**Objective** To investigate methionine metabolism during normal human embryonic development by measuring levels of methionine and total homocysteine in samples of maternal serum, extra-embryonic coelomic fluid, and amniotic fluid.

**Design** Cross-sectional observational study.

**Setting** Collaboration between St Bartholomew’s Hospital, London, and the University Hospital of Nijmegen in The Netherlands.

**Participants** Twenty-three women with uncomplicated pregnancies between 8 and 12 weeks of gestation before surgical termination of an ultrasonographically normal fetus.

**Methods** Maternal serum samples were collected prior to surgery. Samples of extra-embryonic fluid and amniotic fluids were obtained by transvaginal ultrasound-guided coelocentesis and amniocentesis. Methionine was measured using an aminoacid analyser and total homocysteine by high performance liquid chromatography.

**Results** Levels of methionine were four times higher in extra-embryonic coelomic fluid and twice as high in amniotic fluid compared with maternal serum. In contrast, the total homocysteine concentrations were much lower in both extra-embryonic coelomic fluid and amniotic fluid than in maternal serum. All differences were significant ($P < 0.01$).

**Conclusions** The comparatively high concentrations of methionine in extra-embryonic coelomic fluid and amniotic fluid, and the concomitant low levels of total homocysteine in these fluids, suggest a role for methionine metabolism during early human pregnancy.

**INTRODUCTION**

The mechanisms involved in the nutrition of the embryo and fetus are poorly understood. The dynamic and physiology of the transplacental transport of the amino acid methionine, its derivative homocysteine, folate and vitamin B₁₂ which are involved in homocysteine remethylation (Fig. 1) has been studied previously by us in the second and third trimester of pregnancy¹,² as well as by others³,⁴.

Alteration of methionine metabolism in humans due to folate or vitamin B₁₂ shortage may play a role in the aetiology of neural-tube defects, recurrent miscarriage, placental infarcts and placental abruption⁵-⁹. The causes of these pregnancy complications might be found in the first gestational weeks. During the first trimester of pregnancy embryonic nutrition is provided by the transfer of nutrients from the extra-embryonic coelomic and amniotic fluids to the embryo. Campbell et al.¹⁰ reported that the main route for maternal-fetal exchange of folate and methylcobalamin in early human pregnancy may be via the extra-embryonic coelomic cavity. Knowledge about the composition of the extra-embryonic coelomic and amniotic fluids and the transport mechanisms of methionine and homocysteine during that period of pregnancy is lacking.

Therefore the aim of the present study was to investigate the importance of tissue specific methionine metabolism during normal early human pregnancy by measuring the levels of methionine and total homocysteine in samples of maternal serum, extra-embryonic coelomic fluid and amniotic fluid at 8 to 12 weeks of gestation.

**METHODS**

Twenty-three pregnant women were studied after informed consent was obtained. The experimental protocol was approved by the Ethics Committee of St
Bartholomew's Hospital, London. All women were undergoing a therapeutic termination of pregnancy for psycho-social reasons at a gestational age of 8 to 12 weeks. The duration of pregnancy was established by menstrual history and ultrasound measurement of crown-rump length.

Transvaginal ultrasound was performed using a 5 MHz curvilinear vaginal probe (Aloka SSD 620, Aloka Co Ltd, Tokyo, Japan). In each case ultrasonography confirmed a singleton pregnancy with normal development and normal fetal heart activity. The procedure for transvaginal ultrasound, coelocentesis and amniocentesis has been described in detail. Matched samples of amniotic and coelomic fluid were collected in every case.

Maternal blood was collected into glass tubes before induction of anaesthesia; within 30 min, the samples were centrifuged for 10 min at 3000g and the serum aspirated into dry plastic tubes. The fluid or serum was stored at -20°C until assayed for total homocysteine (free plus protein-bound) and methionine. Total homocysteine concentrations were measured by automated high performance liquid chromatography and fluorometric detection in 70 μmol/L of the homogenate. The total homocysteine determination by this method is based on complete reduction of all homocysteine disulfide bonds in plasma by sodiumborohydride and dithioerythritol. After derivatisation by monobromobimane the resulting homocysteine-monobromobimane complex was separated from interfering substances by reverse phase chromatography. The detection limit was 15 pmol. Both intra- and inter-assay coefficients of variation were <5%.

Results have been expressed as median (range). Comparisons between gestational age, blood and fluid concentrations of methionine and homocysteine were performed by the Wilcoxon matched-pairs signed-rank test. Correlations were evaluated by determination of the Spearman coefficient of correlation and careful interpretation of the scatter diagrams. P-values <0.05 were considered statistically significant.

RESULTS

The concentrations of methionine and total homocysteine in maternal venous blood, extra-embryonic coelomic fluid and amniotic fluid from 23 pregnancies at 8 to 12 weeks of gestation are shown in Table 1.

Methionine levels were higher and homocysteine values were lower in extra-embryonic coelomic fluid and amniotic fluid when compared with maternal serum levels (P < 0.01). The highest methionine levels were found in extra-embryonic coelomic fluid and the lowest total homocysteine levels were found in amniotic fluid.

There were no relations between gestational age and methionine and total homocysteine concentrations in the various compartments (Fig. 2). All Spearman correlation coefficients were r ≤ 0.35 and P > 0.10. Positive correlations could be established between methionine in extra-embryonic coelomic fluid and amniotic fluid (Spearman’s coefficient of correlation r = 0.65, P < 0.01), total homocysteine in serum and extra-embryonic coelomic fluid (r = 0.56, P < 0.01), and between methionine in serum and total homocysteine in extraembryonic coelomic fluid (r = 0.43, P < 0.05) (Fig. 3).

**DISCUSSION**

This is the first report on concentrations of methionine and total homocysteine in human extra-embryonic coelomic and amniotic fluids at 8 and 12 weeks of gestation. The comparatively high levels of methionine in both embryonic fluids may suggest that this nutrient is important during early human pregnancy.

Methionine is essential for cell proliferation and DNA and tRNA methylation. It is converted to S-adenosylmethionine and, after decarboxylation, this methyl donor is the source of the 3-carbon moieties of the polyamines spermidine and spermine. In addition, S-adenosylmethionine is involved in the methylation of DNA. In the rat a shortage of methionine and S-adenosylmethionine in embryo cultures can lead to disturbed morphogenesis, especially the development of neural tube defects. The concomitant low total homocysteine concentrations in both fluids together with the high methionine concentrations suggests that the remethylation pathway is likely to be important as well in the extra-embryonic tissues during this early stage of development. Because folate and vitamin B₁₂ are essential in the remethylation of homocysteine into methionine, this hypothesis is supported by the results of the study of Campbell et al. showing high
positive correlation between total homocysteine in serum and coelomic fluid might also be explained by a passive diffusion process.

The positive correlation between the methionine concentration in serum and the total homocysteine concentration in the coelomic cavity is more difficult to explain. It is possible that if large amounts of methionine are actively transported from maternal blood to coelomic fluid, then the remethylation of homocysteine to methionine by extra-embryonic structures would be decreased leading to relatively high total homocysteine concentrations in the coelomic fluid.

The methionine levels in the serum of pregnant women in the present study were slightly lower than those determined in nonpregnant women, and the serum total homocysteine concentrations were slightly higher than those published previously by Andersson et al. in the first trimester of pregnancy.

The derivative homocysteine of methionine is normally present in blood in low concentrations. Elevated intracellular and extracellular homocysteine levels may be cytotoxic, though whether elevated circulating levels of homocysteine are embryotoxic is unknown. In vitro studies in the rat suggest that the embryotoxic effect of L-homocysteine is due to inhibition of methyl donation by S-adenosylmethionine. Also, toxicity of homocysteine for vascular endothelium interfering with spiral or yolk sac arteries cannot be excluded. The development of neural tube defects might be partially explained by a decreased availability of methionine, folate and cobalamin, and subsequent derangement of methionine metabolism during early human pregnancy resulting in decreased synthesis of DNA and thus disordered cell proliferation. The prevention of neural tube defects by periconceptional folate supplementation might partly be explained by the correction of disturbed methionine metabolism. This concept is supported by the results of the present study.

Although the supply, metabolism and synthesis of nutrients during early human pregnancy is poorly understood, the results of the present study suggest that folate and vitamin B12 dependent methionine metabolism may be important for growth and development of the human embryo.
