# On Construction of Robust Composite Indices by Linear Aggregation 

SK Mishra<br>Department of Economics<br>North-Eastern Hill University<br>Shillong (India)

I. Introduction: A composite index ( $\left.I_{k}: k=1, n\right)$ is often a (weighted) linear aggregation of numerous indices $\left(x_{k j}: j=1, m ; k=1, n\right)$ such that $I_{k}=\sum_{j=1}^{m} w_{j} x_{k j}$. As to the assignment of weights to different indices, there are two approaches: the first in which the weights are determined on the basis of some information or considerations exogenous to the data on index variables $\left(x_{k j} \in X\right)$, and the second in which the weights are endogenously determined such that $w=f(X)$. The most robust composite index is the one that is exogenously determined since in that case $w$ is used as a parameter and, therefore, $I=\varphi(X \mid w)$. However, when weights are endogenously determined, we have $I=\varphi(X, f(X))$. In this latter case, the composite index, $I$, depends not only on the index variables, $X$, but also on the specification of the function, $f($.$) , that obtains weights, w$, from $X$.

To make this point clearer, let $x_{k j}$ be perturbed such that $x_{k j} \Leftarrow x_{k j}+\partial_{k j}$ where $\partial_{k j} \neq 0$. If weights are not derived from $X$, then $I_{k} \Leftarrow I_{k}+w_{j} \partial_{k j}$ and $I_{i \neq k} \Leftarrow I_{i \neq k}$. That is, the perturbation affects $I_{k}$ only. However, if weights are derived from $X$, a perturbation of one of the values of $x_{k j}$ would in most cases alter the values of $w$ as well as the values of $I_{k} \forall k=1, n$. A perturbation of $x_{k j}$ will pervade throughout even though all of $x_{i p}: i \neq k \wedge p \neq j$ have remained unchanged. The extent of pervasiveness, which is not a desirable property of the composite index, would depend on the specification of $w=f(X)$.

There is an additional point to be noted. When $I=\varphi(X \mid w)=X w$, the weight, $w_{j}$, which may be viewed as $\partial I / \partial x_{j}$ is constant and hence $I$ is indeed a linear combination of $X$. However, when $I=\varphi(X, f(X))$, the weight, $w_{j}$, in general , is not constant and, therefore, $I$ is not a linear combination of $X$. In that case, these weights, which may also be viewed as the rate of substitution among different constituent indices, lose interpretability in any simple manner and hence go far off the desirable property of easy comprehensibility.
II. Two Desirable Propertied of a Composite Index: Now we enunciate two desirable properties of a composite index: (i) change in $x_{k j}$ best be reflected into a change in $I_{k}$, which we call sensitiveness, and (ii) change in $x_{k j}$ be least reflected into changes in $I_{i}: i \neq k$, which we will call robustness. Sensitiveness implies stronger correlation between the composite index, $I$, and the constituent index variables, $x_{j} \in X$. On the other hand, robustness implies insensitiveness of $w$ to changes in $X$.
III. The Simplest Method of Construction of a Composite Index: Perhaps the simplest method of constructing a composite index is to obtain $I_{k}=(1 / m) \sum_{j=1}^{m} x_{k j}: k=1, n$. It implies $w_{j}=1 / m: j=1, m$. Viewed as such, this method yields a robust composite index. It also follows the law of insufficient reason; that in absence of any indubitable basis of determining the weights assigned to different index variables, they all carry equal weights. In the last few years, after it was used for construction of the 'human development index', this method has won many adherents. In applying this method, on many occasions, the index variables, $x_{j} s$, are standardized or normalized in some manner such that $x_{j} \Leftarrow g\left(x_{j}\right) / \operatorname{norm}\left(g\left(x_{j}\right)\right)$, where $g\left(x_{j}\right)$ is a monotonic function of $x_{j}$. The $\operatorname{norm}\left(g\left(x_{j}\right)\right)$ may be $\max _{k}\left(g\left(x_{k j}\right)\right), \hat{\sigma}\left(g\left(x_{j}\right)\right.$, $\operatorname{med}_{k}\left|x_{k j}-\operatorname{med}\left(x_{j}\right)\right|$, etc. The choice of a suitable norm is important. Certain types of norm may run against the desirable property of robustness. On the other hand, sensitiveness of the composite index constructed by this method is rather suboptimal.
IV. The Method of the Principal Components Analysis: The well known Principal Components Analysis (PCA) is another method to obtain the composite index. It attributes two properties to $I=X w$ : first, that it maximizes the sum of squared (Karl Pearson's or product moment) coefficients of correlation between $I$ and $x_{j} ; j=1, m$, and the second, that it is orthogonal to any other index, $J=X v: v \neq w$, that may be derived from $X$ by maximization of the sum of squared correlation coefficients between $J$ and $x_{j}$. Stated differently, the PCA-based composite index satisfies two criteria: i) $I=X w: \sum_{j=1}^{m} r^{2}\left(I, x_{j}\right)$ is maximum, and ii) if $I=X w: \max \sum_{j=1}^{m} r^{2}\left(I, x_{j}\right)$ and $J=X v: \max \sum_{j=1}^{m} r^{2}\left(J, x_{j}\right) ; w \neq v$, then the coefficient of correlation between the two such composite indices, $r(I, J)=0$. Except in an extremely special case when the constituent index variables themselves are pair-wise orthogonal, $I$ and $J$ both cannot attain the global maximum. The global maximizer composite index is unique.

The technique to obtain such a (unique) global maximizer composite index by PCA consists of, first, obtaining the matrix, $R$, of correlation coefficients, $r_{i j} \in R$, between each pair of index variables, $x_{i}$ and $x_{j}$, and, then, obtaining the eigenvalues ( $\lambda_{1}, \lambda_{2}, \ldots, \lambda_{m}$ ) and the eigenvectors $\left(u_{1}, u_{2}, \ldots, u_{m}\right)$ of $R$. The eigenvectors are then normalized to satisfy the condition $\left\|u_{j}\right\|=1 \forall j$ (or, sometimes, $\left\|u_{j}\right\|=\lambda_{j} \forall j$ ), where \|e\| denotes the Euclidean norm. These normalized eigenvectors are used as weights to construct the composite indices. The index constructed by using the eigenvector associated with the largest eigenvalue is often used as the first best composite index. This index attains the global maximum mentioned earlier.

The composite index thus obtained has many optimal properties. However, this PCA based index is often elitist (Mishra, 2007-b), with a strong tendency to weight highly correlated subset of $X$ favourably and relegating poorly correlated index variables to the subsequent principal components. In practice, when one has to use only one composite index to represent $X$, the poorly correlated index variables remain largely unrepresented. Since correlation is no measure of importance, many highly important but poorly correlated index variables may thus be undermined by the PCA-based composite index.

The said elitist property of the PCA based index may possibly be ameliorated by application of multi-criteria analysis. It has been suggested (Mishra, 1984) that multiple PCAbased composite indices ( $I_{j}: j=1, m$ ) obtained by using different eigenvectors of $R$ (of $X$ ) can be subjected to multi-criteria decision-making/concordance analysis (Hill and Tzamir, 1972; van Delft and Nijkamp, 1976) for establishing outranking relationship among the objects ( $A_{k}$ ) represented by $x_{k}=\left(x_{k 1}, x_{k 2}, \ldots, x_{k m)}: k=1, n\right.$. Each composite index, $I_{j}$, will take on a weight according to its explanatory power measured by the eigenvalue, $\lambda_{j}$ (of $R$ ), associated with it. Since PCA-based composite indices are much fewer than the number of index variables in $X$, it is expected that this approach will be sharper than the approach that applies multicriteria decision-making tools on $X$ itself (Munda and Nardo, 2005-a and 2005-b). It may be noted, however, that the earlier approach derives endogenous weights from $X$ itself, while the latter approach needs exogenous weights.

Another possible approach to abate the elitist tendency of the composite indices is to derive them not by maximization of the sum of squared correlation coefficients between the composite index and the constituent index variables as the PCA does, but by maximization of the sum of absolute (product moment) correlation coefficients between them (Mishra, 2007-a).
That is: the composite index, $I=X w$ maximizes $\sum_{j=1}^{m}\left|r\left(I, x_{j}\right)\right|$. This sort of index is said to be inclusive in nature since it does assign suitable weights to poorly correlated indicator variables. Yet another possible method to obtain a composite index, $I=X w$, consists of maximization of the minimal absolute or squared (product moment) correlation coefficient: $I=X w: \max \left[\left(\min _{j}\left|r\left(I, x_{j}\right)\right|\right]\right.$. This approach assigns the most egalitarian weights to all index variables and hence favours the poorly correlated indicator variables most (Mishra, 2007b).
V. Replacement of Pearson's Correlation Coefficient by Robust Correlation Coefficient: Arithmetic mean, standard deviation and product moment correlation coefficient are the members of the same family, based on minimization of the Euclidean norm. All of them are very much sensitive to perturbation, errors of observation or presence of outliers in the dataset. If the weights, $w$, in $I=X w$ are obtained by maximization of the product moment correlation
(whether $\max \sum_{j=1}^{m} r^{2}\left(I, x_{j}\right), \quad \max \sum_{j=1}^{m}\left|r\left(I, x_{j}\right)\right|$ or $\max \left[\min _{j}\left(\left|r\left(I, x_{j}\right)\right|\right]\right)$, errors of observation, effects of perturbation or presence of outliers on weights would surely be substantial and pervasive. Therefore, there is a need to replace product moment correlation coefficient by some more robust measure of correlation.

Since the formula of computing the product moment correlation is fundamental to development of many other measures of correlation, we present it here. The product moment coefficient of correlation is defined as:
$r\left(x_{1}, x_{2}\right)=\operatorname{cov}\left(x_{1}, x_{2}\right) / \sqrt{\operatorname{var}\left(x_{1}\right) \cdot \operatorname{var}\left(x_{2}\right)}$
where, $\bar{x}_{a}=\frac{1}{n} \sum_{i=1}^{n} x_{i a} ; \operatorname{cov}\left(x_{1}, x_{2}\right)=\frac{1}{n} \sum_{i=1}^{n} x_{i 1} x_{i 2}-\bar{x}_{1}^{2} \bar{x}_{2}^{2}$ and $\operatorname{var}\left(x_{a}\right)=\operatorname{cov}\left(x_{a}, x_{a}\right)$. The quarter square identity (Gnanadesikan and Ketttenring, 1972) gives us:
$\sum_{i=1}^{n} x_{i 1} x_{i 2}=\frac{1}{4}\left[\sum_{i=1}^{n}\left(x_{i 1}+x_{i 2}\right)^{2}-\sum_{i=1}^{n}\left(x_{i 1}-x_{i 2}\right)^{2}\right]$

$$
=\frac{1}{4}\left[\sum_{i=1}^{n} x_{i 1}^{2}+\sum_{i=1}^{n} x_{i 2}^{2}+2 \sum_{i=1}^{n} x_{i 1} x_{i 2}-\sum_{i=1}^{n} x_{i 1}^{2}-\sum_{i=1}^{n} x_{i 2}^{2}+2 \sum_{i=1}^{n} x_{i 1} x_{i 2}\right]=\frac{1}{4}\left[4 \sum_{i=1}^{n} x_{i 1} x_{i 2}\right]
$$

Exploiting this identity we may write

$$
\begin{equation*}
r\left(x_{1}, x_{2}\right)=(1 / 4)\left[\operatorname{var}\left(x_{1}+x_{2}\right)-\operatorname{var}\left(x_{1}-x_{2}\right)\right] / \sqrt{\operatorname{var}\left(x_{1}\right) \cdot \operatorname{var}\left(x_{2}\right)} \tag{2}
\end{equation*}
$$

This formula (2) is of a great relevance for development of some other formulas of correlation.
There is one more identity that may be interesting. This identity is given as:
$\sum_{i=1}^{n} \sum_{j=1}^{n}\left(x_{i 1}-x_{j 1}\right)\left(x_{i 2}-x_{j 2}\right)=\sum_{i=1}^{n} \sum_{j=1}^{n}\left(x_{i 1} x_{i 2}-x_{i 1} x_{j 2}-x_{j 1} x_{i 2}+x_{j 1} x_{j 2}\right)$
$=\sum_{i=1}^{n}\left[n x_{i 1} x_{i 2}-x_{i 1} \sum_{j=1}^{n} x_{j 2}-x_{i 2} \sum_{j=1}^{n} x_{j 1}+\sum_{j=1}^{n} x_{j 1} x_{j 2}\right]$
$=n \sum_{i=1}^{n} x_{i 1} x_{i 2}-\sum_{i=1}^{n} x_{i 1} \sum_{j=1}^{n} x_{j 2}-\sum_{i=1}^{n} x_{i 2} \sum_{j=1}^{n} x_{j 1}+n \sum_{j=1}^{n} x_{j 1} x_{j 2}$
Now, since $\sum_{i=1}^{n} x_{i 1} x_{i 2} \equiv \sum_{j=1}^{n} x_{j 1} x_{j 2}$ and $\sum_{i=1}^{n} x_{i a} \equiv \sum_{j=1}^{n} x_{j a}$ for $a=1,2$, we rewrite (3) as
$2\left[n \sum_{i=1}^{n} x_{i 1} x_{i 2}-\sum_{i=1}^{n} x_{i 1} \sum_{i=1}^{n} x_{i 2}\right]=2 n^{2}\left[\frac{1}{n} \sum_{i=1}^{n} x_{i 1} x_{i 2}-\bar{x}_{1} \bar{x}_{2}\right]=2 n^{2} \operatorname{cov}\left(x_{1}, x_{2}\right)$
Further simplified, $\sum_{i=1}^{n} \sum_{j=i}^{n}\left(x_{i 1}-x_{j 1}\right)\left(x_{i 2}-x_{j 2}\right)=n^{2} \operatorname{cov}\left(x_{1}, x_{2}\right)$. However, for $i=j$ the terms take on zero value and, thus, $\sum_{i=1}^{n-1} \sum_{j=i+1}^{n}\left(x_{i 1}-x_{j 1}\right)\left(x_{i 2}-x_{j 2}\right)=n^{2} \operatorname{cov}\left(x_{1}, x_{2}\right)$. This invariance of sum over $i \leq j$ and $i<j$ has important bearings when $n$ is not vary large.
VI. Robust Measures of Correlation: Statisticians have proposed a number of formulas, other than the one that obtains Pearson's coefficient of correlation, that are considered to be less affected by errors of observation, perturbation or presence of outliers in the data. Some of them transform the variables, say $x_{1}$ and $x_{2}$, into $z_{1}=\phi_{1}\left(x_{1}\right)$ and $z_{2}=\phi_{2}\left(x_{2}\right)$, where $\phi_{a}\left(x_{a}\right)$ is a linear (or nonlinear) monotonic (order-preserving) rule of transformation or mapping of $x_{a}$ to $z_{a}$. Then, $r\left(z_{1}, z_{2}\right)$ is obtained by the appropriate formula and it is considered as a robust measure of $r\left(x_{1}, x_{2}\right)$. Some others use different measures of central tendency, dispersion and co-variation, such as median for mean, mean deviation for standard deviation and so on. In what follows, we present a few formulas of obtaining different types of correlation efficient.
VI.1. Spearman's Rank Correlation Coefficient: If $x_{1}$ and $x_{2}$ are two variables, both in $n$ observations, and $z_{1}=\mathfrak{R}\left(x_{1}\right)$ and $z_{2}=\mathfrak{R}\left(x_{2}\right)$ are their rank numerals, then the Pearson's formula applied on ( $z_{1}, z_{2}$ ) obtains the Spearman's correlation coefficient (Spearman, 1904). There is a simpler (but less general) formula that obtains rank correlation coefficient, given as:

$$
\begin{equation*}
\rho\left(x_{1}, x_{2}\right)=r\left(z_{1}, z_{2}\right)=1-6 \sum_{i=1}^{n}\left(z_{i 1}-z_{i 2}\right)^{2} /\left[n\left(n^{2}-1\right)\right] \tag{5}
\end{equation*}
$$

VI.2. Signum Correlation Coefficient: Let $c_{1}$ and $c_{2}$ be the measures of central tendency or location (such as arithmetic mean or median) of $x_{1}$ and $x_{2}$ respectively. We transform them to $z_{i a}=\left(x_{i a}-c_{a}\right) /\left|x_{i a}-c_{a}\right|$ if $\left|x_{i a}-c_{a}\right|>0$, else $z_{i a}=1$. Then, $r\left(z_{1}, z_{2}\right)$ is the signum
correlation coefficient (Blomqvist, 1950; Shevlyakov, 1997). Due to the special nature of transformation, we have

$$
r\left(z_{1}, z_{2}\right) \cong \operatorname{cov}\left(z_{1}, z_{2}\right)=(1 / n) \sum_{i=1}^{n} z_{i 1} z_{i 2}
$$

In this study we will use median as a measure of central tendency to obtain signum correlation coefficients.
VI.3. Bradley's Absolute Correlation Coefficient: Bradley (1985) showed that if $\left(u_{i}, v_{i}\right) ; i=1, n$ are $n$ pairs of values such that the variables $u$ and $v$ have the same median $=0$ and the same mean deviation (from median) or $(1 / n) \sum_{i=1}^{n}\left|u_{i}\right|=(1 / n) \sum_{i=1}^{n}\left|v_{i}\right|=d \neq 0$, both of which conditions may be met by any pair of variables when suitably transformed, then the absolute correlation may be defined as
$\rho(u, v)=\sum_{i=1}^{n}\left(\left|u_{i}+v_{i}\right|-\left|u_{i}-v_{i}\right|\right) / \sum_{i=1}^{n}\left(\left|u_{i}\right|+\left|v_{i}\right|\right)$.
VI.4. Shevlyakov Correlation Coefficient: Hampel et al. (1986) defined the median of absolute deviations (from median) as a measure of scale, $s_{H}\left(x_{a}\right)=$ median $\mid x_{i a}$-median $\left(x_{i a}\right) \mid$ which is a very robust measure of deviation, and using this measure, Shevlyakov (1997) defined median correlation,
$r_{\text {med }}=\left[\right.$ med $^{2}|u|-$ med $\left.^{2}|v|\right] /\left[\right.$ med $^{2}|u|+$ med $\left.^{2}|v|\right]$
where $u$ and $v$ are given as $u_{i}=\left(x_{i 1}-\operatorname{med}\left(x_{i 1}\right)\right) / s_{H}\left(x_{1}\right)+\left(x_{i 2}-\operatorname{med}\left(x_{i 2}\right)\right) / s_{H}\left(x_{2}\right)$ and $v_{i}=\left(x_{i 1}-\operatorname{med}\left(x_{i 1}\right)\right) / s_{H}\left(x_{1}\right)-\left(x_{i 2}-\operatorname{med}\left(x_{i 2}\right)\right) / s_{H}\left(x_{2}\right)$.
VI.5. Campbell's Correlation Matrix: Unlike the coefficient of correlation defined by the formulations above that consider correlation between any pair of variables at a time (and thus presuming that other variables do not exist, while indeed they do exist), Campbell (1980) obtained the entire matrix of robust correlation coefficients simultaneously, discounting for the effects of outliers. The main idea behind Campbell's correlation is to obtain $V=Z^{\prime} \Omega^{-1} Z$ instead of $Z^{\prime} I Z$ where $\Omega^{-1} \neq I$, but an inverted Mahalanobis-Aitken distance matrix defined in a specific manner.

Campbell's method is an iterative method that obtains the $m$-element vector of weighted (arithmetic) mean, $\bar{x}$, and weighted variance-covariance matrix, $V(m, m)$, in the following manner. Initially, all weights, $w_{i} ; i=1, n$ are considered to be equal, $1 / n$, and the sum of weights, $\sum_{i=1}^{n} w_{i}=1$. Further, we define $d_{0}=\sqrt{m}+b_{1} / \sqrt{2} ; b_{1}=2, b_{2}=1.25$.

Then we obtain

$$
\begin{gathered}
\bar{x}=\sum_{i=1}^{n} w_{i} x_{i} / \sum_{i=1}^{n} w_{i} \\
V=\sum_{i=1}^{n} w_{i}^{2}\left(x_{i}-\bar{x}\right)^{\prime}\left(x_{i}-\bar{x}\right) /\left[\sum_{i=1}^{n} w_{i}^{2}-1\right] \\
d_{i}=\left\{\left(x_{i}-\bar{x}\right) V^{-1}\left(x_{i}-\bar{x}\right)^{\prime}\right\}^{1 / 2} ; i=1, n \\
w_{i}=\omega\left(d_{i}\right) / d_{i} ; i=1, n: \omega\left(d_{i}\right)=d_{i} \text { if } d_{i} \leq d_{0} \text { else } \omega\left(d_{i}\right)=d_{0} \exp \left[-(1 / 2)\left(d_{i}-d_{0}\right)^{2} / b_{2}^{2}\right]
\end{gathered}
$$

It may be noted that execution of the last operation redefines $w_{i} ; i=1, n$ which may be significantly different from the $w_{i} ; i=1, n$ in the first operation. If this process is repeated, $w_{i} ; i=1, n$ stabilizes and so stabilize $\bar{x}, V$, and $d_{i} ; i=1, n$. We will call it Campbell (type-l) procedure. A few points are worth noting. If $V$ is ill-conditioned for ordinary inversion, a generalized (Moore-Penrose) inverse of $V$ or $V^{+}$may be used for $V^{-1}$ and if $d_{i}=0$ or $d_{i} \approx 0$ then $w_{i}=1$. From $V$ one may obtain $R$, the correlation matrix, since $r_{i j}=v_{i j} / \sqrt{v_{i i} v_{i j}}$.

It may also be noted that there can be other approaches to specify $\omega\left(d_{i}\right)$. Any scheme that assigns lower weight to larger magnitude of $d_{i}$ will make $V$ a robust measure of covariance. Assigning weights such as $w_{i}=1$ for $d_{i}-s_{H}(d) \leq d_{i}<d_{i}+s_{H}(d), w_{i}=(1 / 2)^{2}$ for $d_{i}-2 s_{H}(d) \leq d_{i}<d_{i}-s_{H}(d)$ and $d_{i}+2 s_{H}(d) \geq d_{i}>d_{i}+s_{H}(d)$ and so on may also be very effective in robustization of correlation matrix. Although Campbell (1980) has not suggested this procedure to assign weights, we will call it Campbell (type-II) procedure since in all other respects it is similar to his method of obtaining the robust correlation matrix.
VII. Robustness of Correlation Matrices in Simulated Data: Now we propose to compute different measures of correlation coefficient listed above and to compare their performance as to robustness in presence of outliers and mutilating perturbations in the data (indicator variables, $X$ ). This exercise is based on simulated data. We generate a single variable, $x_{1}: x_{i 1} ; i=1, n(n=30)$ randomly and scale the values such that each $x_{i 1}$ lies between 10 and 50 with equal probability. With $x_{1}$ we generate $x_{i j} ; i=1, n ; j=1, m \quad(m=6)$ such that $x_{i j}=x_{i 1}+e_{i j}$, where $e_{i j}$ are random and uniformly distributed between (-10, 10). As a result of this mutilation the correlation between any two variables, $x_{j}, x_{k} \in X$ would be appreciably large. These six variables are then used to construct composite index, $I=X w$. The generated variables $(X)$ and the correlation matrix $(R)$ obtained from them by using different formulas (Pearson, Spearman, Signum, Bradley, Shevlyakov and Campbell) are presented in Table-1 and Table-2.1 through Table-2.3.

It may be noted that unless we add $e_{i j}$ to $x_{i j}$, the coefficient of correlation $r\left(x_{i}, x_{j}\right)$ between any two variables $x_{i}, x_{j} \in X$ is unity. Once errors are introduced, correlation decreases. The range and magnitude of $e_{i j}$ determines the reduction in the magnitude of correlation. We have chosen $(-10,10)$ as the range of $e_{i j}$ so as to keep high correlation among the variables, and all $x_{i j}$ to lie between zero and sixty. With this $X$ we compute thirteen composite indices as detailed out in section VIII. Then we mutilate or introduce an outlier into $X$ and compute thirteen composite indices as spelt out in section VIII and compare them. For mutilation, we add 1000 to $x_{11}$ (the first observation on $x_{1}$ ) which shifts the median of $x_{1}$ from 30.46484 to 31.02664 and mean of $x_{1}$ from 29.89639 to 63.229724 . Now, $x_{11}$ is clearly an outlier observation. Effect of this outlier permeates through all correlation coefficients, presented in Table 3.1 through 3.3.

A perusal of Tables 3.1 through 3.3 reveals that Karl Pearson's, Signum, Bradley's and Campbell's (type-I) correlation matrices have been evidently poor at containing the effects of mutilation. A number of correlation coefficients have changed significantly in magnitude, sign or
both. However, Shevlyakov's correlation matrix has been affected only slightly. Campbell (typeII) correlation matrix has been most robust (table-3.4).
VIII. Construction of Composite Indices: As mentioned above, from $X$ we construct thirteen indices by using the following procedures:
(i) By averaging over variables: $I_{0 i}=(1 / m) \sum_{j=1}^{m} x_{i j}$
(ii) By maximizing $\sum_{j=1}^{m}\left|r\left(I_{1}, x_{j}\right)\right|: I_{1}=X w_{1}$, where $r\left(I_{1}, x_{j}\right)$ is Pearson's correlation between $I_{1}$ and $x_{j}$
(iii) By maximizing $\sum_{j=1}^{m} r^{2}\left(I_{2}, x_{j}\right) \mid: I_{2}=X w_{2}$, where $r\left(I_{2}, x_{j}\right)$ is Pearson's correlation between $I_{2}$ and $x_{j}$
(iv) By maximizing $\sum_{j=1}^{m}\left|\tilde{r}\left(I_{3}, x_{j}\right)\right|: I_{3}=X w_{3}$, where $\tilde{r}\left(I_{3}, x_{j}\right)$ is Bradley's correlation between $I_{3}$ and $x_{j}$
(v) By maximizing $\sum_{j=1}^{m}\left|\rho\left(I_{4}, x_{j}\right)\right|: I_{4}=X w_{4}$, where $\rho\left(I_{4}, x_{j}\right)$ is Spearman's correlation between $I_{4}$ and $x_{j}$
(vi) By maximizing $\sum_{j=1}^{m} \rho^{2}\left(I_{5}, x_{j}\right): I_{5}=X w_{5}$, where $\rho\left(I_{5}, x_{j}\right)$ is Spearman's correlation between $I_{5}$ and $x_{j}$
(vii) By maximizing $\sum_{j=1}^{m}\left|\widehat{r}\left(I_{6}, x_{j}\right)\right|: I_{6}=X w_{6}$, where $\hat{r}\left(I_{6}, x_{j}\right)$ is the signum correlation between $I_{6}$ and $x_{j}$
(viii) By maximizing $\sum_{j=1}^{m} \breve{r}^{2}\left(I_{7}, x_{j}\right): I_{7}=X w_{7}$, where $\hat{r}\left(I_{7}, x_{j}\right)$ is the signum correlation between $I_{7}$ and $x_{j}$
(ix) By maximizing $\sum_{j=1}^{m}\left|\breve{r}\left(I_{8}, x_{j}\right)\right|: I_{8}=X w_{8}$, where $\breve{r}\left(I_{8}, x_{j}\right)$ is the Shevlyakov correlation between $I_{8}$ and $x_{j}$
(x) By maximizing $\sum_{j=1}^{m} \breve{r}^{2}\left(I_{9}, x_{j}\right): I_{9}=X w_{9}$, where $\breve{r}\left(I_{9}, x_{j}\right)$ is the Shevlyakov correlation between $I_{9}$ and $x_{j}$
(xi) $\quad I_{10}$ obtained from the first principal component of $R$, where $R$ is the Campbell's correlation matrix with the $\omega(d)$ as defined in Campbell (1980) mentioned above.
(xii) $\quad I_{11}$ obtained from the first principal component of $R$, where $R$ is the Campbell's correlation matrix with the $\omega(d)$ defined in Campbell (type-II) above.
(xiii) $\quad I_{M}$ obtained by $\max \left(\min _{j}\left(\left|\hat{r}\left(I_{M}, x_{j}\right)\right|\right)\right.$ where $\hat{r}\left(I_{M}, x_{j}\right)$ is any specific (Pearson's, Spearman's, Signum or Shevlyakov or any other type of) correlation between $I_{M}$ and $x_{j}$. Thus $I_{M}$ is a class of indices whose members are different according to the type of correlation coefficient they use, but generically they all use the maxi-min criterion. In this paper we will use Spearman's correlation only to obtain $I_{M}$.

The thirteen types of composite indices enumerated above have been constructed with and without mutilation of $x_{11}$ of $X$. The composite indices, the weights used to construct them and the relevant correlation of the composite indices ( $I$ ) with the constituent indicator variables $(X)$ are presented in Tables 4.1 through 5.2. Except $I_{0}$, which is constructed by a simple arithmetic averaging of variables $\left(I_{i 0}=(1 / 6) \sum_{j=1}^{6} x_{i j}\right)$ all other composite indices ( $I_{1}$ through $I_{11}$ and $I_{M}$ ) are based on maximization of different types of correlation. Since $I_{0}$ is not based on correlation, it is not relevant to compare its correlation with the constituent variables across the Tables 4.2 and 5.2. They are presented only for the completeness of those tables.
IX. A Comparison of the Two Properties of Composite Indices: Earlier in section II of this paper we have noted two desirable properties of indicators, viz. sensitiveness to autochthonous changes (alpha, $\alpha$ ), and robustness or immunity to allochthonous changes (beta, $\beta$ ). We define them as follows:
$\operatorname{Alpha}(\alpha)=\left(\left(1 / n_{p}\right) \sum_{p}\left(I_{p u}-I_{p v}\right)^{2}\right)^{0.5} ; p \in N=(1,2, \ldots, n)$; where $n_{p}=$ no. of elements of N that refer to the mutilated row(s) $p$ of $X$ (that contain(s) outliers); in our present case, $n_{p}=1$. Higher value of $\alpha$ indicates higher sensitivity and is a desirable property.
$\operatorname{Beta}(\beta)=\left(\left(1 / n_{q}\right) \sum_{q}\left(I_{q u}-I_{q v}\right)^{2}\right)^{0.5} ; q \in N=(1,2, \ldots, n)$; where $n_{q}=$ no. of elements of $N$ that refer to un-mutilated rows $q$ of $X$ (that do not contain outliers); presently, $n_{p}=29=(30-$ $\left.n_{p}\right)=(30-1)$. A lower value of $\beta$ is preferable to a higher value. Ideally $\beta$ should be zero. Further, $n_{p}+n_{q}=n$, and $I_{. u}($ Table -4.1$)$ and $I_{. v}($ Table -5.1$)$ are the composite indices constructed from un-mutilated (outlier-free) variables and mutilated (outlier-infested) variables.

A perusal of Table-6 reveals that the beta values of mean-based, squared (S-) Spearman, Campbell-II, absolute (A-) Spearman and maxi-min correlation based composite indices are lower. That means that in these composite indices the effects of outliers/mutilation are largely contained only by those observations that are directly affected and their effects do not percolate or pervade through all other observations. On the other hand, the alpha values (direct sensitivity) of S-signum, Campbell-II, Campbell-I and Mean-based indices are relatively much higher than those of the other indices. Taking both criteria together, Mean-based, Campbell-II and maxi-min composite indices are better than others. Among the correlation-based indices, Campbell-II is the best one, seconded by the maxi-min composite index. If $S$-Spearman weights are used on X to compute composite index, $I_{5}$ has an excellent performance.

Concluding Remarks: When dealing with the real data obtained from the field, one does not know the location, magnitude or sign of outliers/errors of observation. When these (defective) data are used for sophisticated multivariate analysis, the results may be far from the reality. Correlation matrices (or covariance matrices) make a basis for a number of statistical methods. When correlation matrices are affected by outliers/errors/mutilations, the subsequent results become misleading. The composite indices are only a case in the large spectrum.

Our findings suggest that when we suspect the data to contain outliers or errors of a large magnitude, we should use a robust measure of correlation such as Campbell-II. For constructing indices, either the simple mean-based method (with suitable scaling of indicator
variables) or the Campbell-II correlation, S -Spearman or maxi-min correlation based method should be used. In particular, S -Spearman weights should be used on $X$ rather than $\mathfrak{R}(X)$. For multivariate analysis such as the principal component analysis (Devlin, et al. 1981), the factor analysis, the discriminant analysis and the canonical correlation analysis including the regression analysis, one should prefer to use robust measures of correlation (covariance) than the Karl Pearson's correlation.
