Abstract

Characterizing changes in protein-protein interactions associated with sequence variants (*e.g.* disease-associated mutations or splice forms) or following exposure to drugs, growth factors or hormones is critical to understanding how protein complexes are built, localized and regulated. Affinity purification (AP) coupled with mass spectrometry permits the analysis of protein interactions under near-physiological conditions, yet monitoring interaction changes requires the development of a robust and sensitive quantitative approach, especially for large-scale studies where cost and time are major considerations. To this end, we have coupled AP to data-independent mass spectrometric acquisition (SWATH), and implemented an automated data extraction and statistical analysis pipeline to score modulated interactions. Here, we use AP-SWATH to characterize changes in protein-protein interactions imparted by the HSP90 inhibitor NVP-AUY922 or melanoma-associated mutations in the human kinase CDK4. We show that AP-SWATH is a robust label-free approach to characterize such changes, and propose a scalable pipeline for systems biology studies.

Introduction

Protein-protein interactions (PPIs) are essential to cellular functions, and are attractive therapeutic intervention targets^{1, 2}. PPIs are also becoming increasingly recognized for their potential in contributing to disease phenotypes induced by genetic variations, including splice variants, allelic variants and point mutations³⁻⁶. Systematic assessment of the consequences of sequence variation on protein-protein interactions by yeast two hybrid (Y2H) revealed clear interaction changes associated with disease-associated mutants⁷. However, limiting PPI screening to Y2H analysis generates results that do not easily capture quantitative differences in interaction potential and work best to highlight interactions that are lost rather than *de novo* interactions that may be gained via sequence variation.

Affinity purification coupled with mass spectrometry (AP-MS) can identify interactions in near-physiological conditions, providing proper functional context to the studied protein modules⁸. While many groups have employed AP-MS to identify static interactomes, very few publications have focused on the identification of differential interactions; in all cases, these studies have employed quantitative proteomics, with or without isotopes, to discriminate between condition-specific interactions (reviewed in ^{9, 10}). Notably, in these studies, MS acquisition was performed in a data-dependent manner (DDA), where peptides to be sequenced are selected based on the relative abundance of their precursor ion signals. DDA introduces a degree of stochasticity in this process, which makes it very difficult to conclude that a peptide or protein is truly absent in a given sample, especially for lower abundance species^{11, 12}. This is especially problematic for comparative quantification¹⁰.

In recent years, a different paradigm for MS-based quantification of proteins has gained increased acceptance. Quantification using MS/MS (MS2) increases specificity and signal-to-noise ratios as compared to MS1. This is the basis behind Selected/Multiple Reaction Monitoring (S/MRM), which has been efficiently coupled to affinity purification, permitting the detailed analysis of dynamic signaling modules^{13, 14}. The utility of SRM in quantification of AP samples is highlighted by its simplicity, accuracy and sensitivity¹⁵. SRM quantification does not rely on the measured abundance of the precursor ion in MS1, decreasing the chances for missing values in the dataset. However, SRM requires a substantial investment in assay development for each peptide of interest¹⁶. Furthermore, the list of analyzed peptide species is predetermined, precluding *a posteriori* reanalysis of this type of data as new information becomes available, and the number of peptides quantified per LC-MS/MS run is limited.

The advantages of quantification at the level of MS2 may also be harnessed in another type of acquisition strategy, namely data-independent acquisition (DIA¹⁷; reviewed in ¹²). In DIA, precursor ions are fragmented independently of their signal in MS1. A type of DIA that is particularly promising for the analysis of AP samples is termed SWATH (Sequential Window Acquisition of all THEoretical spectra)¹⁸. In SWATH, the entire useful mass range is scanned in a cycle time compatible with liquid chromatography using wide mass isolation windows. All precursors in each window are fragmented, resulting in an MS2 map of all compounds. A list of peptide fragment masses (e.g. acquired by a parallel DDA experiment) is used to correlate MS2 peaks within the dataset to specific peptides allowing quantification as in SRM data. The method benefits from many of the SRM attributes, such as throughput and accuracy of quantification^{18, 19}, and possesses a dynamic range compatible with even the most complex interaction proteomics experiments (see accompanying manuscript by Collins *et al.*). Here we present a complete experimental and computational pipeline that couples affinity purification with SWATH quantification.

Results

A pipeline for quantitative interactome monitoring

SWATH utilizes a fast-scanning QqTOF mass spectrometer²⁰ to systematically fragment all ions within a given m/z range. Eluting peptide precursor ions are isolated in sequential, slightly overlapping windows of 25 amu (for 100 ms per window) and fragmented. The composite MS/MS spectra for all co-eluting/co-isolated precursors are recorded as a complete fragment ion map of the sample studied (Supplementary Fig. 1). As previously reported¹⁸, quantification of SWATH data can be accomplished by targeted data extraction using a list of fragment masses (see, e.g.¹⁸). To analyze our AP samples, each of the bait samples was purified in biological replicates using FLAG magnetic beads, and peptides were prepared by tryptic digestion. Each of the biological replicates was analyzed by SWATH. We generated reference spectral libraries for targeted extraction by analyzing at least one biological replicate for each of the groups of samples by Data-Dependent Acquisition (DDA) (Fig. 1a, Supplementary Tables 1-2; Online Methods). The DDA samples generated across a complete dataset were collectively searched using the ProteinPilot™ software, and the MS2 spectra matching peptide sequences were used to create a reference list of fragment masses for high confidence hits (see Methods for details). This library was used to interrogate each SWATH run, enabling peptide quantification across all SWATH samples, even if a given peptide was not identified in the matched DDA run. The PeakView® SWATH Processing Micro App was used to identify the correct peak group in a set of fragment chromatograms with peaks at the same retention time (Supplementary Fig. 1c, 1e). Peak group scoring was similar to that described previously¹⁸ and used a combination of chromatographic correlation (related peaks should have the same shape, width and retention time), mass error and additional predicted fragments ions; a decoy strategy was used to select most likely peak groups for export and quantitative analysis (Online Methods; Supplementary Fig. 1d).

Because of the amount of data generated by the SWATH approach and the goal of minimizing manual processing, we developed a statistical method to calculate Fold Change values and evaluate the confidence of these calculations. Normalization was performed by calculating the most likely ratio between pairs of samples (see Methods), which generates a scaling factor and metrics about the similarity of the samples and the quality of the measurements. Normalization is applied stepwise, first to the samples that are expected to be most similar (replicates) and then to the different sample groups (Figure 1b, 1c). The quality metrics are combined with signal metrics, such as signal to noise ratio, and used as weights in calculating Fold Change values using a strategy first described for the analysis of SRM data for AP samples¹³, and referred to here as “Fold Change calculation”. With this approach poor quality measurements are down-weighted, removing the need to manually reject samples or measurements or to perform outlier rejection. Essentially, this statistical tool evaluates the quality of each measurement using weights based on reproducibility (results for each dataset used here are in Supplementary Fig. 2-7) and performs Fold Change calculation of pairwise samples at the level of transitions, peptides, and proteins (see Online Methods).

To determine whether the automated method yielded reproducible data, the variance for all quantifiable peptides (with peak group FDR = 1%; Supplementary Fig. 8) was measured on a dataset consisting of cyclin dependent kinase CDK4 AP samples derived from three biological replicates and analyzed in parallel by DDA and by SWATH (additionally, three technical replicates were acquired for each biological replicate for SWATH). SWATH data extraction led to quantification of 79% peptides within 20% CV (Fig. 2a), resulting in 87% of proteins with < 20% CV. These results were compared to MS1 area measurements extracted using ProteinPilot software from the DDA data of the same replicates and used to

determine both the level of stochasticity and variance in the measurement between samples. 5089 peptides were identified in any of the 3 DDA runs with an ID confidence > 99%, but only 2741 were common to all three DDA runs with an ID confidence > 99% in at least one of the replicates. These values highlight the issues of stochasticity associated with DDA data. For comparison with the SWATH results, calculation of variance was performed only on the 1320 high confidence peptides identified in all DDA runs and with < 1% peak group FDR in the SWATH data. As shown in Fig. 2b, SWATH had a higher proportion (82.1% versus 74.5%) of peptides detected with CV < 20% and also a smaller variance at the protein level. More importantly, however, SWATH had the same reproducibility for extraction of peptides targeted across all samples. From these studies, we conclude that our extraction and normalization pipeline for SWATH data is reliable (also see Online Methods for additional benchmarking measures), and we next benchmarked it on AP samples.

To test whether the automated pipeline could reproduce known interactions in complex AP samples, we tested it for measuring interactions for well characterized baits, namely EIF4A2 and MEPCE, which we compared to a negative control (Green Fluorescent Protein fused to a 3XFLAG tag). Here and throughout the manuscript, all proteins were stably expressed in the Flp-In T-REx system, enabling recombinant protein expression to be driven in a tetracycline-inducible manner from a single locus. N-terminal 3XFLAG tags permits purification on FLAG M2 magnetic beads, followed by on-bead tryptic digestion as previously described²¹. The resulting peptides were analyzed by DDA and SWATH in triplicates. Following analysis by our automated pipeline, we observed that known interaction partners of EIF4A2 and MEPCE showed large (> 2) fold change over the GFP control (Fig. 2c; Supplementary Figs 9-11). In fact, the relative Fold Change values detected for EIF4A2 (a component of the trimeric eIF4F complex) mirrored the known assembly of the pre-initiation machinery in human cells²². The highest Fold Change values were detected for the bait, followed by PDCD4 (a known negative regulator of EIF4A2 which binds to the bait directly²³) and the other components of eIF4F and the eIF3 complex (which are tethered to EIF4A2 via direct association to eIF4G proteins). Next on the enrichment list were many of the components of the 40S ribosomal subunit, which is recruited to EIF4A2 via the eIF3 complex; very few of the 60S ribosomal subunits were detected confidently with > 2-fold over the GFP control, consistent with the fact that this subunit only assembles onto the 48S pre-initiation complex when translation is poised. Similarly, MEPCE, the methylphosphate capping enzyme for 7SK RNAs, associated most strongly with components of the 7SK small nuclear ribonucleoprotein complex²⁴, followed by splicing components and several components of the 60S ribosomal subunit which were in this case enriched in preference to the 40S ribosomal components. In summary, after scoring based on the comparison to negative control samples the AP-SWATH pipeline is robust, reproducible and amenable to interactome mapping.

AP-SWATH rapidly identifies differential interactomes

We were interested here not only in scoring protein interactions over a negative control, but importantly to systematically monitor interactome changes in pairs of samples (either sequence variants, or drug-treated samples; Fig. 3a). We elected to study a well-described series of sequence variants for the cyclin-dependent kinase CDK4 that have been identified in melanoma patients^{25, 26}. Structurally, mutation at Arg24 precludes association of CDK4 with a family of polypeptide inhibitors, the INK proteins (p15INK, p16INK, p18INK and p19INK²⁷ see Supplementary Table 1), resulting in derepressed CDK4 activity and accelerated cellular proliferation^{7, 28}. We first demonstrated that the sequence variants behaved as expected, by performing AP-western with antibodies directed against known endogenous partners. All recombinant proteins were expressed at similar levels to each other and to the endogenous CDK4 (Fig. 3b). As expected, CDK4 wild-type, but not the two

mutants (R24C and R24H) interacted with p18INK/CDKN2C (Fig. 3b). These samples – and a negative control – were chosen to explore quantification by the AP-SWATH method.

Principal component analysis of the data from the four tested sample pairs revealed clear separation of the negative controls from any of the baits (Fig. 4a). 17 proteins were enriched at least two-fold in one of the three CDK4 baits: these were deemed CDK4 interactors (Fig. 4b; Supplementary Figs 12-14). To assess how these interactors were associating with either of the two mutants in relation to the WT protein (clearly separated by PCA analysis; Fig. 4a), we implemented a stringent two-step filtering approach. Only CDK4 interactors (as per Fig. 4b) were considered in an additional test to assess confidence of a change (up or down in this case; we set an arbitrary threshold at 2-fold; Fig. 4c). When using the pipeline described above to characterize interactions for the CDK4 proteins, we observed a number of differentially regulated interactions between the WT and the two mutant proteins (R24C and R24H). In contrast, the two mutants shared most interactions (Fig. 4d; Supplementary Fig. 15). As expected, both mutants largely lost interactions with members of the INK family of CDK inhibitors (5.7 to 9.8 fold reduction; Fig. 4d and Supplementary Figs 15-17; see Online Methods for the description of the criteria for inclusion). However, we also noticed a pronounced increase in the association of HSP90 proteins (*HSP90AA1* and *HSP90AB1*; 3.0 fold) and the CDC37 co-chaperone (3.9 fold) with the two mutant proteins. In addition, the immunophilin FKBP51 (gene *FKBP4*) and to a lesser extent HSP70 (gene *HSPA8*) were also significantly enriched in the mutants. To further cross-validate these results, we performed an additional series of CDK4 affinity purification coupled with iTRAQ labeling (Fig. 4d) and extracted abundance ratios for the 10 proteins modulated in the R24 mutants as compared to the WT. The iTRAQ measurements revealed modulation consistent with SWATH for these 10 proteins (Fig. 4d), though the variance associated with iTRAQ measurements was considerably higher (Supplementary Fig. 18), at least in part due to stochasticity between independent iTRAQ runs. The regulated interactions with CDC37 and HSP90 were validated by AP-western analysis, confirming the trends observed by AP-SWATH (Fig. 4e). Taken together, this indicated a higher propensity of the mutant proteins to interact with HSP90 and suggested that the enriched interactors may be recruited to CDK4 via interactions with HSP90 core components. These effects were however not observed to the same extent with two other CDK4 mutants for which interaction with the INK proteins is not modulated (N41S and S52N; Supplementary Figs 19-22), suggesting some degree of specificity in the recruitment of HSP90 to CDK4 mutants at Arg24. In summary, the AP-SWATH method enabled confirmation of known regulated interactions and quantification of the changes, and permitted the discovery of new modulated interactions.

AP-SWATH can identify drug-regulated interactions

While increased interaction between CDK4 mutants and HSP90 has never been reported, mutations in several other kinases (including EGFR and BRAF) increase their interaction with CDC37 and HSP90^{29, 30}. This was recapitulated here using a LUMIER approach (as in ³¹; Fig. 5a; Supplementary Fig. 23). A model of addiction to HSP90 has been proposed where mutant kinases become dependent on CDC37-HSP90 folding for stability and activity³², offering a rationale for the use of HSP90 inhibitors that prevent the recruitment of client proteins as a therapeutic avenue. Using AP-SWATH we thus assessed the consequences on recruitment of CDC37 and HSP90 to the kinase constructs following treatment with NVP-AUY922 (a potent HSP90 inhibitor currently undergoing clinical trial³³). We also reasoned that proteins that were displaced at the same time as CDC37 and HSP90 may be dependent on the interaction with the core HSP90 network for their interactions.

As expected, treatment of the cells expressing CDK4 WT with the HSP90 inhibitor resulted in marked dissociation of CDC37 and HSP90 (Fig. 5b, c; Supplementary Fig. 24-27). Many of the proteins that showed increased association with the mutant proteins as compared to WT were also affected in their interactions with the NVP-AUY922 treatment, indicating that they are likely mediated by the CDC37/HSP90 bridge. Some other partners however, including the chaperone HSP70 (genes *HSPA1A* and *HSPA8*) and some of its cofactors (HOP (STIP1) and HIP (ST13))³⁴, interacted more strongly with CDK4 WT in the presence of the inhibitor, suggesting that not only are they not recruited via CDC37/HSP90 but that they may compete with them for binding (Fig. 5c). Importantly, and in contrast to the report that other mutant kinases show increased sensitivity for HSP90 inhibitors^{29, 30, 35}, we found that association of CDC37, HSP90 and FKBP4 to the mutant kinases was less affected than that to the WT following inhibitor treatment (Fig. 5c). Since the mutants also bound significantly more to these proteins in the absence of treatment (Fig. 4), this results in a much larger net binding in the presence of the inhibitor. Similarly, HSP90 almost completely dissociated from the WT CDK4 upon NVP-AUY922 treatment, whereas mutant CDK4s still associated with significant amounts of the chaperone (Fig. 5d-e). This effect was further explored by performing time-course and dose-dependence analysis of the dissociation of the interactions. In all cases, association of the mutants with HSP90 and CDC37 was preserved as compared to the WT kinase, with longer treatment or higher dosages required for the dissociation of the CDK4 R24 mutants (Fig. 5f, g; Supplementary Fig. 28). Taken together, these results indicate that tumors driven by CDK4 oncogenic kinases may not benefit from treatment with HSP90 inhibitors, or may require higher dosages to obtain the desired therapeutic results. Furthermore, our experiments set the stage for analyzing other drug-regulated interactions, including for other kinase oncogenic variants.

Discussion

Here we report the development of an efficient pipeline to quantitatively study changes in interactomes in an unbiased and reproducible manner. Key aspects of the method are an unbiased data independent acquisition method, SWATH, and the use of weighted statistics to determine changes and associated confidence values. The latter is critical since it allows automatic analysis of the large amounts of data that can be generated in these experiments.

We have also shown that AP-SWATH is able to identify true interaction partners by scoring against negative control samples, and to rapidly identify interaction changes for disease-associated mutations and or pharmacological treatment. As detailed in Supplementary Figs 29-32, the method is generally applicable, and we have implemented it to analyze the consequences on the interactome of alternative splicing, this time using three splice variants for another kinase, GRK6³¹ (Supplementary discussion). In all the cases we analyzed in more detail, the changes could be validated by AP-western analysis or iTRAQ quantitation.

As for all targeting methods, the key for SWATH quantification is the generation of a spectral library. This can be provided from publicly-available resources (as in ¹⁸), but can also be built for a particular set of proteins of interest. Here we generated a spectral library from DDA data collected from the analysis of samples in each experimental set. We also note that samples could – for example – be pooled for the DDA identification run, and libraries could be built (as in ¹⁸) for extracting the quantitative information. As there are a number of efforts to further understand the limits of DIA and SWATH and to evaluate ways to build libraries, it is likely that new ways to analyze the data will become available. In fact, this is a key strength of DIA: the data provides a permanent record of the whole sample, enabling future reanalysis. In combination with proper data annotation (e.g. using LIMS such as ProHits³⁶), and deposition in public repositories (as we have done here with

MassIVE), this should provide an important source of information for computational and cancer biologists alike.

METHODS

Methods and any associated references are available in the online version of the paper.

ONLINE METHODS

Generation of stable cell lines and drug treatment

The vector pDEST-5'Triple-FLAG-pcDNA5-FRT-TO was constructed from the pcDNA5-FRT-FLAG vector³⁸ and pMX-pie-pDEST-3X-FLAG³⁹ by first preparing a HindIII/XhoI cassette from pMX-pie-pDEST-3X-FLAG by PCR using the following oligos: 5' ccttggAAGCTTCCACCATGGACTACAAAGACCATGACGG and 3' ggacttCTCGAGtcagACCACTTTGTACAAGAAAGCTGAAC. This cassette was then subcloned into the pcDNA5-FRT-FLAG vector (previously digested with HindIII/XhoI). Entry clones of wild-type and cancer-derived allelic series for the cyclin dependent kinase CDK4 (c70t, g71a, a122g and g155a; all expressed in nucleotide base pair changes, resulting in the expression of mutants R24C, R24H, N41S and S52N, respectively) were previously described⁷. Three splice variants of the GPCR-coupled receptor kinase GRK6 (variants A, B and C that differ only in their C-terminal extension; Supplementary Fig. 29a) were as previously reported³¹. Each entry clone was shuffled into the destination vector pDEST-5'Triple-FLAG-pcDNA5-FRT-TO through homologous recombination using LR clonase II (Gateway system; Invitrogen). The resulting vectors were co-transfected with the pOG44 recombinase in Flp-In T-REx HEK 293 (Invitrogen, grown in DMEM supplemented with 5% FBS, 5% calf serum, 100 U/mL penicillin/streptomycin) using Lipofectamine (Invitrogen) as per supplier instructions. pcDNA5-FLAG-MEPCE and pcDNA-FLAG-EIF4A2 were as previously described³⁸. Cells stably expressing the constructs were selected in 200ug/mL hygromycin for approximately 2 weeks at which point cells colonies were pooled and expanded in 150mm plates. Upon reaching approximately 70% confluence, tetracycline was added to a final concentration of 200 ng/mL to cell media for 24 hours, inducing the expression of the recombinant tagged protein. For experiments involving HSP90 inhibition, the HSP90 inhibitor NVP-AUY922³³ (20mM stock in DMSO) was added for the indicated times and inhibitor concentrations to cells previously induced with tetracycline for 24 hours.

Affinity purification for mass spectrometry and validation by immunoblotting

Affinity purification was performed as previously described²¹ with minor modifications. Briefly, cells expressing FLAG-tagged proteins were washed with 10mL of PBS before being scraped in PBS using a rubber spatula. Cells from two 150mm plates were pelleted by centrifugation, the supernatant removed, frozen on dry ice and kept frozen at -80°C until ready to be used. Cells were lysed by resuspension in 1:4 (pellet weight/volume) ratio of lysis buffer (50mM HEPES-KOH (pH 8.0), 100mM KCl, 2mM EDTA, 0.1% NP40, 10% glycerol, 1mM PMSF, 1mM DTT and protease inhibitor cocktail (Sigma-Aldrich; P8340; 1:500)) followed by two freeze/thaw cycles. The resulting cell extract was then clarified by centrifugation at 20 800 rfc for 20 min (4°C) before transferring the supernatant to a fresh tube. Affinity purifications were performed by incubating the cleared lysate with 30uL of pre-washed magnetic M2 anti-FLAG beads (Sigma-Aldrich) for 2 hours at 4°C on a nutator. Two washes with 1mL of lysis buffer were then performed followed by an additional wash with 1mL of 20mM Tris-HCl pH8 2mM CaCl_2 . For mass spectrometry analysis, 7.5uL of 20mM Tris-HCl pH8 containing 750ng of trypsin (Sigma-Aldrich) was added to the washed beads and incubated at 37°C for approximately 15 hours. The next morning, the tubes were

quickly centrifuged, the beads magnetized and the partially digested sample transferred to a fresh tube before addition of an extra 2.5 μ L of 20mM Tris-HCl pH8 containing 250ng of trypsin. The samples were incubated for 3 hours at 37°C before addition of 1 μ L of 50% formic acid. The samples were stored at -80°C until analysis. For Western blot analysis, the beads were resuspended in 2X Laemmli sample buffer, boiled for 5 minutes and the samples transferred to fresh tubes. Proteins were separated by SDS-PAGE, and transferred onto nitrocellulose membranes. For CDK4, the membranes were blocked in TBS containing 5 mg/mL non-fat milk and 1% Tween 20 for 1 hour at room temperature. Blots were treated with primary and secondary antibodies as described in Supplementary Table 3: detection was performed by chemiluminescence detection with the LumiGLO reagent (Cell Signaling Technology; #7003; 1:20) on film. For GRK6, the membranes were blocked in 5% non-fat milk for 30 minutes at room temperature, then treated with primary antibodies overnight, followed by incubation for 1.5 hours with IRDye® 800CW anti-mouse and IRDye® 680 anti-rabbit secondary antibodies (shown in Supplementary Table 3). The GRK6 membranes were then visualized by direct fluorescence scanning with a Li-Cor Odyssey Imager. HSP90 bands were quantified with Li-Cor Odyssey software.

LUMIER analysis

LUMIER analysis¹ was performed essentially as described in³¹. Briefly, wild type kinases and indicated mutants C-terminally tagged with 3X FLAG and V5 tags were transiently transfected in a 96 well format into 293T cells stably expressing Renilla luciferase-tagged HSP90beta (*HSP90AB*). After passive lysis (in 50 mM HEPES-KOH pH 7.9, 150 mM NaCl, 20 mM Na₂MoO₄, 2 mM EDTA, 5% glycerol, 0.5% Triton X-100, supplemented with protease and phosphatase inhibitors), the lysate was transferred into 384 well plates precoated with anti-FLAG M2 (Sigma-Aldrich) and incubated for 3 hours, followed by extensive washing and reaction with Gaussia FLEX luciferase kit (New England Biolabs). Subsequently, the levels of the FLAG-tagged bait were detected by ELISA using HRP-conjugated anti-FLAG antibody. Data analysis was performed as described in³¹.

Description of the datasets used here

This manuscript contains several datasets, organized in groups as detailed in Supplementary Table 2. For Fig. 1 and 2a and b, the CDK4 WT runs from a set containing 9 SWATH replicates (3 biological \times 3 technical) and 3 DDA replicates (3 biological) was employed (group 5 in the Supplementary Table). For Fig. 2c, the dataset consisted of three biological replicates of each of the following: MEPCE, EIF4A2 and a GFP negative control (group 6). Fig. 4a and b employed 2 biological replicates each of DMSO-treated CDK4 WT, R24C, R24H and an empty vector negative control (partial selection from group 3). Fig. 4d (left) employed three biological replicates for the CDK4 WT, R24C and R24H mutants from group 1 while the right panel was from the iTRAQ dataset in group 7. Fig. 5 used the entire HSP90 inhibitor dataset (group 3). Datasets groups 2 and 4 were used for Supplementary Figures.

iTRAQ labeling

For validation of SWATH-MS results, an extra set of triplicate purifications of CDK4 samples were processed as described above except that Hepes buffer was substituted for Tris buffer during trypsin digestion, and samples were not acidified following tryptic digestion. Rather, the peptides were dried in a speedvac without heat and subsequently resuspended in 5 μ L of iTRAQ dissolution buffer (as per the manufacturer, AB-SCIEX, protocol). 20 μ L of the appropriate iTRAQ reagent (from a stock solution of 50 μ L in isopropanol) was added to each sample. Samples were labeled as follow: 3XFLAG-GFP control (115), 3XFLAG CDK4 WT (116), 3XFLAG-CDK4 R24C (118) and 3XFLAG-CDK4 R24H (119). After

completion of the labeling reaction (2 hours at room temperature), equal volumes of samples from individual biological replicates were mixed and evaporated to dryness in a speedvac. The dry peptides were resolubilized in 5% formic acid solution in water and one eighth of the labeled peptides was used per MS analysis. This corresponded to loading twice as much peptides (in relation to the starting material) on the column as in the SWATH experiments.

Mass spectrometry data acquisition

Samples were analyzed on an AB SCIEX 5600 TripleTOF in two phases: data dependent acquisition (DDA) was followed by SWATH acquisition on the same sample, using the same gradient conditions and the same amounts of sample (in most cases; detailed in Supplementary Table 2, DDA acquisition was performed on a single biological replicate, except for datasets 5 and 6 for which three DDA runs per bait were generated). For DDA, a quarter of the volume of the digested sample was analyzed on a 5600 TripleTOF, using a Nanoflex cHiPLC system at 200 nL/min (Eksigent ChromXP C18 3 μm \times 75 μm \times 15 cm column chip) or a home-packed emitter column (Dr. Maish Reprisil C18 3 μm \times 75 μm \times 10 cm) as indicated in Supplementary Table 2. Buffer A was 0.1% formic acid in water; buffer B was 0.1% formic acid in ACN. The HPLC delivered an acetonitrile gradient over 120 min (2-35% buffer B over 85 min, 40-60% buffer B over 5 min, 60-90% buffer B over 5 min, hold buffer B at 90% 8 min, and return to 2% B at 105min). The DDA parameters for acquisition on the TripleTOF 5600 were 1 MS scan (250ms; mass range 400-1250) followed by a) up to 50 MS/MS scans (50ms each) b) up to 20 MS/MS scans (100ms each) or c) up to 10 MS/MS scans (100ms each) as indicated in Supplementary Table 2. Candidate ions between 2-5 charge state and above a minimum threshold of 200 counts per second were isolated using a window of 0.7 amu. Previous candidate ions were dynamically excluded for 20 sec with a 50 mDa window. The SWATH setup was essentially as in Gillet et al.¹⁸, using the same chromatographic conditions as the DDA run described above, a 50 ms MS1 scan, followed by 32 \times 25 amu isolation windows covering the mass range of 400 to 1250 amu (cycle time of 3.25 sec); an overlap of 1 Da between SWATH was preselected. The collision energy for each window was set independently as defined by $CE = 0.06 * m/z + 4$, where m/z is the center of the each window, with a spread of 15eV performed linearly across the accumulation time. For the GRK6 experiments, the retention times were realigned based on landmark peptides to correct for the different chromatographic systems employed in this experimental set. The iTRAQ samples were acquired by DDA as described above (with the iTRAQ CE option applied), using a packed tip emitter system with direct injection, and up to 20 MS/MS scans were performed in each cycle.

Data Dependent Acquisition processing for targeted extraction

Data generated by DDA was searched against the human complement of the Uniprot release 8.8 database containing 40476 sequences using ProteinPilot™ AB SCIEX Beta 4.1.46, revision 460. Searches were performed using ProteinPilot's standard "rapid search" parameter space that includes common modifications as part of the search. The search is undertaken using the Paragon search engine (v 4.0.0.0). The specific nature of this search engine and its mode of operation are described elsewhere⁴⁰. Raw data for each experimental set were searched in a single batch (the description of the files is in Supplementary Table 2) to create a results file that was subsequently used for library generation.

Library generation

For each set of experiments (defined as per Supplementary Table 2), a specific library of precursor masses and fragment ions was created and used for subsequent SWATH processing. ProteinPilot result files were processed to extract matched peptide IDs and the matched ions from the original input spectra. The matched spectra were filtered to produce a list of parent masses and fragment masses and intensities to be used for SWATH processing

Filtering removed peptide redundancy and identified the optimal spectrum for each peptide according to the following scheme: 1) Spectra were grouped based on unique peptide identification; 2) The grouped spectra were ranked based on identification confidence in ProteinPilot; 3) The highest confidence identification closest to the LC parent ion peak apex was selected (The chromatographic peak apex is estimated by ProteinPilot and is exported as the intensity of the peak); 4) The highest ranked spectra were then reinterpreted and y and b-ions identified; 5) A library entry was made from the y and b-ions for each top ranked unique peptide spectrum. No attempt was made to generate a consensus spectrum from all identifications of each peptide. The data within this library contained modified forms as well as peptides which were shared between different protein isoforms.

SWATH data file processing

Prior to data processing, peptides were selected automatically from the library using the following decision tree: 1) The extracted results from the ProteinPilot results file contains all identified unique peptides for a specific targeted protein. These unique peptides were ranked by the intensity of the MS1 precursor ion from the DDA analysis as estimated by the ProteinPilot software; 2) Peptides which contained modifications and or were shared between different protein entries / isoforms were excluded from selection; 3) Peptides which were represented by multiple charge states in the list were collapsed to charge state which had the most intense precursor ion in the DDA data. Up to 15 peptides were chosen per protein and SWATH quantitation was attempted for all proteins in library files that were identified below 1% FDR from Protein Pilot searches.

Target fragment ions, up to a number specified by the user and typically 4 or 5, were automatically selected as follows: 1) Fragment ions for a selected peptide were ranked based on ion intensity; 2) Ions higher in m/z than the y_4 fragment ion for each selected peptide were ranked highest; 3) Ions within the SWATH isolation window were excluded from selection; 4) If insufficient target ions were found, ions lower than y_4 but outside of the SWATH window were chosen; 5) If there were still insufficient ions then fragment ions from within the SWATH window region were chosen. Avoiding ions within the SWATH window as much as possible decreases potential interferences from unfragmented precursor ions.

The specifics of the scoring for the different peak groups will be described elsewhere (R.A. and S.T, unpublished). In essence: 1) The fragment ions for each peptide were used to generate extracted ion chromatograms (XIC) from the SWATH experiment which contained the parent m/z ; 2) Peaks identified in the different XICs were aligned by the peak apex retention time and peaks which aligned across the different XICs were marked as potential candidate peak groups; 3) For each candidate peak group on list, the overlap of the different XIC peaks was evaluated, since related fragment ions should have the same peak width, and those which did not have well correlated peak widths were removed from the candidate list. Overlap was assessed by using the half-height width of the most intense fragment peak to define a time window and verifying that the apex value of the other fragments was within the window; 4) All the remaining peak groups were scored based on the closeness to the expected retention time for the eluting component determined from the DDA data acquired using the same chromatographic system; 5) The MS/MS spectra for the peak apex of each of the remaining peak group candidates were extracted; 6) The extracted spectra were scored based on the isotopic state of the individual ions extracted in the MS/MS spectra. Those peak groups which contained measurements extracted from ^{13}C isotopes were scored lower. 7) The MS/MS spectra were also scored based on the mass accuracy (both absolute and median accuracy) of the extracted peaks. 6) The individual peak group scores were a linear combination of all sub-scores and the peak group with the best score was taken forward.

Determination of a robust peak extraction cutoff

To select the peak group confidence threshold for automated extraction, a method based on mProphet⁴¹ was used to determine the false detection of peak groups. In essence, each peptide had both a forward and a reverse (decoy) sequence extracted and the decoy sequence scores were used to generate a median score value for the retention time region of each forward sequence. This median score was used to normalize the score values and generate a recomputed score that was ranked. As this ranked score list contains both forward and reverse sequences, standard methods for determining false positive results can be used. Here, we used data from the CDK4 WT dataset (group 5) to evaluate the impact of varying FDR threshold selection on the CV values and the final Fold Change calculations. As shown in Supplementary Figure 8a, the % peptides with CV values $\geq 20\%$ were strongly impacted by reducing the FDR stringency for peak extraction, consistent with the fact that FDR thresholding properly acts to reduce noise. Surprisingly, however, initial FDR selection had only a minimal impact on the final results of the Fold Change calculations (see below for Methods), suggesting that robustness is built into the normalization process that weights down the “bad” fragments/peptides (Supplementary Figure 8c). Despite this robustness (the final list of the proteins passing the Fold Change confidence thresholds in this study was virtually unaffected by extracting at 1% FDR or 10% FDR), for some proteins there was a clear negative effect on the confidence scores associated with the 10% FDR extraction (Supplementary Figure 8d). Therefore, we elected to use a consistent 1% extraction FDR threshold for all the analyses performed in the main text.

Extraction of MS1 and comparative CV analyses

MS1 intensities for identified peptides were extracted directly from the ProteinPilot results by exporting the ProteinPilot group files as a peptide summary table that includes the expected precursor intensity. DDA peptides were filtered as follows: 1) the peptides should be in common to all 3 DDA runs (otherwise, the missing value(s) drastically increases the variance); 2) the peptides should have been identified with ID confidence $\geq 99\%$ in at least one of the three runs; 3) all peptides, including modified peptides, are considered; 4) each charge state is considered as a separate instance for quantification; 5) instances of the same peptide (with same charge) are considered the same peptides if they are within ± 5 min retention time window. This set of criteria led to 2741 common peptides, including different charge state and modifications.

To best compare the MS1-DDA variance to that of SWATH, we used a subset of these peptides that were deemed most reproducible (unmodified and present in only one protein) and also detected in the SWATH analysis of the most similar samples, i.e. the DDA run and the first SWATH analysis for each replicate. The SWATH data was restricted to those peptides which had a FDR $\leq 1\%$ in at least 2 samples (note that we are only attempting to quantify the top 400 proteins in this analysis) and this list was merged with the DDA peptides to identify common peptides and remove modified peptides. The resulting list contains 1320 common peptides which were used to evaluate the CV values for the SWATH and the DDA-MS1 measurements.

iTRAQ data analysis

iTRAQ data was analyzed using ProteinPilot 4.2, and the default ProGroup algorithm iTRAQ processing parameters were used. After a rapid search against Uniprot protein iTRAQ ratios were exported and standard deviations calculated across the replicate data sets. To generate the Supplementary Fig. 18, quantitative information for proteins used in the SWATH measurements were extracted, alongside their standard deviation.

Determination of signal quality metrics

A signal quality value was determined for all raw data extracted. For the purpose of this study the area of the peak was used as surrogate value for the signal-to-noise. The values for each transition were normalized to a scale of 0 to 1.0 where a value of 1.0 corresponded to an intensity of greater than $10e^5$. A sigmoidal distribution was used and the inflection point of the curve was set to a value of $10e^4$. The signal quality metric is used during the fold change determination of the peptides and proteins.

Normalization of peak area data

In a previous study¹³ which used SRM to monitor the changes in the GRB2 interactome induced by stimulation or drug treatment, we normalized all data to the expression of the GRB2 bait itself. This was possible as a single cell line was used for all studies and GRB2 levels were invariant across all conditions. Here, by contrast, we profiled the interactions established by bait proteins expressed in independent cell lines. Though a major strength of the expression system that we used is that the different alleles are expressed at a *similar* level, there are small variations in expression levels that preclude normalization to the bait level (when we did this analysis, proteins that non-specifically interacted with the affinity matrix tended to be identified as varying). We and others have previously realized that many of the proteins detected in AP-MS are interacting non-specifically with the affinity matrix, but that these interactions were reproducibly detected, both qualitatively and quantitatively³⁷. With this knowledge, we therefore selected to use a normalization method that is independent of the bait expression. As defined in¹³, the identification of features for the normalization of data is critical. In this study we used features which had intensity greater than 3000 (peak area) for normalization by a method similar to⁴² but modified since mass spectrometry intensity data is linearly dependent on the amount of material present.

The same normalization scheme was used for each experiment set. The procedure starts by examining the measurement ratios in biological replicates as follows: 1) The ratio between the measurements for each feature in each pair of replicates is determined; 2) The ratios are represented as a histogram and the delta of the most likely ratio to the zero point is taken for each sample comparison (Fig. 1b). These values represent the sample differences and are used for normalization of the data as described below; 3) The width of the ratio histogram is determined and is used as an indication of pairwise sample similarity. Here a narrow histogram will represent a good similarity between the different samples; 4) Measurement reproducibility is also determined from the histogram as the distance of the feature ratio to the peak apex of the histogram. Fig. 1c, top panel, shows the ratio histograms for all samples compared to one WT sample prior to normalization.

The first stage of normalization adjusts the values for a set of replicates (here, for example, biological replicates for the CDK4 WT samples are adjusted separately from the CDK4 R24C or R24H) since these values should be most similar. For each set, the best sample, as measured by overall reproducibility, is determined and the values for all other samples are adjusted using the appropriate apex ratio. The result of this intermediate normalization step is represented by the middle panel in Fig. 1c, which shows the resulting ratio histograms and indicates that replicates are now very similar. This data – referred to as the “biological sample normalized data” - is then used to normalize between different experiments.

The second stage is normalization between the different experiment conditions, e.g. wild type and a selected mutant, using the output from stage 1. These data were processed as described above to determine the normalization factor for each experimental condition that were applied to the “biological sample normalized data” generating the final “experimental

normalized data”. The final result is represented in Fig. 1c, bottom, which shows that the apex ratio between all samples is now unity.

Selection of the normalization method

The method used for normalization of the data (Most Likely Ratio Normalization, MLR) was compared to other recognized methods of data normalization, including Total Area Sums (TAS), and normalization to bait protein. TAS is performed by summing the responses for each sample and then determining a ratio of each sample to the largest sum. This ratio is used as a normalization factor for each sample. When normalizing to a bait protein, the responses for the bait proteins are summed, and then the median ratio between the peptides determined and this value is used to normalize all other measurements in each sample. Supplementary Figure 33a shows the differences on the resulting PCA analysis between sample grouping using TAS, normalization to the bait protein, and MLR for an experimental dataset from triplicate analyses of three bait proteins where one replicate for two of the baits had a much lower overall intensity. While the normalization to the bait clearly fails in this case, there was an improvement in obtaining separation from using MLR over TAS. This was most obvious when visualizing the ratio histograms after normalization (Supplementary Figure 33b). As the primary aim of normalization is to minimize experimental variance, balancing the ratio histograms ensures that the variance has been minimized. The variance of the samples is defined as the range of the peak apexes of the ratio histograms. Here, the issues associated with the normalization to the bait protein (significant sample variance even after normalization) are clearly depicted. While the TAS approach minimized this variance between samples, the two outliers (intensity-wise) were still unaligned. By contrast, MLR was successful at minimizing the variance, even for these samples with a poor intensity response.

Note that in terms of the Fold Change determination, while normalization of the data to the bait protein makes sense if the bait protein itself is expected to be a constant value (this was in fact the method we used for the analysis of the SRM data in a previous publication¹³), even small variations in the abundance of the bait protein across the samples strongly affected the results (essentially, boosting all contaminant proteins in the samples in which the bait was expressed to a lesser extent). Here, as seen in the western blots in Fig. 3b and 4e (and accompanying quantitative mass spectrometry analysis), though the WT and mutants CDK proteins were expressed at similar levels, these levels were not identical (the WT was expressed to a higher level than the mutants). This prevented us from using the bait normalization which we had previously employed; MLR was not impacted by these differences.

Determination of fold change of values

All of the raw data collected was used to provide an input to the fold change determinations. In essence the fold change of the protein was determined using the method reported in¹³. Data after normalization – experimental normalized data - is used for the fold change determination. This data is treated in the following manner: 1) For each set of biological replicates a table of weighted average areas is determined using the transition reproducibility values determined during normalization – “weighted area response”; 2) Weighted analysis of variance is used to determine the likelihood of difference between the experimental test conditions. The output is in essence a p-value as if a t-test was performed between the different experiments but the use of weighted values better accounts for poor quality values in the data being processed; 3) The “signal quality values” and “analysis of variance values” (from step 2) are used to determine the peptide fold change values using a weighted average fold change calculation; 4) A peptide signal quality table is determined from the transition signal quality table by calculating the median signal quality for each set of transitions; 5)

The peptide variance is determined by calculating the summed weighted average for the transitions analysis of variance using the signal quality table as the weighting factor for the individual transitions; 6) A protein fold change value is determined as described in Bisson et al.¹³, with a slight modification that the protein value is again a weighted average using both the peptide signal quality (step 4) and also the peptide variance (step 5) values as weights.

As described before, the output of this fold change determination is a fold change up and down for each protein and a confidence value as determined from the peptide variance and the peptide signal quality values.

All calculations were performed in MATLAB 2012 by executing custom coded algorithms and data exported either in figure format or as text.

Determination of data quality metrics

Data quality is determined for the transitions, peptides and proteins and used to reject lower quality values from subsequent processing and display: 1) The transition quality matrix is determined by taking the maximum median value of the data in the transition reproducibility matrix as determined in the normalization of the data; 2) The peptide quality matrix is determined by taking median value for the transition quality values; 3) The protein quality is determined from the median of the individual peptide quality values.

Filter parameters for data visualization and figure generation

Data represented in all figures was generated using a series of custom algorithms executed within the MATLAB environment. The output from these scripts were figures and tables representing the fold change and corresponding confidence values.

Although data was filtered primarily using a confidence threshold of 0.75, we also required a minimum log₁₀ (fold change) value of 0.2. This latter value is based on distributions of pairwise fold change values for all measurements with confidence values less than 0.75 (i.e. most likely not changing) in the initial CDK4 mutant experiment which showed that ca. 95% of the log₁₀ (fold change) values were less than 0.2. Further, to ensure that each protein is represented by high quality measurements, we required at least 2 peptides per protein and used signal quality and reproducibility thresholds of 0.15 (determined from the appropriate histograms).

For the data presented in the main text figures, an additional filtering scheme, based on the Fold Change calculations, was applied to ensure that only specific interactors for a bait are considered as “potentially modulated interactors”. Essentially, we applied two criteria: 1) the prey protein must have passed the confidence and Fold Change thresholds as defined above and be up-regulated in comparison to a set of negative control samples processed in parallel (we consider any proteins passing the thresholds across the entire set of baits to be tested a “specific interactor” for the bait); 2) pairwise comparisons between sequence variants and/or drug treatments are then performed, only considering the “specific interactors”, and the same thresholds (this time, up or down) are applied. Data resulting only from the second step (meaning without first ensuring that the proteins analyzed are non-contaminants) can be found in Supplementary Figs 20-22 and 30-32; 34-39). However, since we did not use the two-step filtering process for the Supplemental data presented for additional mutants of CDK4 and splice variants of GRK6, these values should be interpreted with caution.

The layout of the figures was also generated in MATLAB and annotated in Illustrator: In the case of the complete dataset representation for each experiment set, the rank is based on the global view where proteins are ranked by decreasing confidence of fold change across any two pairs.

The figures presented in the main text utilize the same filtering criteria and cutoffs and represent the Fold Change data as a heat-map generated (increasing ratios) using MultiExperiment Viewer version 4.8.1 (MeV; <http://www.tm4.org/mev/>).

Access to data

All mass spectrometry data as well as each of the steps of the analysis can be found at prohibits-web.lunenfeld.ca. Raw mass spectrometry files were also deposited in the MassIVE repository, housed in the Center for Computational Mass Spectrometry at UCSD (<http://massive.ucsd.edu/ProteoSAFe/datasets.jsp>); see Supplementary Table 4 for IDs and links to each of the datasets.

AP-SWATH pipeline. **(a)** MS analysis pipeline: each sample is processed separately for DDA and SWATH, and the spectral library built from all DDA runs within an experimental set is used to retrieve quantitative information from each of the SWATH runs. A series of tools are used to automatically match the DDA and SWATH spectra, extract quantitative information, normalize the transitions, peptides and proteins, and determine the Fold Change differences between samples, and the confidence on the Fold Change. **(b)** Schematic of the parameters used for normalization. Intensity ratio histograms are generated between pairs of samples, and a number of metrics are derived. **(c)** Effects of the normalization steps on the area ratio histograms demonstrated for a dataset consisting of 9 samples derived from CDK4 WT, 9 from CDK4 R24C and nine from CDK4 R24H. The top panel shows the ratio histograms before normalization; the middle panel, after normalization based on experimental types (here biological replicates); and the bottom panel shows the final results after normalization of the experimental bias.

**Figure 2.**

AP-SWATH for scoring protein interactions. **(a)** Reproducibility metrics for the SWATH extraction at 1% FDR in relation to the binned % CV values; the upper boundary is indicated. **(b)** Reproducibility metrics for the common peptides identified in all DDA experiments and extracted from SWATH data with 1% FDR. The numbers of peptides and proteins identified/quantified within the %CV indicated are listed, and the overall percentages of peptides/protein within the 20% CV interval are indicated. **(c)** Fold Change calculation results for the FLAG-EIF4A2 bait in relation to a negative control, FLAG-GFP (left), and for FLAG-MEPCE in relation to FLAG-GFP (right). The proteins that changed 2-fold with a confidence ≥ 0.75 are displayed: increased proteins (yellow scale) are specific to the bait in relation to the control while the decreased proteins (blue scale) are more abundant in the negative control samples, and likely contaminants (these tend to be enriched in the Contaminant Repository for Affinity Purification, CRAPome.org³⁷). Several components of well-characterized protein complexes that were enriched with EIF4A2 and MEPCE are indicated by the colored dots to the right of the heatmaps (See Supplementary Figs 9-11 for an expanded view). In this and all other heatmaps, values exceeding the Fold Change (\log_{10}) indicated in the color-coding bars are depicted as the maximal intensity values.

Figure 3. Selected biological samples. **(a)** Schematic representation of the effects of mutations, splice variants and chemical perturbations on the modulation of specific protein-protein interactions. In the reference interactome, interaction of the central protein with three binding partners is represented. If this protein is absent from the cells, all three interactions are lost (blue interactome; node removal). Interactions can also be selectively lost (green interactome; edge lost) or gained (red interactome, edge gain). In these cases, the loss/gain can be absolute (represented here by the presence or absence of an edge), or partial (depicted by changes in edge width; the magnitude of these changes can be measured by quantitative proteomics). **(b)** AP-western validation of a test case for monitoring interactome changes. FLAG-tagged CDK4 WT and mutant proteins are expressed at similar amounts (to each other and to the endogenous CDK4 protein) in Flp-In T-REx 293 cells and purified on an anti-FLAG resin. Association of the endogenous p18INK (CDKN2C) protein was detected by immunoblotting.

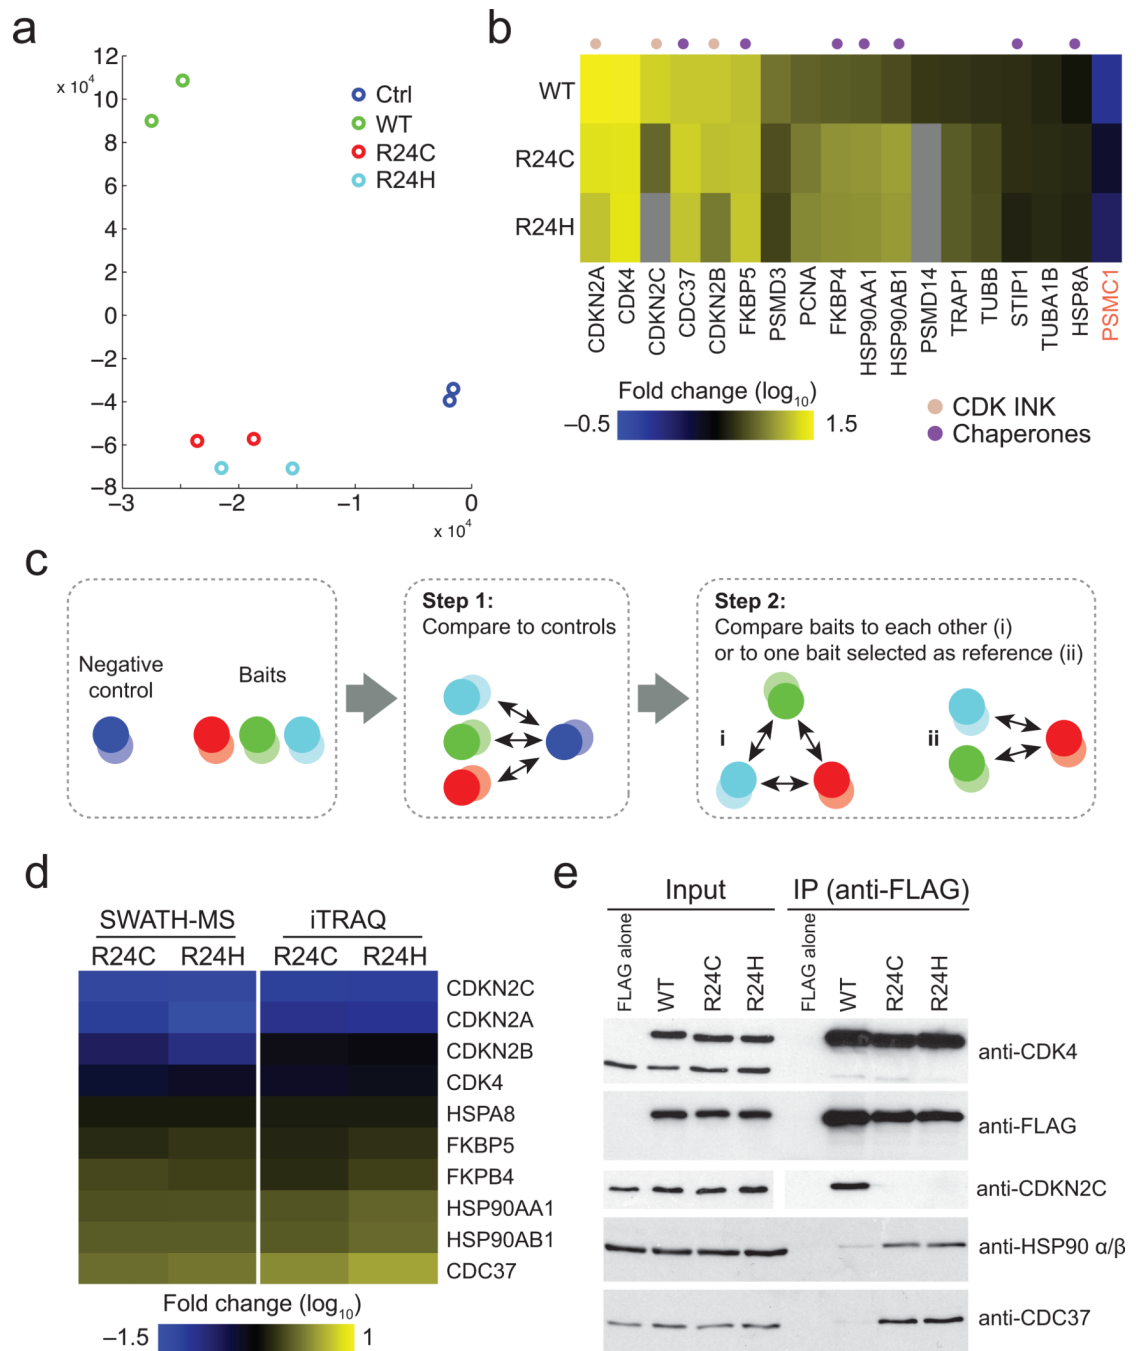

Figure 4. Identification of differential interactomes for CDK4 cancer-associated mutants. **(a)** Principal component analysis showing the clear separation of two control (FLAG alone) samples and two CDK4 WT samples in comparison to the two CDK4 R24 samples that show little separation. **(b)** Heatmap representation of the proteins passing the confidence threshold in one of the CDK4 baits relative to the negative controls. The grey cells indicate that the thresholds for confidence, Fold Change or signal-to-noise were not met in this particular pairwise comparison (See Supplementary Fig 12 for a global view of all the data without these missing values and Supplementary Figs 13-14 for expanded views). **(c)** Schematic of

the scoring process for differential interactome mapping: in the first step, the potential interactions for a set of baits are collectively scored against a negative control and proteins confidently up-regulated with 1 baits are considered further. In the second step, systematic pairwise comparisons between all baits, or comparison to a bait used as a reference point, are performed. **(d)** *Left*: Heatmap depicting the high confidence proteins differentially detected in the R24C and R24H mutants in relation to the WT sample. Only proteins changing with a confidence ≥ 0.75 and that passed filtering criteria defined in Methods are depicted. See Supplementary Fig. 15-17 for all pairwise comparisons. *Right*: Heatmap showing the iTRAQ ratios of the high confidence SWATH proteins (see Supplementary Fig. 18 for iTRAQ ratio standard deviation). **(e)** Validation of selected regulated interactions by AP-western.

**Figure 5.**

Use of AP-SWATH to probe drug-modulated interactions. **(a)** Increased association of kinase mutants with HSP90 as determined by LUMIER. **(b)** Heatmap depicting the high confidence differentially recovered proteins as a consequence of NVP-AUY922 treatment (all comparisons are pairwise, for the same bait treated with NVP in comparison to the mock treated sample). See Supplementary Fig. 24 for the heatmap of the first filtering step (normalization to the negative control) and Fig. 25 for an expanded view). **(c)** Fold Change and Median Absolute Variance (error bars) for all proteins from panel. **b.** See Supplementary Fig. 26-27 for an expanded view of protein and peptide level changes. **(d)**

Fold change of selected proteins in the mutants as compared to the WT following NVP-AUY922 treatment. **(e)** Validation of selected regulated interactions by AP-western: 500nM NVP-AUY922 was used for 1 hour. **(f, g)** AP-western analysis of time course of CDK4 WT **(f)** and R24C mutant **(g)** dissociation from CDC37-HSP90 in the presence of 100nM NVP-AUY922. In **e, f** and **g**, * indicates the position of the FLAG-tagged bait protein; • indicates endogenous CDK4.
