### Abstract

Recognizing direct relationships between variables connected in a network is a pervasive problem in biological, social and information sciences as correlation-based networks contain numerous indirect relationships. Here we present a general method for inferring direct effects from an observed correlation matrix containing both direct and indirect effects. We formulate the problem as the inverse of network convolution, and introduce an algorithm that removes the combined effect of all indirect paths of arbitrary length in a closed-form solution by exploiting eigen-decomposition and infinite-series sums. We demonstrate the effectiveness of our approach in several network applications: distinguishing direct targets in gene expression regulatory networks; recognizing directly-interacting amino-acid residues for protein structure prediction from sequence alignments; and distinguishing strong collaborations in co-authorship social networks using connectivity information alone.

---

Network science has been widely adopted in recent years in diverse settings, including molecular and cell biology<sup>1</sup>, social sciences<sup>2</sup>, information science<sup>3</sup>, document mining<sup>4</sup> and other data mining applications. Networks provide an efficient representation for variable interdependencies, represented as weighted edges between pairs of nodes, with the edge weight typically corresponding to the confidence or the strength of a given relationship. Given a set of observations relating the values that elements of the network take in different conditions, a network structure is typically inferred by computing the pairwise correlation, mutual information or other similarity metrics between each pair of nodes.

The resulting edges include numerous indirect dependencies owing to transitive effects of correlations. For example, if there is a strong dependency between nodes *1* and *2*, and between nodes *2* and *3* in the true (direct) network, high correlations will also be visible between nodes *1* and *3* in the observed (direct and indirect) network, thus inferring an edge from node *1* to node *3*, even though there is no direct information flow between them (Fig. 1a). Moreover, even if a true relationship exists between a pair of nodes, its strength may be over-estimated owing to additional indirect relationships, and distinguishing the convolved direct and indirect contributions is a daunting task. As the size of networks increases, a very large number of indirect edges may be due to second-order, third-order and higher-order

interactions, resulting in diffusion of the information contained in the direct network, and leading to inaccurate network structures and network weights in many applications<sup>1,5–11</sup>.

Several approaches have been proposed to infer direct dependencies among variables in a network. For example, partial correlations have been used to characterize conditional relationships among small sets of variables<sup>12–14</sup>, and probabilistic approaches, such as maximum entropy models, have been used to identify informative network edges<sup>10,15,16</sup>. Other works use graphical models and message passing algorithms to characterize direct information flows in a network<sup>17,18</sup>, or variations of Granger causality<sup>19</sup> to capture the dynamic relationships among variables<sup>20–22</sup>. Alternative approaches formulated the problem of separating direct from indirect dependencies as a general feature-selection problem<sup>23–25</sup>, using Bayesian networks<sup>26–28</sup>, or using an information-theoretic approach to eliminate indirect information flow in the network<sup>29</sup>. These methods are limited to relatively low-order interaction terms<sup>29</sup>, or are computationally very expensive<sup>12–14</sup>, or are designed for specific applications<sup>10,15–17,30,31</sup>, thus limiting their applicability.

In this paper, we formulate the problem of network deconvolution in a graph-theoretic framework. Our goal is a systematic method for inferring the direct dependencies in a network, corresponding to true interactions, and removing the effects of transitive relationships that result from indirect effects. When the matrix of direct dependencies is known, all transitive relationships can be computed by summing this direct matrix and all its powers, corresponding to the transitive closure of a weighted adjacency matrix, which convolves all direct and indirect paths at all lengths (Fig. 1b). Given an observed matrix of correlations that contains both direct and indirect effects, our task is to recover the original direct matrix that gave rise to the observed matrix. For a weighted network where edge weights represent the confidence, mutual information or correlation strength relating two elements in the network, the inverse problem seeks to recognize the fraction of the weight of each edge attributable to direct vs. indirect contributions, rather than to keep or remove unit-weight edges. This inverse problem is dramatically harder than the forward problem of transitive closure, as the original matrix is not known.

We introduce an algorithm for Network Deconvolution (ND) that can efficiently solve the inverse problem of transitive closure of a weighted adjacency matrix, by use of decomposition principles of eigenvectors and eigenvalues, and by exploiting the closed form solution of infinite Taylor series. We demonstrate the effectiveness of this approach and our algorithm in several large-scale networks from different domains and with different properties (Supplementary Table S1). First, we seek to distinguish likely direct targets in gene regulatory networks as a post-processing step for diverse gene network inference methods, and show that ND improves both global and local network quality. Second, we show effectiveness of network deconvolution in distinguishing directly-interacting amino-acid residues based on pairwise mutual information data in multi-species protein alignments. Third, we apply ND to a social network setting using a co-authorship network that contains solely connectivity information, and show that the resulting edge weights are able to distinguish strong and weak ties independently inferred based on the number of joint papers and additional co-authors. The wide applicability of ND suggests that such a closed-form solution is not only of important theoretical use in reversing the effect of matrix transitive closure, but also of wide practical applicability in a diverse set of real-world networks.

## Results

### Resolving direct and indirect dependencies in a graph

Mathematically, we model the weights of an observed network  $G_{obs}$  whose diagonal is set to zero as the sum of both direct weights in the true network  $G_{dir}$  and indirect weights due to

indirect paths of increasing length in  $G_{dir}^2, G_{dir}^3$ , etc (Fig. 1a). The inverse problem of inferring the direct network from the observed network is seemingly intractable, as the direct information has now diffused through the observed network beyond recognition. However, expressing  $G_{obs}$  as an infinite sum of the exponentially-decreasing contributions of increasingly-indirect paths leads to a closed form solution for  $G_{obs}$  as a function of  $G_{dir}$  using an infinite-series summation (Fig. 1b). Moreover, by decomposing the observed network into its eigenvalues and eigenvectors, we can express each eigenvalue of the direct matrix as a function of the corresponding eigenvalue of the observed matrix (Fig. 1c). This decomposition leads to a simple closed-form solution for  $G_{dir}$  and provides a framework for an efficient globally-optimal algorithm to deconvolve the contributions of direct and indirect edges given an observed network (**Methods** and Supplementary Note S1).

The resulting Network Deconvolution (ND) algorithm can be viewed as a nonlinear filter over eigenvalues of a locally observed network to compute global edge significance, for each eigenvalue computing the inverse of a Taylor series expansion. This results in the decrease of large positive eigenvalues of the observed dependency matrix that are inflated owing to indirect effects. The eigenvalue/eigenvector matrix decomposition holds for all symmetric matrices, including all correlation or information-based matrices, and also for some asymmetric input matrices as we show in Supplementary Note S1.4.1. For non-decomposable matrices, we present an iterative conjugate gradient descent approach for network deconvolution that converges to a globally optimal solution by convex optimization (Supplementary Note S1.4.2 and Fig. S2).

Our formulation of network deconvolution has two underlying modeling assumptions: first that indirect flow weights can be approximated as the *product* of direct edge weights, and second, that observed edge weights are the *sum* of direct and indirect flows. When these assumptions hold, network deconvolution provides an exact closed-form solution for completely removing all indirect flow effects and inferring all direct interactions and weights exactly (Fig. 1d). We show that ND performs well even when these assumptions do not hold, by inclusion of non-linear effects through simulations when the direct edges are known (Fig. 1e and Supplementary Note S1.3) and by application to diverse real-world biological and social networks where additional properties can be independently evaluated. Our Taylor series closed-form solution assumes that all eigenvalues of the direct dependency matrix are between -1 and 1, which leads to a geometric decrease in the contributions of indirect paths of increasing lengths (Supplementary Note S1.2). This assumption can be achieved for any matrix by scaling the observed input network by a function of the magnitude of its eigenvalues (Supplementary Note S1.6).

We also provide a useful generalization of network deconvolution when the observation dependency matrix is itself noisy (Supplementary Note S1.5). Although direct dependency weights cannot be recovered exactly from the noisy observations, we show that the resulting estimates are close to true weights for moderate noise levels in the input datasets (Fig. S3). We also present two extensions of the network deconvolution algorithm (Supplementary Note S1.7) that make it scalable to very large networks: the first exploits the sparsity of eigenvalues of low rank networks, and the second parallelizes network deconvolution over potentially-overlapping subgraphs of the network (Fig. S5).

We next apply our network deconvolution approach to three settings of inferring gene regulatory networks, inferring protein structural constraints and inferring weak and strong ties in social networks..

## Application to gene regulatory networks

We first apply our network deconvolution algorithm to gene regulatory networks, which are pervasively used in molecular biology to describe regulatory relationships between transcription factors (regulators) and their target genes<sup>1</sup>. Regulatory network inference from high-throughput gene expression data<sup>1,6,32</sup>, or by integrating complementary types of datasets<sup>33–35</sup>, is a well-studied problem in computational molecular biology<sup>26,29,36,37</sup>, enabling us to benefit from available datasets and community efforts for direct method comparisons<sup>1,6</sup>. Perhaps the largest such comparison is the recently published network inference challenge part of the Dialogue on Reverse Engineering Assessment and Methods (DREAM) project<sup>5</sup>.

In the DREAM5 network inference challenge<sup>5</sup>, different methods were applied to reconstruct networks for the bacterium *E. coli* and the single-cellular eukaryote *S. cerevisiae* based on experimental datasets, and to reconstruct an *in silico* network based on simulated datasets (Supplementary Note S2.1 and Fig. S6). True positive interactions were defined as a set of experimentally validated interactions from the RegulonDB database for *E. coli*<sup>38</sup>, and a high-confidence set of interactions supported by genome-wide transcription-factor binding data (ChIP-chip) and evolutionarily conserved binding motifs for *S. cerevisiae*<sup>39</sup>. All methods were evaluated using the same four performance evaluation metrics: (a) the area under the precision-recall curve; (b) the area under the receiver operating characteristic curve; (c) a combined per-network score that utilizes both previous metrics for each individual network; and (d) an overall per-method score that summarizes the combined performance across all three networks (Methods and Supplementary Note S2.3). The DREAM5 challenge provides an ideal benchmark for evaluating ND, given the uniform benchmarks for network reconstruction used, and the participation of many of the research teams at the forefront of network inference research, with a total of 35 different prediction methods applied across a wide array of methodologies.

Given that ND is designed as a way to eliminate indirect edge weights in mutual information-based and correlation-based networks, we first applied it to the networks predicted by the top-scoring such methods, including CLR<sup>37</sup>, ARACNE<sup>29</sup> and basic mutual information (Relevance networks)<sup>40</sup>. In all cases, we found that network deconvolution substantially improved the performance of each method according to all metrics used and for all networks tested in DREAM5 (Fig. 2a). The average per-method score increased by 59%, and the per-network scores increased by 53%, 78% and >300-fold in the *in silico*, *E. coli* and *S. cerevisiae* networks respectively (the strong *S. cerevisiae* improvements are due to low scores for all methods). It is notable that ARACNE, which seeks to remove transitive edges by studying feed-forward loops directly, showed a 75% improvement by network deconvolution, indicating that these indirect effects are not always detectable at the local level but instead require a global network deconvolution approach. As information theoretic methods are among the most widely-used network inference approaches<sup>5,6</sup>, their use in combination with ND can be of great general use.

We next applied ND to other top performing inference methods that are not based on mutual information or correlation. These include ANOverence<sup>41</sup> that uses a non-parametric non-linear similarity metric between transcription factors and target genes, GENIE3<sup>23</sup> that uses regression and a tree-based ensemble method, TIGRESS<sup>42</sup> that uses a sparse regression formulation and feature selection, and Inferelator<sup>32</sup> that uses regression and variable selection based on expression data. We found that network deconvolution was effective even when applied to these methods, leading to an overall performance increase of 11% on average. The performance was increased for three of the four methods, including for the top performing method (GENIE3), which increased by 13%. As GENIE3 was the overall top-performing method, this suggests that the combination of GENIE3 and ND provides the new

top-performing method, outperforming all other 35 methods that were assessed in the DREAM5 challenge<sup>5</sup>. We also applied ND in combination with the community prediction method from DREAM5<sup>5</sup>. We found that community prediction after ND showed 22% greater performance than community prediction on the original networks, suggesting that network deconvolution maintains the complementary aspects of these networks important in community prediction approaches. We note that the community prediction approach is not the best predictor here, with or without ND, likely owing to the insufficiently diverse nature of the original networks. Overall, these results suggest that despite the ability of even the best-performing methods to recover high-quality networks, strong indirect effects remain, which can be reduced by use of ND.

We next studied how ND affects the prediction of local network connectivity patterns. We specifically focused on the ability to correctly predict feed-forward loops, that truly contain both an indirect  $A \rightarrow B \rightarrow C$  path and a feed-forward  $A \rightarrow C$  edge, and regulatory cascades, for which  $A$  and  $C$  are only connected through  $B$  (Supplementary Note S2.4). Consistent with previous studies<sup>5,43</sup>, we found that network inference methods tend to perform better on one or the other network motif, based on their approach for dealing with indirect information (Fig. 2b). For example, mutual information-based network inference (MI) is biased towards including feed-forward edges, leading to increased accuracy for feed-forward loops but many spurious transitive edges for cascades, while the Inferelator and ANOverence are biased towards excluding feed-forward edges, leading to increased accuracy for cascades but many missing feed-forward edges in feed-forward loops. Notably, the ARACNE algorithm, which seeks to directly remove transitive edges, shows a decreased performance for feed forward loops relative to MI, highlighting the difficulty of distinguishing transitive edges from true feed-forward edges. If ND can accurately identify spurious indirect edges but preserve true feed-forward edges, we should expect substantially increased accuracy for cascades, and no decrease in accuracy for feed-forward edges. Indeed, we found that deconvolved networks lead to improved prediction accuracy for true cascades for each method, thus correctly eliminating spurious  $A \rightarrow C$  edges (Fig. 2b). Importantly, the improved performance on cascades did not lead to an increased error rate on feed-forward loops, where prediction accuracy remained similar or improved in most deconvolved networks, with the exception of TIGRESS, which was also the only method where ND did not lead to an improved overall performance. Taken together, these results show that ND effectively distinguishes direct from indirect edges, improving the predictions of a wide range of gene regulatory network inference approaches.

### Application to protein structural constraints

We next applied ND to infer structural constraints between pairs of amino-acids for protein structure prediction<sup>44–46</sup>. Prior work used evolutionary information to reveal pairs of amino acid residues that are proximal in the three-dimensional protein structure. However, the pairwise evolutionary correlation matrix may contain many transitive relationships between pairs of residues<sup>7–10,17,31,47–50</sup>. For example, if two amino-acid residues both interact with an intermediate residue, but are not directly interacting with each other, they will show high mutual information owing to indirect effects. One approach to remove transitive noise is to use a probabilistic maximum entropy solution<sup>10</sup> that is specifically designed for inferring directly interacting residues<sup>15,16,30</sup>. Our aim here is to demonstrate effectiveness of using network deconvolution as a general method to infer directly interacting residues over protein contact networks.

As strong clusters of high mutual information have been shown to hinder identification of directly-interacting residues, we reasoned that network deconvolution may be able to break up these clusters and reveal directly-interacting residues, by distinguishing those correlations that can be explained by transitive relationships. Here, we build on an approach which uses

comparative genomics information of residue co-variation across evolutionarily-diverged species.

We applied network deconvolution to predict contact maps on fifteen proteins in different folding classes with sizes ranging from 50 to 260 residues<sup>15</sup>. In our input network, the nodes represent amino acid residues, and each edge between a pair of residues represents their co-variation across multiple sequence alignments spanning 2,000–72,000 sequences, quantified by their mutual information. Applying ND to a mutual information network leads to a systematic and substantial increase in the discovery rate of interacting amino-acids, based on non-adjacent amino-acid contact maps for known structures (Fig. 3a and Supplementary Figure S7). High mutual information residue pairs contain both physically-interacting residues and non-interacting residues, presumably owing to indirect interactions. Application of ND specifically reduces the scores of non-interacting pairs and enables distinguishing directly interacting ones (Fig. 3b).

We also applied ND to a weighted interaction network based on direct information<sup>15</sup>. Although using ND over direct information led to a small but consistent improvement over the top predictions especially for non-redundant interacting pairs (Supplementary Figure S7), a robust performance assessment requires comparison of predicted proteins 3D structures which is beyond the scope of this manuscript.

### Application to co-authorship collaboration relationships

We next applied our network deconvolution approach to a social network of co-authorship information<sup>51</sup> to distinguish strong and weak collaborations, that can play different key roles in social networks<sup>11,52–54</sup>. Given the recent surge of social networks like Facebook or ResearchGate, recognizing weak and strong ties is increasingly important for recommending friends or colleagues, recognizing conflicts of interest or evaluating an author's contribution to a team. Previous approaches have defined strong ties using shared indirect contacts<sup>55</sup>, edges that increase network distance upon removal or edges connecting nodes within the same module<sup>53</sup>. In co-authorship networks, strong ties have been defined by using additional information beyond network connectivity (Supplementary Note S4), including the number of co-authored papers and the number of other co-authors of these papers<sup>51,56</sup>.

We used an unweighted input network of 1,589 scientists working in the field of network science<sup>51</sup>, in which two authors are connected by an edge if they have co-authored at least one paper. We then applied our network deconvolution approach directly on the edges provided by the co-authorship network, to recognize whether network connectivity information alone is sufficient to capture additional information about strong and weak ties previously computed on the same network. Our assumption is that edges resulting from indirect paths likely correspond to weak collaborations, diluted over many other co-authors, while edges with low indirect contributions are more likely to correspond to meaningful collaborations. Application of ND to this unit-weight network led to a weighted network whose transitive closure most closely captures the input network information, and whose weights represent the inferred strength of likely direct interactions. We then ranked all co-authorship edges according to the weight assigned to each by the ND approach.

We found that the resulting edge weights indeed capture co-authorship tie strengths previously computed by summing the number of co-authored papers and down-weighting each paper by the number of additional co-authors<sup>56</sup>. We defined true strong ties based on Newman's weight 0.5 (36% of edges) that incorporates additional publication information, and our predictions based on the network deconvolution weight corresponding to the same fraction of edges (ND weight 0.64). We found that network deconvolution correctly recovered 77% of strong co-authorship ties solely by use of the network topology,

demonstrating that additional information about collaboration strength lies within network connectivity information, and that ND is very well-suited for discovering it (Fig. 4a). Beyond the binary classification of edges into strong and weak, we found a strong overall agreement between the rank obtained by the true collaboration strength and the rank provided by the ND weight (correlation coefficient  $R^2=0.76$ , Fig. 4b). The exception was a population of edges that had strong collaboration scores but weak ND weights, likely due to the number of co-authored publications that factors in the collaboration score but is not available in the ND network input. Indeed, collaborators connected by a strong edge that were incorrectly predicted by ND had on average co-authored 6-fold more papers per author than collaborators correctly predicted as weak, suggesting a very strong additional bias beyond the information provided by the topology. With the wide-spread availability of social networks and the current interest in predicting strong and weak social ties, we expect that network deconvolution will be widely useful in many social network applications beyond co-authorship.

## Discussion

Network deconvolution provides a general framework for computing direct dependencies in a network by use of observed similarities. It can recognize and remove spurious transitive edges due to indirect effects, decrease edge weights that are overestimated due to indirect relationships, and assign edge weights corresponding to direct dependencies to the remaining edges. Thereby, network deconvolution can improve the quality of a broad range of observed networks that are tainted by indirect edge weights due to transitive effects. We introduced an efficient and scalable algorithm for deconvolving an observed network based on a nonlinear filter computing the inverse of a Taylor series expansion over each eigenvalue. We demonstrated that network deconvolution is effective for gene regulatory network inference, protein contact prediction based on protein sequence alignment and inference of collaboration strength from co-authorship social networks. In each case, even though we did not use domain-specific knowledge, ND was effective illustrating the generality and wide applicability of the approach.

The problem of indirect spurious edges has been widely recognized in network inference, but characterized mostly at the local level. In particular, even top-performing network inference methods have been shown to contain many false transitive edges in cascade network motifs, and efforts to remedy this situation lead to incorrect removal of true edges in feed-forward loops<sup>5</sup>. At this local level, we have shown that network deconvolution has the ability to correctly remove spurious transitive edges in true cascade network motifs, while maintaining true feed-forward edges in feed-forward network motifs. In contrast to previous methods that make well-documented tradeoffs in sensitivity vs. specificity for these transitive edges<sup>5</sup>, network deconvolution reduces the number of false positives on indirect interactions, while maintaining true positives in feed-forward loops.

However, network deconvolution has a much broader effect than simply removing local indirect edges. In contrast to previous approaches that study local patterns of dependencies to recognize potential indirect edges, network deconvolution takes a global approach by directly inverting the transitive closure of the true network. Previous algorithms<sup>29</sup> have sought local approximations to the removal of indirect effects which have been limited to indirect paths of only limited lengths (typically of length 2), owing to the computational complexity of enumerating and evaluating all higher-order paths, and the lack of a systematic way to compute their combined effects. By exploiting eigenvector decomposition and Taylor series closed form solutions, network deconvolution provides four advantages over local approaches: (1) it leads to a much more computationally efficient solution, (2) it has the power to remove indirect effects over paths with arbitrary lengths, (3) it can remove

the combined effects of arbitrarily many indirect paths between two nodes, and (4) it eliminates the need for iterative network refinement. These advantages are due to the fact that network deconvolution is essentially a single global operation to subtract the transitive effects of all powers of an adjacency matrix, rather than testing only pair-wise relationships or small network motifs one at a time.

Moreover, we showed that network deconvolution can be applied to networks with very different properties. The networks used here were of different size, density, clustering coefficient, or network centrality, showing that network deconvolution is robust to these parameters. The input networks were also based on different properties, including mutual information and correlation that network deconvolution was designed for, but also networks based on regression, tree-based ensemble methods, feature selection approaches, and other non-linear similarity metrics. We also applied network deconvolution to both weighted and unweighted networks, and used the results both for re-weighting of edges and for edge classification, demonstrating the discrete and continuous applications of the approach. More generally, network deconvolution is not just about edge inclusion or removal, but about probabilistic weighing of individual edges to reveal direct interactions based on observed relationships across the complete network.

We believe that the network deconvolution algorithm introduced here will serve as a foundational graph theoretic tool for computing direct dependencies in many problems in network science and other fields. Although the forward problem of repeated matrix multiplication, also known as network convolution or matrix interpolation in applied fields, has been a key graph theoretical tool, the inverse problem has received relatively little attention. Matrix interpolation has been used in protein-protein interaction networks to propagate functional information through the network<sup>57</sup>, in movies and shopping applications to make recommendations for users based on previous actions<sup>58</sup>, in social networks to make friend recommendations, etc. We similarly expect network deconvolution to lead to a rich set of applications in network science, molecular and cell biology and many other fields.

## Methods

### Network deconvolution

Network deconvolution framework is outlined in Figure 1 (full description in Supplementary Note S1). A perennial challenge to inferring networks is that, observed similarity weights are the sum of both direct and indirect relationships. A direct information flow modeled by an edge in  $G_{dir}$ , can give rise to two or higher level indirect flows. Such indirect flows are captured in  $G_{indir}$ :

$$G_{indir} = G_{dir}^2 + G_{dir}^3 + \dots$$

where the power associated with each term in  $G_{indir}$  corresponds to the number of edges of indirect paths.  $G_{dir} + G_{indir}$  together capture both direct and indirect dependencies which in fact comprise the observed dependencies. Note that, the observed dependency matrix is linearly scaled so that the largest absolute eigenvalue of  $G_{dir}$  is smaller than 1. Therefore, the effects of indirect information flows decrease exponentially with the length of indirect paths (Supplementary Notes S1.2 and S1.6). Self-loops of observed dependency network are excluded by setting its diagonal components to zero.

Suppose  $G_{obs}$  represents the matrix of observed dependencies: a properly-scaled similarity matrix between variables (nodes in the network).  $G_{obs}$  can be derived by use of different pairwise similarity metrics such as correlation or mutual information, and scaled linearly based on the largest absolute eigenvalue of the un-scaled similarity matrix. The observed dependency matrix captures both direct and indirect effects; i.e.,  $G_{obs} = G_{dir} + G_{indir}$ . Note that, the indirect dependency matrix,  $G_{indir}$ , is a function of another unknown  $G_{dir}$ . The main question is how to compute  $G_{dir}$  by using the tainted observed similarities  $G_{obs}$ .

Although  $G_{indir}$  may at first appear intractable because it is an infinite sum, one may note that, similarly to Taylor series expansions, under mild conditions (Supplementary Note S1.1 and S1.2) that are generally present in the setting that we consider, we have:

$$G_{obs} = G_{dir} + G_{indir} = G_{dir}(I + G_{dir} + G_{dir}^2 + \dots) = G_{dir}(I - G_{dir})^{-1}.$$

The above observation leads to a simple closed-form expression for  $G_{dir}$  (Fig. 1b):

$$G_{dir} = G_{obs}(I + G_{obs})^{-1}.$$

For symmetric input matrices and some asymmetric ones, we show that, the observed dependency matrix  $G_{obs}$  can be decomposed to its eigenvalues and eigenvectors (Supplementary Note S1.4). Say  $U$  and  $\Lambda_{obs}$  represent the matrix of eigenvectors and a diagonal matrix of eigenvalues of matrix  $G_{obs}$ . The  $i$ -th diagonal component of the matrix  $\Lambda_{obs}$  represents the  $i$ -th eigenvalue  $\lambda_i^{obs}$  of the observed dependency matrix  $G_{obs}$ . Then, by using the eigen decomposition principle, we have  $G_{obs} = U \Lambda_{obs} U^{-1}$ .

In this framework, an optimal solution to compute direct dependencies can be computed in the following steps, which comprise the main parts of the proposed Network Deconvolution (ND) algorithm (Fig. 1c)

**Step 1 (Decomposition Step)**—Decompose the observed dependency matrix  $G_{obs}$  to its eigenvalues and eigenvectors such that  $G_{obs} = U \Lambda_{obs} U^{-1}$ .

**Step 2 (Deconvolution Step)**—Form a diagonal matrix  $\Lambda_{dir}$  whose  $i$ -th diagonal

component is  $\lambda_i^{dir} = \frac{\lambda_i^{obs}}{1 + \lambda_i^{obs}}$ . Then, the output direct dependency matrix is  $G_{dir} = U \Lambda_{dir} U^{-1}$ .

We show that this algorithm finds a globally optimal direct dependency matrix without error (Supplementary Note S1.2).

## Performance metrics for gene regulatory networks

A detailed description of gene regulatory network performance metrics is given in Supplementary Note S2.3. Network predictions were evaluated as binary classification tasks where edges were predicted to be present or absent. Then, standard performance metrics from machine learning were used: precision-recall (PR) and receiver operating characteristic (ROC) curves. Similar to DREAM5<sup>5</sup>, only the top 100,000 edge predictions were accepted. Then, AUROC and AUPR were separately transformed into  $p$ -values by simulating a null distribution for 25,000 random networks. To compute an overall score that summarizes the performance over the three networks with available gold standards (*E. coli*, *S. cerevisiae* and

*in silico*), we used the same metric as in the DREAM5 project, which is defined as the mean of the (log-transformed) network specific  $p$ -values:

$$\begin{aligned} \text{ROC}_{\text{score}} &= \frac{1}{3} \sum_{i=1}^3 -\log_{10}(p_{\text{ROC}_i}) \\ \text{PR}_{\text{score}} &= \frac{1}{3} \sum_{i=1}^3 -\log_{10}(p_{\text{PR}_i}) \\ \text{score} &= (\text{ROC}_{\text{score}} + \text{PR}_{\text{score}}) / 2 \end{aligned}$$

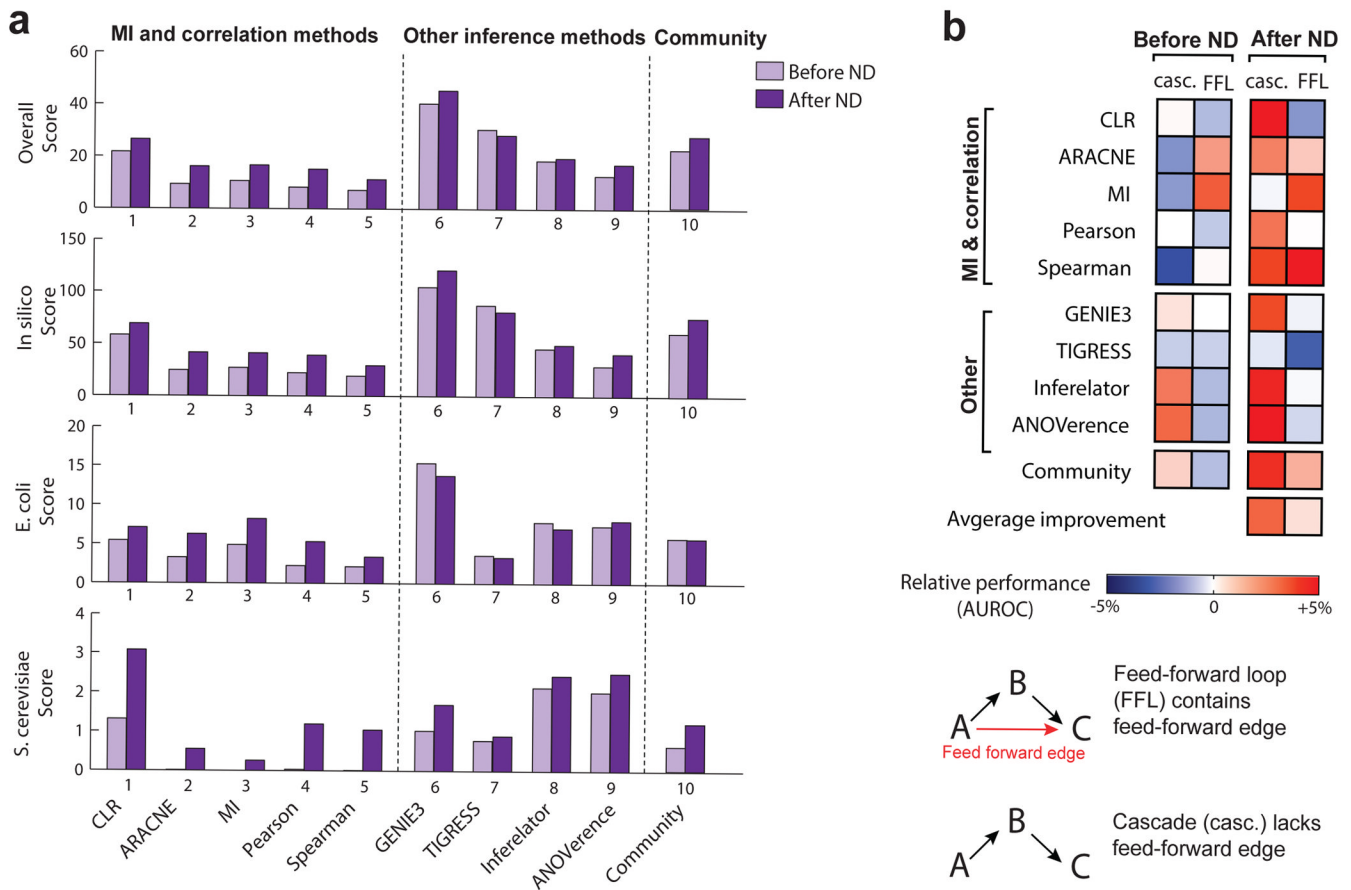

**Figure 1. Network deconvolution overview**

**a.** Direct edges in a network (solid blue arrows) can lead to indirect relationships (dashed red arrows) as a result of transitive information flow. These indirect contributions can be of length two (e.g. 1 → 2 → 3), three (e.g. 1 → 2 → 3 → 5) or higher, and can combine both direct and indirect effects (e.g. 2 → 4), and multiple indirect effects along varying paths (e.g. 2 → 3 → 5, 2 → 4 → 5). Self-loops are excluded from networks. Network deconvolution seeks to reverse the effect of transitive information flow across all indirect paths, in order to recover the true direct network (blue edges,  $G_{dir}$ ) based on the observed network (combined blue and red edges,  $G_{obs}$ ). **b.** Algebraically, the transitive closure of a network can be

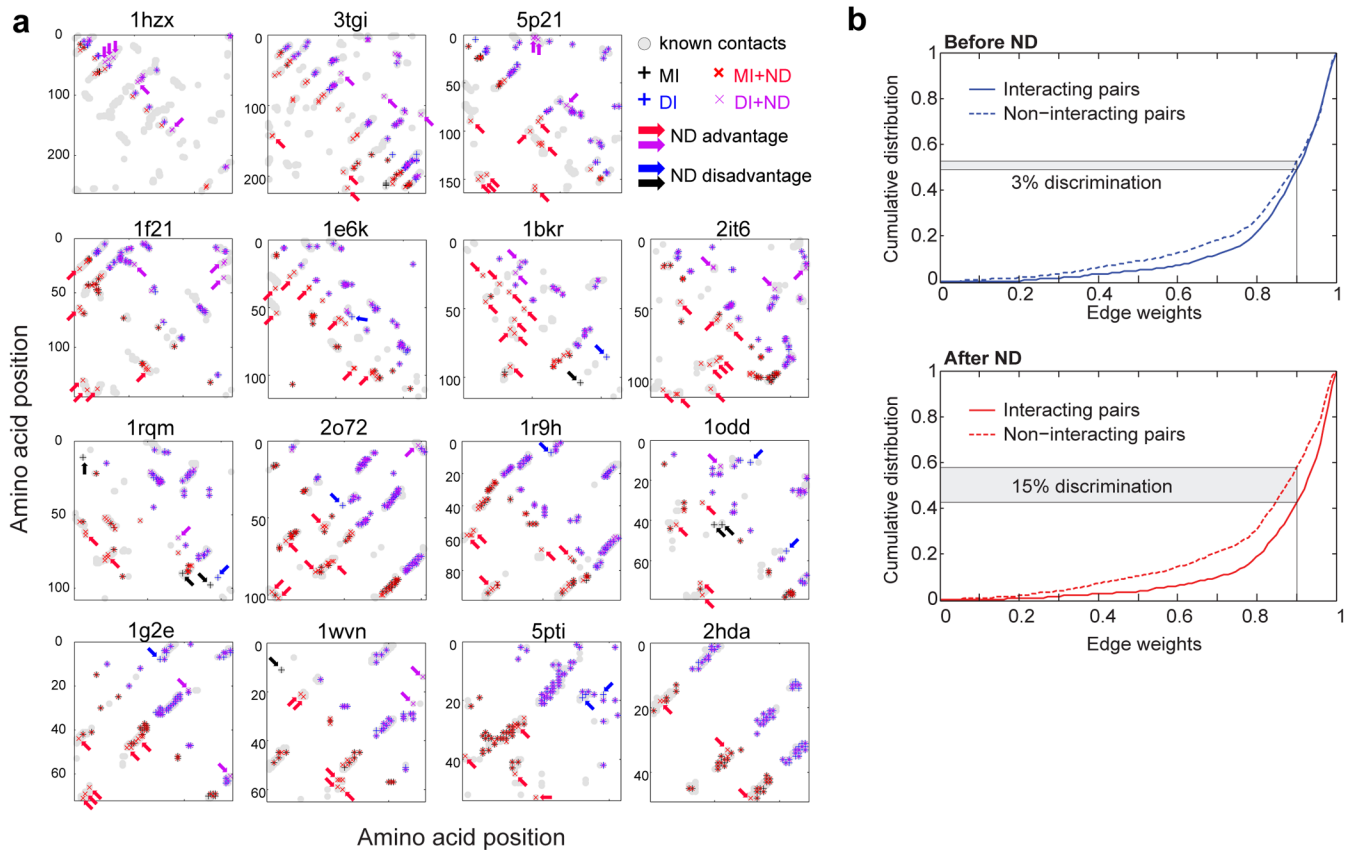

expressed as an infinite sum of the true direct network and all indirect effects along paths of increasing lengths, which can be written in a closed form as an infinite-series sum. Network deconvolution exploits this closed form to express the direct network  $G_{\text{dir}}$  as a function of the observed network  $G_{\text{obs}}$ . **c.** To efficiently compute this inverse operation, we express both the true and observed networks  $G_{\text{dir}}$  and  $G_{\text{obs}}$  by decomposition into their eigenvectors and eigenvalues, which enables each eigenvalue  $\lambda_i^{\text{dir}}$  of the original network to be expressed as a nonlinear function of a single corresponding eigenvalue  $\lambda_i^{\text{obs}}$  of the convolved observed network. **d,e.** Network deconvolution assumes that indirect flow weights can be approximated as the product of direct edge weights and that observed edge weights are the sum of direct and indirect flows. When these assumptions hold (**d**), network deconvolution removes all indirect flow effects and infers all direct interactions and weights exactly. Even when these assumptions do not hold (**e**), ND infers 87% of direct edges, showing robustness to non-linear effects.

## Figure 2. Deconvolution of gene regulatory networks

**a.** Network Deconvolution (ND) applied to the inferred networks of top-scoring methods from DREAM5 leads to consistent improvements for mutual information (MI) and correlation based methods (average performance increase 59%). ND also improves other top-scoring methods (11% on average), including the best performing method of the DREAM5 challenge (GENIE3), thus leading to a new overall highest performance. Moreover, the community network obtained by integrating network predictions from individual methods (1–9) before ND is outperformed by the community network based on deconvolved networks by ~22%.

**b.** Network motif analysis showing the relative performance of inference methods for cascades (casc.) and feed-forward loops (FFL) before and after ND. Red/blue corresponds to increased/decreased prediction accuracy of the two motif types relative to the overall performance of the method *before ND* (measured by the area under the ROC curve, AUROC; Supplementary Note S2.4). The original methods (before ND, left side) have different relative performances for cascades and FFLs, e.g., mutual information-based network inference (MI) tends to include feed-forward edges (red arrow), resulting in higher accuracy for FFLs but lower accuracy for cascades, while the opposite is true for the Inferelator and ANOverence. The deconvolved networks (after ND, right side) show significantly higher accuracy for true cascade network motifs for all methods, and moderately improved accuracy for FFLs on average, showing that ND successfully eliminates spurious indirect feed-forward edges for true cascade motifs, without sacrificing accuracy for true FFLs.

### Figure 3. Application to protein structure prediction

**a.** Applying ND to predict experimentally-determined residue contacts (gray dots) based on amino-acid sequence alignments on fifteen proteins in different folding classes with sizes ranging from 50 to 260 residues in human. We applied ND to networks derived by mutual information (MI, lower left triangles) and direct information<sup>15</sup> (DI, upper-right triangles). Arrows highlight distinct residue interactions captured by each method, highlighting the improvement over both MI and DI. **b.** Cumulative distributions of graph weights for interacting (solid lines) and non-interacting (dashed lines) amino acid pairs, for both MI (blue) and ND (red). Network deconvolution assigns higher weights to true positive edges and lower weights to false negatives, leading to 5-fold higher discrimination between true contacts and indirect mutual information for the 10% of edges with highest scores

**Figure 4. Application to co-authorship social network**

**a.** Use of network deconvolution to distinguishing strong ties (red) and weak ties (green) in the largest connected component of a co-authorship network containing 379 authors. True collaboration strengths were computed by summing the number of co-authored papers and down-weighting each paper by the number of additional co-authors. ND only had access to unweighted co-authorship edges, but exploiting transitive relationships to weigh down weak ties resulting in 77% accurate predictions (solid lines) and only 23% inaccurate predictions (dashed lines), demonstrating that this information lies within the network edges, and that ND is well-suited for discovering it. **b.** Beyond the binary classification of strong and weak ties, we found a strong correlation ( $R^2=0.76$ ) across all 2,742 edges connecting 1,589 authors, between the weights assigned by ND (y-axis) and the true collaboration strengths (x-axis) obtained using additional publication details.
