenhouse gases. However, the evidence in favor of two unit roots is present in more than one unit root test. It is also recognized in Stern and Kaufmann (1999, 2000), and Kaufmann and Stern (2002).

When the time series are non-stationary there is room to test for cointegration, that is, the possible existence of

² A time series y_t is integrated of order d , which is denoted by $I(d)$ if d differences are needed to transform it into a stationary time series. Therefore, $I(1)/I(2)$ means that the series has to be differenced one/two times to achieve stationarity.

³ See Haldrup and Lildholdt (2002).

long-run relationships between sets of variables analyzed. In other words, it is possible to find linear combinations of the variables that annihilates the stochastic trends. The rest of linear combinations are still stochastic trends and they drive the behavior of the time series. The cointegrating relations are named also static long-run relations because they represent a steady-state relation between sets of variables. Because in the short term the variables are not in the steady state, they will react to these disequilibria. In the case of temperature, for example, it is possible to find a steady-state relation with greenhouse gases and natural factors (solar irradiance, for example). In the short term, the temperature (and the other variables) reacts to the disequilibria exhibiting an error correction behavior.

The only two trials to deal with the identification of cointegration relations have been [Stern and Kaufmann \(1997\)](#) and [Kaufmann and Stern \(2002\)](#). Using the methodology of [Johansen \(1988, 1995b\)](#),⁴ they arrive at the conclusion that there exists a long-run relationship between time series of temperature, solar irradiance and a set of greenhouse gases. The estimates of the short-run dynamic model indicate that temperature is correcting around 40–60% of the disequilibria each year. The authors consider that this value is too high and they attribute its cause to the existence of I(2) trends.

The acceptance that time series of greenhouse gases contain I(2) trends is also present in [Stern and Kaufmann \(1999, 2000\)](#). In both papers, the authors apply a multivariate structural time series approach to model temperature, natural factors and greenhouse gases.⁵ The advantage of this kind of models is that different alternatives for the deterministic components are allowed. Also, it is possible to allow for I(1) and I(2) trends. The model is also flexible in including cyclical components. The basic conclusions are that most time series analyzed contain a stochastic trend with the greenhouse gases containing stochastic I(2) trends. Therefore, the two independent stochastic trends in the data are associated to the radiative forcings due to greenhouse gases, solar irradiance, and tropospheric sulfate aerosols that are found in the northern hemisphere, respectively. More recent research but applied to the temperature of Australia is [Lenten and Moosa \(2003\)](#). According to their results, temperatures in six Australian locations are I(1) processes, the cyclical component is not significant, seasonality is deterministic and the irregular (or noise) component is very significant.

On the other hand, some different results are proportionated by [Kelly \(2000\)](#). He finds that temperature series contains a unit root but that greenhouse

gases are stationary around a time trend. This impressive result implies that temperature rise is due to long run cycles, and that the relationship with greenhouse gases is spurious. These results are in complete opposition to most of the research detailed before. However, applying first difference to temperature series, [Kelly \(2000\)](#) estimated a regression between growth rates of temperature and greenhouse gases, finding support to previous results regarding the significant influence of these gases on temperature series.

One important and uncertain parameter of the general circulation models (GCMs) is the temperature sensitivity which is measured as the equilibrium temperature change per unit of the change in radiative forcing. As [Kelly \(2000\)](#) argues, an alternative measure, directly proportional to the climate sensitivity, is the total equilibrium (steady-state) temperature change from a doubling of greenhouse gases, frequently denoted as ΔT_{2x} . [Kelly \(2000\)](#) finds that this parameter is between 1.27 and 1.33 °C; while for [Kaufmann and Stern \(2002\)](#) its value is around 2.0 and 2.5 °C, in agreement with the general circulation models. It is worthwhile to mention that the [IPCC \(2001\)](#) argues that the average value of ΔT_{2x} is 3.5 °C after considering 15 different models.⁶

In this paper we still use time series tools to analyze for the existence of steady-state relations between temperature series, solar irradiance and a set of greenhouse gases. However, unlike the traditional approach of using the so called I(1) model, as [Stern and Kaufmann \(1997\)](#) and [Kaufmann and Stern \(2002\)](#), we use econometric tools allowing for the presence of I(2) trends in the identification of the long-run relationships. The use of more sophisticated econometric tools taking into account for the presence of I(2) trends has been recognized by [Stern and Kaufmann \(1999\)](#). The presence of two unit roots in time series allows us to use the so called I(2) model (see [Johansen, 1992, 1995a, 1995b](#)). In this model the number of cointegrating relations are detected, so are the number of I(1) and I(2) stochastic trends that still in the system and drive the behavior of some variables. In terms of the cointegrating relations, unlike the analysis of the I(1) model, the I(2) model allows for the existence of two types of cointegration. The first type is a linear combination of the variables in their levels, which is the same definition as that in the I(1) model. The second type of cointegration is the possibility that there are linear combinations between the levels of the variables and their growth rates. It is named polynomial cointegration and also dynamic steady-state relations. Further details of I(1) and I(2) models are presented in the next section.

⁴ See the I(1) model below for further methodological details.

⁵ This methodology is based on [Harvey \(1989\)](#).

⁶ The standard deviation is 0.92 °C and the range goes from 2.0 to 5.1 °C.

3. Methodological issues

In this section we provide elements relevant to understanding the methodological approach applied in the empirical analysis. Regression with nonstationary time series implies spurious regression except when there exists a linear combination (or more than one) between these variables that reduce the dimension of the space spanned by them. This is known as cointegration.

3.1. The $I(1)$ model

Let y_t , a vector containing n variables, be represented by the following $VAR(k)$:

$$y_t = \sum_{i=1}^k \Pi y_{t-i} + \Phi D_t + \varepsilon_t \quad (1)$$

where it is assumed that ε_t is a sequence of *i.i.d.* zero mean with covariance matrix Ω . In most cases it is also assumed that the errors are Gaussian which is denoted by $\varepsilon_t \sim N(0, \Omega)$. The variable D_t contains the possible deterministic components of the process, such as a constant, a time trend, seasonal dummies and intervention dummies. This is the model proposed by Johansen (1988, 1995b) and is widely used in empirical applications.⁷

The system (1) is reparameterized as a vector error correction model (VECM):

$$\Delta y_t = \Pi y_{t-1} + \sum_{i=1}^{k-1} \Gamma_i \Delta y_{t-i} + \Phi D_t + \varepsilon_t \quad (2)$$

with

$$\Pi = -I + \sum_{i=1}^k \Pi_i, \quad \Gamma_i = \sum_{j=i+1}^k \Pi_j.$$

Notice that the matrix

$$\Gamma = I - \sum_{i=1}^{k-1} \Gamma_i.$$

$I(1)$ cointegration occurs when the matrix Π is of reduced rank, $r < n$ where Π may be factorized into $\Pi = \alpha\beta'$, α and β are both full rank matrices of dimension $n \times r$; the matrix α contains the adjustment coefficients and β the cointegration vectors. These vectors have the property that $\beta' y_t$ is stationary, even though y_t itself is non-stationary. Notice that there also exist full rank matrices α_{\perp} and β_{\perp} of dimension $n \times (n-r)$ which are orthogonal to α and β , such that $\alpha'_{\perp} \alpha = 0$ and $\beta'_{\perp} \beta = 0$, and the $rank(\beta_{\perp}, \beta) = n$.

An alternative representation of the cointegrated VAR model is in terms of the common stochastic trends representation, see Stock and Watson (1998). According to that, the y_t vector is represented by

$$y_t = \Phi D_t + C \sum_{i=1}^t \varepsilon_i + C(L)\varepsilon_t \quad (3)$$

where $C = \beta_{\perp}(\alpha'_{\perp} \Gamma \beta_{\perp})^{-1} \alpha'_{\perp}$ and $C(L)\varepsilon_t$ corresponds to a n -dimensional $I(0)$ component. Using this representation it is possible to observe that although y_t is n -dimensional, the vector series is driven by just $n-r$ common stochastic $I(1)$ trends which are

$$\alpha'_{\perp} \sum_{i=1}^t \varepsilon_i.$$

In terms of observable variables the $I(1)$ directions are calculated as $\beta'_{\perp} y_t$ which are just a particular linear combinations of the stochastic trends.

To test the rank of matrix Π , Johansen (1995a,b) developed maximum likelihood cointegration testing method using the reduced rank regression technique based on canonical correlations. The procedure consists of obtaining an $n \times 1$ vector of residuals r_{0t} and r_{1t} from auxiliary regressions (regressions of Δy_t and y_{t-1} on a constant and the lagged $\Delta y_{t-1} \dots \Delta y_{t-k+1}$). These residuals are used to obtain the $(n \times n)$ residual product matrices:

$$S_{ij} = (1/T) \sum_{t=1}^T r_{it} r'_{jt}, \quad (4)$$

for $i, j=0, 1$. The next step is to solve the following eigenvalue problem

$$|\lambda S_{11} - S_{10} S_{00}^{-1} S_{01}| = 0 \quad (5)$$

which gives the eigenvalues $\hat{\lambda}_1 \geq \dots \geq \hat{\lambda}_n$ and the corresponding eigenvectors $\hat{\beta}_1$ through $\hat{\beta}_n$, which are also the cointegrating vectors. A test for the rank of matrix Π can now be performed by testing how many eigenvalues λ equals to unity. One test statistic for the resulting number of cointegration relations is the Trace statistic (see Johansen, 1988), which is a likelihood ratio test defined by

$$\text{Trace} = -T \sum_{i=r+1}^n \log(1 - \hat{\lambda}_i) \quad (6)$$

Another useful test is given by testing the significance of the estimated eigenvalues themselves

$$\lambda_{\max} = -T \log(1 - \hat{\lambda}_i). \quad (7)$$

In trace test, the null hypothesis is $r = 0$ (no cointegration) against the alternative hypothesis that $r > 0$ (cointegration). The λ_{\max} statistic tests the null hypothesis that $r = r_0$ versus the alternative hypothesis that $r = r_0 + 1$, where

⁷ There are large number of empirical applications using this statistical framework. Two very detailed and influential applications are Johansen and Juselius (1992 and 1994).

$r_0=0, 1, \dots, n-1$. For further details regarding the construction of these statistics, see Johansen (1995b).

In summary, the I(1) model allows to identify the rank of cointegration (r) and the number of stochastic trends driving the y_t vector. Because in this model it is assumed that y_t contains variables with order of integration no larger than one, it is clear that the number of unit roots left in the system is $n-r$. Notice that the estimate of β (the cointegration vector) is not identified in the sense that any linear combination of β is also a cointegration vector. In this sense, researchers have to identify these vectors by imposing restrictions that are in most cases suggested by the economic theory. For example, in a vector containing four variables, a possible restriction is that the coefficient associated to the second variable is zero. If the statistic (distributed as a χ^2) does not reject the null hypothesis, it means that the second variable is long-run excluded from the cointegration vector. Another example is the restriction of long-run homogeneity between a set of variables. If the null hypothesis is not rejected, it means that the unit vector (i.e. $[1, -1, \dots, -1]$) may be used in the subsequent analysis. The estimated adjustment coefficients (α) are also tested for restrictions but in this case, the restrictions are associated with the null hypothesis of weak exogeneity.

3.2. The I(2) model

In the I(1) model, the matrix Π is of reduced rank and the matrix $\alpha'_\perp \Gamma \beta_\perp$ is of full rank. For the system to be I(2) it is also required that the matrix $\alpha'_\perp \Gamma \beta_\perp$ be of reduced rank $s_1 < n-r$. Following Johansen (1992, 1995a,b), the model (2) can be reparameterized as

$$\Delta^2 y_t = \Pi y_{t-1} - \Gamma \Delta y_{t-1} + \sum_{i=1}^{k-2} \Psi_i \Delta^2 y_{t-i} + \Phi D_t + \varepsilon_t \quad (8)$$

where the matrix Γ is included as a parameter and

$$\Psi_i = - \sum_{j=i+1}^{k-1} \Gamma_j.$$

With the matrix $\alpha'_\perp \Gamma \beta_\perp$ of reduced rank (s_q), it is possible, as in the I(1) model, to define parameter matrices ξ and η such that the second reduced rank condition is $\alpha'_\perp \Gamma \beta_\perp = \zeta \eta'$ with ζ and η both matrices of dimension $(n-r) \times s_1$.

As in the I(1) model, the number of cointegration relations (or I(0) relations) is denoted by r . However, unlike I(1) models, $n-r$ does not only represent the number of I(1) trends in I(2) models. It contains both the total of I(1) trends and that of I(2) trends, denoted as s_1 and s_2 , respectively. Consequently there are parameters describing the I(0), I(1) and I(2) directions of the

variables and an important goal of the I(2) model is their identification. Following the notation of Juselius (1999), these matrices are β , $\beta_{\perp 1}$ and $\beta_{\perp 2}$ associated with dimensions r , s_1 and $n-r-s_1=s_2$ respectively.⁸ Paruolo (1996) denotes r , s_1 , s_2 as the integration indices of the VAR.

In a similar way as in the I(1) model, the common trends representation of I(2) model is given by

$$y_t = \Phi D_t + C_2 \sum_{j=1}^t \sum_{i=1}^j \varepsilon_i + C_1 \sum_{i=1}^t \varepsilon_i + C^*(L) \varepsilon_t \quad (9)$$

where $C_2 = \beta_{\perp 2} (\alpha'_{\perp 2} \Theta \beta_{\perp 2})^{-1} \alpha'_{\perp 2}$ and $C^*(L)$ is a matrix polynomial with all roots strictly outside of the unit circle. The first clear observation is that y_t has s_2 common I(2) trends given by

$$\alpha'_{\perp 2} \sum_{j=1}^t \sum_{i=1}^j \varepsilon_i.$$

In terms of observable variables, it is given by $\beta'_{\perp 2} y_t$ which are just linear combinations of the I(2) stochastic trends.

Furthermore, as mentioned by Haldrup (1999), the combinations $\beta' y_t$ can cointegrate to I(0) level and/or have the property that they potentially cointegrate with $\beta'_{\perp 2} \Delta y_t$, which is I(1) by construction. This is named as polynomial cointegration. These r relations are $\beta' y_t - \delta \beta'_{\perp 2} \Delta y_t$ which define the I(0) directions. However, not all the r I(0) relations need include the differenced I(2) components. In fact, after defining δ_\perp such that $\delta'_\perp \delta = 0$, there will be $r-s_2$ non-polynomially cointegrated relations given by $\delta'_\perp \beta' y_t$; and s_2 polynomial cointegrating relations given by $\delta' \beta' y_t - \delta' \delta \beta'_{\perp 2} \Delta y_t$.⁹

The approach suggested by Johansen (1992, 1995b) to identify the number of I(2) trends is conducted as a combination of regression and reduced rank regression. It is performed in a similar way as the determination of the cointegration rank in the I(1) model. The difference is that now two reduced rank conditions need to be examined. This is more complicated in the sense that the second reduced rank condition depends on the first reduced rank condition. Instead of a joint

⁸ The notation and technical details of the I(2) model are complex. Further details regarding the calculation of matrices $\beta_{\perp 1}$ and $\beta_{\perp 2}$ are in Juselius (1999), also Haldrup (1999) using a slightly different notation. In summary, because ζ and η exist, their complements, ζ_\perp and η_\perp , also exist. Then it is possible to define $\alpha_\perp = \{\alpha_{\perp 1}, \alpha_{\perp 2}\}$ and $\beta_\perp = \{\beta_{\perp 1}, \beta_{\perp 2}\}$, where $\alpha_{\perp 1} = \alpha_\perp (\alpha'_\perp \alpha_\perp)^{-1} \zeta$, $\alpha_{\perp 2} = \alpha_\perp \zeta_\perp$, $\beta_{\perp 1} = \beta_\perp (\beta'_\perp \beta_\perp)^{-1} \eta$ and $\beta_{\perp 2} = \beta_\perp \eta_\perp$. Therefore, β , $\beta_{\perp 1}$ and $\beta_{\perp 2}$ are mutually orthogonal and thus jointly describe a basis for the n -dimensional space. The α has a similar property.

⁹ The possibility to decompose r (in r_0 and r_1 , say) exists only when $r > s_2$. In this case, the r cointegrating relations can be divided into $r_0=r-s_2$ directly stationary CI(2,2) relations and $r_1=s_2$ polynomially cointegrating relations.

estimation of the indices r and s_1 , Johansen (1992, 1995a) suggests a two step procedure. The first step is to solve the reduced rank problem associated with the matrix $\Pi = \alpha\beta'$. It calculates the estimates of α_r , β_r , $\alpha_{\perp r}$, and $\beta_{\perp r}$ for each value of $r=0, 1, \dots, n-1$. The second step deals with the second reduced rank condition problem by replacing the unknown matrices $\alpha_{\perp r}$, and $\beta_{\perp r}$ with the estimates from the first step. The problem is solved for $r=0, \dots, n-1$. Then what remains to be determined is which combinations of r and s_1 should be chosen. Because steps 1 and 2 proportionate an array of different values for r and s_1 corresponding to different sub-models, the selection of r and s_1 can be performed in the following way.¹⁰ The array is read starting from the left corner. If the null hypothesis is rejected, the next element (continuing to the right) is read and so on. After the first row is done, and if no acceptance is observed, we read the second row of the array. We continue until the first non-rejection is found. The associated values of r , s_1 and s_2 are selected as the integration indices. Complete technical details can be found in Paruolo (1996); Johansen (1992, 1995a).

It must be emphasized that only the space spanned by the cointegrating vectors is identified; the single cointegration relations are unidentified. This issue is also present in the I(1) model but this problem is more complex in I(2) models.¹¹

What is perhaps more interesting is the fact that in an I(2) model there exist more than one steady-state relations. Recall that in an I(1) models, the cointegration relations $\beta'y_t$ represents the static long-run steady-state relation. In the present case, we have two additional steady-state relations. One is medium-run steady-state relations represented by $\beta'_{\perp 1}\Delta y_t$. The other is dynamic long-run steady-state relations represented by the polynomially cointegrating relations (see Juselius, 1999, 2003). In consequence, there exist different adjustment coefficients associated with each of these steady-state relations.

One should keep in mind that tools for analyzing I(2) models and statistics used to select integration indexes are not yet fully developed in econometric literature. This is the reason why the selection of the number of I(2) trends should be combined with other tools. One of them, as suggested by Juselius (1999), is the calculus of the roots of the companion matrix. If y_t vector contains variables that are integrated no more than order one, then the total number of unit roots (or close to the unit circle) of the companion matrix must be $n-r$. If there exists more than $n-r$ roots close to the unit circle, it

constitutes a indicator for the presence of I(2) trends. When there are I(2) trends, the number of roots close to the unit circle is $s_1 + 2s_2$.

Another useful indicator for the presence of I(2) trends is to compare the graphs of $\beta'y_t$ and $\beta'R_{1t}$, where R_{1t} is a vector of residuals from regressing y_{t-1} on lagged short-run effects (Δy_{t-i} , $i=1, 2, \dots, k-1$) and D_t . If the first graph looks non-stationary whereas the second graph looks stationary, it can be considered as a strong support for the presence of I(2) trends.

Recently a few empirical applications in the field of economics have used the I(2) framework. Without the intention to be exhaustive, some of these references are Rahbek et al. (1999), Kongsted (2003), Holtemöller (2002), Vostroknutova (2003), Juselius (1999, 2003), Fiess and MacDonald (2001), and Haldrup (1999). It is worthwhile to mention that some of these papers, after identifying for the presence of I(2) trends, proceed with transforming the variables in such a form that a standard I(1) analysis can be performed (see Fiess and MacDonald, 2001). Almost all references mentioned study nominal variables such as money supply, nominal wages, and fundamentally prices. We do not know that a similar methodology has been applied to climate series.

4. Empirical analysis

4.1. The data and preliminary issues

The data used in this paper include the time series of global mean temperature deviation (denoted by *temp*), the concentrations of methane (*ch₄*), nitrous dioxide (*n₂o*), carbon dioxide (*co₂*).¹² All data are from the web site of Goddard Institute for Space Studies available at <http://www.giss.nasa.gov>. The data are transformed into radiative forcing,¹³ which affects the temperature

¹² A preliminary version of the paper included data of chlorofluorocarbons (*cfc11* and *cfc12*). Graphical inspection of both time series indicates zero values until 1950, after what they increased very fast. These two variables were found to be I(2) processes in Stern and Kaufmann (2000). We decided exclude both time series for the following reasons: (i) the visual analysis indicates a particular behavior that may distort the analysis; (ii) their importance in terms of all greenhouse is reduced; (iii) increasing the dimension of the system of equations to be estimated, therefore reducing the number of freedom degrees given our sample size; and (iv) identification of cointegration relations is complex and unlike the field of economics, we are not sure what are the physical relationships and interactions between all these greenhouse gases series, solar irradiance and temperature time series. Therefore, by excluding both variables, we reduce the possibility to find too many cointegration relations which are always difficult to identify and interpret.

¹³ Radiative forcing is the change of the net irradiance caused by factors such as greenhouse gases, water vapor, solar radiation. Greenhouse gases are of particular interest, as they are most likely to change radiative forcings over the next decade. The net irradiance is the difference of the irradiance that the earth absorbed minus the irradiance the earth emitted, expressed in Wm^{-2} , where W is a measure of energy (Watt) and m indicates meters.

¹⁰ The test statistic is denoted as $H_{r,s}$ and it is the same notation used in the empirical analysis.

¹¹ Regarding the adjustment coefficients, for example, the notion of weak exogeneity is now different. Paruolo and Rahbek (1999) have proposed a sequential approach to test for weak exogeneity in the I(2) model.

Fig. 1. Global temperature deviations (*temp*), radiative forcing of solar irradiance (*rfsun*), carbon dioxide (*rfco₂*), methane (*rfch₄*) and nitrous dioxide (*rfn_{2o}*); units in Wm^{-2} ; 1856–2001.

directly and indirectly. The formulae are tabulated in the Intergovernmental Panel of Climate Change (IPCC, 2001). Therefore the radiative forcing of greenhouse gases at time t are denoted by $rfch_{4t}$, $rfn_{2o,t}$, $rfco_{2t}$. We also include radiative forcing of solar irradiance ($rfsun_t$) as another variable in the system.

Fig. 1 presents the evolution of the time series for the period under study, 1856–2001. It is a similar period as analyzed by the previous literature but with more recent information. A clear observation appearing from Fig. 1 is the fact that all greenhouse gases variables present strong upward trends that have been observed in the previous literature.

As that argued in the literature (Stern and Kaufmann, 2000), an essential preliminary step in the analysis of these variables is the identification of the time series properties. One way to approach this issue is the application of univariate unit root tests. Stern and Kaufmann (2000) proceeded using three different univariate unit root tests. However, as documented by Haldrup and Lildholdt (2002), these statistics are incorrect. Because when testing for I(2) and the underlying series is indeed integrated of order two, these statistics give rise to an excessive rejection of the null hypothesis of a unit root in favor of the stationary and explosive alternatives. This size distortion is caused by the fact that the test statistics have a different distribution originated by one additional unit root. In consequence, the recommendation of Haldrup and

Lildholdt (2002) is to test I(2) against I(1) prior to testing I(1) against I(0). The authors conclude that all basic univariate unit root tests suffer from this issue.

In a set of results not reported here,¹⁴ we applied the approach suggested by Dickey and Pantula (1987) and also the statistic proposed by Hasza and Fuller (1979). The results indicated that the carbon dioxide series contains two unit roots, that is, it is an I(2) process. The temperature and solar irradiance series were found to be I(1) processes, the other greenhouse gases series under study (nitrous dioxide and methane) appeared containing explosive roots. The last result is not totally clear after the application of all statistics. The difficulty with this case is the fact that explosive roots mimic the behavior of I(2) processes, see Haldrup and Lildholdt (2002).

In summary, most of the results confirm the previous results found in the literature, see Stern and Kaufmann (2000). Although it appears to be the case, we adopt another strategy in this paper. This approach consists of applying multivariate techniques to detect the number of I(0), I(1) and I(2) trends in the system. As we will see in

¹⁴ But they are available upon request. We applied standard ADF test (Dickey and Fuller, 1979; Said and Dickey, 1984), Phillips-Perron test (Phillips and Perron, 1988), and ADF based on GLS detrended data as suggested by Elliott et al. (1996).

Table 1
Testing for cointegrating ranks

H_0	λ_{\max}	Trace	λ_{\max} 90% critical values	Trace 90% critical values
$r=0$	83.6	196.2	34.8	82.7
$r=1$	49.4	112.5	29.1	59.0
$r=2$	41.9	63.1	23.1	39.1
$r=3$	14.2	21.3	16.9	23.1
$r=4$	7.1	7.1	10.5	10.6

$$Y_t = (temp_t, rfsun_t, rfcO_{2t}, rfch_{4t}, rfn_2o_t)'$$

the next analysis, there are more than one possible case in the selection of the integration indices.¹⁵

4.2. The first case

The first case is represented by the system with our five variables, i.e., $y_t = \{temp_t, rfsun_t, rfcO_{2t}, rfch_{4t}, rfn_2o_t\}$. Table 1 presents the results obtained from the application of the approach of Johansen (1988, 1995b) in determining the rank of matrix Π ¹⁶. Both Trace and λ_{\max} statistics indicate that $r=3$, that is, there exist three cointegration relations. Because $n=5$, we have $s_1 + s_2 = n - r = 2$.

Table 2 presents the results of the statistic $H_{r,s}$ for selecting s_2 . The first row represents the value of the statistic, the second and third rows are the critical values at 95.0% and 97.5% (in italics). As we explained in the previous section, reading of this table starts from the left-corner and we continue to the right. If no acceptance is found, we continue to the second row of values ($r=1$). The procedure stops when a non-rejection is found. In the present case, the results indicate that $s_2=0$ and consequently $s_1=2$. Then, there are two I(1) trends and there is no I(2) trends in the system. However, note that using critical values at 97.5%, it is possible to find $s_2=1$ and consequently $s_1=1$.

As suggested by Juselius (1999), a good way to complement this information is the calculus of the eigenvalues of the companion matrix. The eight largest modules obtained from the unrestricted VAR are: 1.0292, 1.0292, 0.9641, 0.9641, 0.9384, 0.9384, 0.7163, 0.7163. It appears to exist two explosive roots and four eigenvalues close to the unit circle. In other words, there appears to exist four unit roots in the system. Now,

¹⁵ Analysis of I(1) and I(2) models was performed using CATS for RATS, see Hansen and Juselius (1995). A slightly modified version of the program of Rahbek et al. (1999) has been used. We also thank electronic communications with H.C. Kongsted who proportionated his program used in Kongsted (2003). The estimations of the error correction models were performed using PcGive 10.0, see Doornik and Hendry (2001).

¹⁶ In all cases, we consider linear trends in the data. An intercept and a time trend are also allowed in the cointegration space. In terms of the I(2) framework, it is the model suggested by Rahbek et al. (1999).

Table 2
Testing for integration indices

r	$H_{r,s}$				Q_r	
0	418.0 (198.2) (203.2)	312.6 (167.9) (173.4)	252.0 (142.2) (147.1)	220.8 (119.8) (124.4)	198.2 (101.5) (105.6)	196.2 (87.2) (91.2)
1		268.6 (137.0) (141.5)	171.4 (113.0) (117.4)	136.8 (92.2) (96.5)	114.8 (75.3) (79.0)	112.5 (62.8) (66.1)
2			163.4 (86.7) (90.8)	91.2 (68.2) (71.4)	69.0 (53.2) (55.9)	63.1 (42.7) (45.8)
3				57.9 (47.6) (50.7)	36.2 (34.4) (36.8)	21.3 (25.4) (27.9)
4					15.3 (19.9) (22.2)	7.1 (12.5) (14.2)
$n-r-s=s_2$	5	4	3	2	1	0

$$Y_t = (temp_t, rfsun_t, rfcO_{2t}, rfch_{4t}, rfn_2o_t)'$$

because the first step (in the I(1) framework, see Table 1) indicates $r=3$, we proceed with imposing this restriction and now the eight largest modules of the restricted VAR are: 1.0283, 1.0283, 1.000, 1.000, 0.9378, 0.9378, 0.7179, 0.7179. There are two unit roots as a consequence of the restriction of $r=3$ but there are two more eigenvalues close to the unit circle. It indicates, again, the existence of four unit roots.¹⁷ Remember that in the I(2) framework the total number of unit roots is given by $s_1 + 2s_2$, which in the present case indicates that $s_1=0$ and $s_2=2$.

In summary, we have some different information using the $H_{r,s}$ statistic and the eigenvalues of the companion matrix. We decide to working with both alternatives. Then, they are $r=3, s_1=1, s_2=1$ and $r=3, s_1=0, s_2=2$, respectively. In the following, they are named as Case 1 and Case 2, respectively.

Following the notation used in the previous section, Table 3a presents cointegration relations and adjustment parameters corresponding to Case 1. Notice that there are two cointegrating relations including only the levels of the variables ($\hat{\beta}_{0,i}y_t, i=1,2$). Furthermore, the relation $\hat{\beta}_1 y_t - \hat{\kappa}_1 \Delta y_t$ denotes the polynomially cointegration relation or what we denoted in the previous section as the dynamic steady-state relation. The bottom panel gives the corresponding loadings ($\hat{\alpha}_{0,1}, \hat{\alpha}_{0,2}, \hat{\alpha}_1$), and the coefficients that reflect the composition of the stochastic I(1) and I(2) trends $\hat{\alpha}_{\perp 1}$ and $\hat{\alpha}_{\perp 2}$. The table also presents vectors $\hat{\beta}_{\perp 1}$ and $\hat{\beta}_{\perp 2}$ that denote the loadings (adjustment parameters) to the stochastic I(1) and I(2) trends.

Table 3a specifies that around 46.6% of the disequilibrium in the static long-run steady-state is

¹⁷ Notice that the two explosive roots seem to confirm the univariate analysis.

Table 3a
Decomposing the systems into I(0), I(1) and I(2) spaces; Case 1

	$\hat{\beta}_{0,1}$	$\hat{\beta}_{0,2}$	$\hat{\beta}_1$	$\hat{\kappa}_1$	$\hat{\beta}_{\perp 1}$	$\hat{\beta}_{\perp 2}$

$$Y_t = (temp_t, rfsun_t, rfco_{2t}, rfch_{4t}, rfn_{2}o_t)'$$

corrected by the temperature series each year. This is similar as that found by Stern and Kaufmann (2000). On the other hand, the result that temperature series do not react to the second static long-run relation is also interesting. The response of the temperature series to the dynamic steady-state relations is 19.1%. As we know, these dynamic steady-state relations (polynomially cointegration relations) include the levels and the growth rates of the variables. Therefore, the result indicates the response of temperature series to disequilibria towards the steady-state. Regarding to the medium-run steady-state relation ($\hat{\beta}_{\perp 1} \Delta y_t$), we observe that it is composed by temperature, solar irradiance, carbon dioxide and methane series.

Regarding the stochastic I(1) and I(2) trends, we have the following observations. Firstly, it appears that both I(1) and I(2) trends are driven by three greenhouse gases ($\hat{\alpha}_{\perp 1}, \hat{\alpha}_{\perp 2}$), whereas the influence of methane and nitrous dioxide is higher in stochastic I(2) trend ($\hat{\alpha}_{\perp 2}$). In other words, permanent shocks to the three greenhouse gases seem to have generated the I(2) trend. Secondly, the respective loadings (or adjustment parameters) to these stochastic I(1) and I(2) trends indicate that temperature series, solar irradiance and carbon dioxide are influenced by them ($\hat{\beta}_{\perp 1}, \hat{\beta}_{\perp 2}$). The results also show that temperature, carbon dioxide, and solar irradiance are more influenced by the stochastic I(1) trend ($\hat{\beta}_{\perp 1}$). However, the stochastic I(2) trend seems to affect strongly the temperature series ($\hat{\beta}_{\perp 2}$).

Regarding the equilibrium temperature change for a doubling of carbon dioxide (ΔT_{2x}), the results indicate that it is 3.4 °C; see the first long-run steady-state relation. This value is higher than those found in the literature but it is in agreement with the average of estimates from 15 general circulation models coupled to mixed-layer ocean models reported in IPCC (2001).

Table 3b proportionates similar information but for the case $r=3; s_1=0; s_2=2$. In this case the results show that there is only one static long-run steady-state

Table 3b

<i>rfch₄</i>	0.002	0.000	-0.005			0.000	0.139
<i>rfn₂o</i>	0.000	-0.000	0.000			0.065	0.048

$$Y_t = (temp_t, rfsun_t, rfco_{2t}, rfch_{4t}, rfn_{2}o_t)'$$

relation and two dynamic steady-state relations. The loading corresponding to the long-run steady-state relation seem to indicate that temperature series is not error correcting which may indicate that the disequilibria are not corrected at all. The response to the dynamic steady-state is, as before, higher and with the correct sign. In fact, it appears that temperature series is correcting 4.8% and 64.6% (each year) of the disequilibria presented in these relations.

Because in this case $s_1=0$, there are not I(1) trends in the system. The two I(2) trends seem to be driven by carbon dioxide and nitrous dioxide in the first case ($\hat{\alpha}_{\perp 2,1}$) and by the three greenhouse gases in the second case ($\hat{\alpha}_{\perp 2,2}$). Observing the coefficients in $\hat{\beta}_{\perp 2,1}$ and $\hat{\beta}_{\perp 2,2}$, it is clear that the higher influence (in both cases) is on temperature series. All these results confirm the analysis of Kaufmann and Stern (2002).

4.3. The second case

Univariate and multivariate analysis seem to indicate that there are explosive roots in the system. Therefore, an alternative analysis is to separate the five-variable system into two sub-systems. The first system contains three variables: temperature, solar irradiance and carbon dioxide. The second system has two variables: methane and nitrous dioxide, the two variables that seem to have explosive roots.

Tables 4a and b present the Trace and λ_{max} statistics. Notice that the selection of the rank of matrix Π is valid even when there are explosive or I(2) trends, see Nielsen (2001, 2002). Table 4a (3-variables system) indicates that $r=1$. The same result is found for Table 4b (2-variables system).

Tables 5a and b present the results from the $H_{r,s}$ statistic. The numbers in italic are critical values at 95% quantiles. In the case of the 3-variables system (Table 5a), we found $s_2=1$ and consequently $s_1=1$. The seven largest modules of the companion matrix

Table 4a
Testing for cointegrating ranks

H_0	λ_{\max}	Trace	λ_{\max} 90% critical values	Trace 90% critical values
$r=0$	36.1	54.5	23.1	39.1
$r=1$	14.7	18.4	16.9	23.0
$r=2$	3.7	3.7	10.5	10.6

$$Y_t = (temp_t, rfsun, rfcO_{2t})'$$

Table 4b
Testing for cointegrating ranks

H_0	λ_{\max}	Trace	λ_{\max} 90% critical values	Trace 90% critical values
$r=0$	43.3	52.2	16.9	23.0
$r=1$	8.9	8.9	10.5	10.6

$$Y_t = (rfch_{4t}, rfn_{2o_t})'$$

corresponding to the unrestricted VAR are: 0.9942, 0.9297, 0.8402, 0.8402, 0.7796, 0.6543, 0.6543. It seems there are two roots close to the unit circle. When $r=1$ is imposed, the seven largest modules are: 1.000, 1.000, 0.9546, 0.8494, 0.8494, 0.6844, 0.6844. We have two unit roots as the results of restriction $r=1$. However, there is another root 0.9546 very close to the unit circle, and this indicates the presence of I(2) trends. Therefore, according to the results of the eigenvalues of the companion matrix, the total number of unit roots is $s_1 + 2s_2 = 3$. This is in agreement with the results of the statistic $H_{r,s}$. Because we have the evidence that solar irradiance and temperature are both I(1) variables from univariate tests, it seems that carbon dioxide is the one responsible for the existence of the I(2) trend.

For the system with 2 variables (Table 5b), the results indicate $s_2=1$, therefore, $s_1=0$. In this case, the existence of one I(2) trend is difficult to accept since our preliminary results (see the last sub-section) indicate that there are two explosive roots which should be attributed to the two variables in the 2-variable system. The five largest modules of the companion matrix from the unrestricted VAR are: 1.0393, 1.0393, 0.8374, 0.6901, 0.6901. When $r=1$ is imposed, the eigenvalues are: 1.029, 1.029, 1.000, 0.714, 0.714. We have one unit root corresponding to the restriction of $r=1$ and two explosive roots. Others are not close to the unit circle. This information indicates that there is no I(2) trend in this system, whereas it seems to verify that explosive roots mimic the behavior of I(2) trends, as reported by Haldrup and Lildholdt (2002). Therefore in this case we conclude with $r=1$, $s_1=1$ and $s_2=0$.

Table 6 shows the estimates of $\hat{\beta}_1, \hat{\kappa}_1, \hat{\alpha}_1, \hat{\beta}_{\perp 1}, \hat{\beta}_{\perp 2}, \hat{\alpha}_{\perp 1}$ and $\hat{\alpha}_{\perp 2}$.¹⁸ Each year the temperature series corrects 12.6% the disequilibria in the dynamic long-run

¹⁸ There is no similar estimates in the case of the 2-system variables because there are not I(2) trends.

Table 5a
Testing for integration indices

r	$H_{r,s}$		Q_r	
0	213.5 (86.7)	114.9 (68.2)	58.0 (53.2)	54.5 (42.7)
1		102.0 (47.6)	21.6 (34.4)	18.4 (25.4)
2			6.4 (19.9)	3.7 (12.5)

$$Y_t = (rfch_{4t}, rfn_{2o_t})'$$

steady-state relation (polynomial cointegration). It is interesting to observe that the I(1) trend is driven by temperature and radiative forcing of solar irradiance but not by radiative forcing of carbon dioxide. However, the I(2) trend is completely driven by this greenhouse gas. The magnitude of the estimates of $\hat{\beta}_{\perp 1}$ tells us that the I(1) trend affects significantly all variables in the system, with the major effect on temperature series. Because this I(1) trend is driven by the temperature series itself and for the radiative forcing of solar irradiance, the estimates of $\hat{\beta}_{\perp 1}$ indicate that this trend corresponds to ‘inertial’ (or persistent) factors (temperature itself) and natural factors (radiative forcing of solar irradiance). In the case of the magnitudes of $\hat{\beta}_{\perp 2}$, the effects are also appreciated on temperature series. This I(2) trend could correspond to the human factors, that is, the greenhouse gases effects, in this case represented by radiative forcing of carbon dioxide.

The cointegration relation detected in the 2-variable system indicates a relationship between radiative forcing of methane and nitrous dioxide. We introduce this relation (together with the polynomial cointegration relation found in the 3-variable system) in the error correction model to calculate the response of the temperature series to these steady-state relations.¹⁹ The results indicate that temperature series responds 50.18% to the static long-run relation between radiative forcing of methane and nitrous. These results are in agreement with those results found in the last sub-section.

¹⁹ For each one of the cases presented, we estimated the respective VECM. These estimated were submitted to different test to evaluate for the presence of autocorrelation, heteroskedasticity, misspecification, normality and stability. The equation of temperature appears robust to all these diagnostic tests. Results are available upon request.

Table 6
Decomposing the systems into I(0), I(1) and I(2) spaces

	$\hat{\beta}_1$	$\hat{\kappa}_1$	$\hat{\beta}_{\perp 1}$	$\hat{\beta}_{\perp 2}$
temp	1.000	-0.819	10.505	2.606
rfsun	-3.341	-0.085	4.396	0.269
rfco ₂	-0.500	-1.073	-8.366	3.414
trend	0.006			
	$\hat{\alpha}_1$		$\hat{\alpha}_{\perp 1}$	$\hat{\alpha}_{\perp 2}$
temp	-0.126		0.046	0.000
rfsun	0.069		0.085	-0.001
rfco ₂	-0.001		-0.001	-0.096

$$Y_t = (temp_t, rfsun_t, rfco_{2t})'$$

From Table 6, we found that $\Delta T_{2x} = 2.15 \text{ }^\circ\text{C}$, which is in agreement with past literature, see Kaufmann and Stern (2002).

4.4. The third case

Another alternative is to transform the variables in such a way that an I(1) framework can be performed. Based on the results outlined before, temperature series and radiative forcing of solar irradiance are I(1) processes. Hence they enter the new system in levels. Radiative forcing of carbon dioxide is most likely an I(2) process and then enters the system in the first differences ($\Delta r f c o_2$). For the case of radiative forcing of methane and nitrous dioxide, we found evidence of explosiveness. Therefore we apply filter $\Delta_\lambda (\Delta_\lambda y_t = y_t - \lambda y_{t-1})$ to these variables with $\lambda = 1.029$. In summary, our 5-variables system is now composed of $y_t = \{temp_t, r f s u n_t, \Delta r f c o_{2t}, \Delta_\lambda r f c h_{4t}, \Delta_\lambda r f n_2 o_t\}$.

Table 7 presents the results from the application of the Trace and λ_{max} statistics and it suggests $r=2$. In order to be sure that our system does not contain I(2) trends, Table 8 presents the results of the $H_{r,s}$ statistics. The results confirm our claim. Therefore the integration indices are $r=2$ and $s_1 = n-r=3$. The eight largest modules of the companion matrix for the unrestricted VAR are: 0.9581, 0.9581, 0.923, 0.923, 0.861, 0.861, 0.848, 0.848. In the case of the restricted VAR ($r=2$), these modules are: 1.000, 1.000, 1.000, 0.890, 0.890, 0.858, 0.858, 0.838. We have three unit roots corresponding to the restriction of $r=2$ and no other roots

Table 7
Testing for cointegrating ranks

close to the unit circle.²⁰ The results seem to confirm that the total number of unit roots is three implying that there are not I(2) trends.

Table 9 presents the estimates of the two cointegrating vectors, the loadings values and the I(1) trends. The null hypothesis for the long-run exclusion of solar irradiance in the first steady-state relation and the imposition of a coefficient of -0.5 associated to carbon dioxide was not rejected with a $\chi^2_{(1)} = 2.75$ corresponding to a P -value of 0.10. The long-run exclusion of the time trend was always strongly rejected.

The estimates of the adjustment parameters show that temperature series is error correcting 10.8% and 12.3% each year. The first I(1) trend is driven by three greenhouse gases with a larger weight on radiative forcing of methane. The second I(1) trend is almost completely driven by radiative forcing of nitrous dioxide but with a small participation of radiative forcing of solar irradiance. The last I(1) trend is driven by two greenhouse gases with a larger weight on radiative

²⁰ In economics, some researchers consider that an eigenvalue of 0.89 is close to the unit circle. In our case, we prefer preclude this kind of possibility.

forcing carbon dioxide and again, a small participation of radiative forcing of solar irradiance.

5. Conclusions

This paper applies multivariate I(1) and I(2) tools to identify for the existence and the number of long-run steady-state relations between temperature series and radiative forcing of solar radiance and a set of three greenhouse gases. One of the results indicate that temperature and radiative forcing of solar irradiance series appear to be I(1) processes, radiative forcing of carbon dioxide is an I(2) process, and radiative forcing of methane and nitrous dioxide seem to contain explosive roots. In most variables (temperature, radiative forcing of solar irradiance and carbon dioxide), our results confirm previous evidence in the literature.

Given the complex structure and properties of the time series, we analyzed three alternative cases. In the first case, a 5-variable system is considered. The second case consisted of variables with I(1) and I(2) characteristics and the ones with explosive behavior separately. The last system considers a transformation of the variables in such a way that the I(1) framework can be used. Overall, all systems show that temperature series is error correcting the disequilibria towards the static steady-state or dynamic steady-state relations. The degree of adjustment of the temperature depends on which cointegrating relations is considered but it goes from 5% to 65%. The higher rates of adjustment are comparable to the results found by Stern and Kaufmann (2000). In some cases, however, temperature series is not error correcting for the long-run disequilibria. It means that there is nothing in the system (the earth and its components) that allows for correcting these disequilibria. On the other hand, the higher rates of adjustment respect to other disequilibria could suggest abrupt changes in temperature in order to correct for these disequilibria.

Another interesting result is the composition of the I(1) and I(2) trends. According to our results, both trends are essentially composed by a linear combination of greenhouse gases that are affecting the temperature series strongly. In an specific case, we find that the I(1) trend is driven by temperature and radiative forcing of solar irradiance, whereas the I(2) trend is driven by a linear combination of the three greenhouse gases or exclusively by the radiative forcing of carbon dioxide. The first component could be associated to inertial and/or natural factors. In the case of the second component, it could be related to human factors.

Finally, we find that the equilibrium temperature change for a doubling of carbon dioxide is between 2.15 and 3.4 °C, which is agreement with previous literature and the report of the IPCC (2001) using 15 different general circulation models.

Acknowledgements

An earlier version of this paper has benefited from useful comments from the participants to the 35th Annual Conference of the Canadian Economic Association, Calgary, 2001. We thank constructive comments from two referees and the Editor. The writing of this paper was finished while G.R. was visiting the School of Economics of the University of New South Wales, Australia, and he thanks particularly Garry Barret. Financial support from the Faculty of Social Sciences is acknowledged.
