CYCLIC CREEP AND FATIGUE OF TD-NiCr (THORIA-DISPERSION-  
STRENGTHENED NICKEL-CHROMIUM), TD-Ni,  
AND NiCr SHEET AT 1200 C

by Marvin H. Hirschberg, David A. Spera, and Stanley J. Klima  
Lewis Research Center

SUMMARY

Testing and calibration procedures are presented that make it possible to generate strain-range-against-life data from very simple, thin, sheet specimens subjected to cyclic flexure at elevated temperature. The resistance of thin TD-NiCr sheet to this type of cyclic deformation was evaluated at 1200 C in air and compared with that of TD-Ni and a conventional nickel-chromium alloy. The test specimens were strips of sheet material 0.38 or 0.51 millimeter thick, 10 millimeters wide, and 76 millimeters long, bent into semicircular arcs. The strips were self resistance heated in air and cycled by square-wave end displacement at 0.05 hertz. Strains were determined by a calibration technique which combined room-temperature strain gage and deflection measurements with high-temperature deflection measurements.

Analyses of the cyclic tests using tensile and creep-rupture data indicated that the TD-NiCr and NiCr alloy specimens failed by a cyclic creep mechanism. The TD-Ni specimens, on the other hand, failed by a fatigue mechanism. Metallographic examination of failed specimens confirmed the expected failure modes. The TD-NiCr and NiCr specimens exhibited intergranular cracking, and the TD-Ni exhibited transgranular cracking.

INTRODUCTION

This investigation was undertaken in order to obtain a relatively fast and simple evaluation of the elevated-temperature fatigue resistance of three commercial nickel-base sheet materials under very restrictive loading and temperature conditions. These materials were a thoria-dispersion-strengthened nickel-chromium alloy (TD-NiCr), a thoria-dispersion-strengthened nickel alloy (TD-Ni), and a conventional nickel-chromium

alloy (NiCr). All materials were evaluated in a static air environment at 1200 C. These test conditions, with the exception of velocity, simulated potential reentry conditions to be encountered by the skin material of the NASA Space Shuttle Vehicle (ref. 1). There is presently very limited cyclic data available for TD-NiCr, which is a candidate Space Shuttle material. Such data, along with cyclic life comparisons with more conventional materials are needed to assist designers responsible for choosing materials for this specific application. Although the TD-Ni and NiCr materials are not candidates for the Space Shuttle Vehicle, they were included in this investigation to provide a basis for comparison.

The design of Space Shuttle skin structure requires high-strain, low-life cyclic data; reversed strain-cycling tests provide the most useful data for this type of application (ref. 2). The common and most direct method of generating these data would be by fully reversed axial strain-cycling tests. Such testing techniques are available and widely employed for conventional specimens tested at moderate temperatures (refs. 3 to 7). For thin sheet at temperatures as high as 1200 C, the conventional techniques are limited due to complexities encountered in putting thin sheet into direct compression. When this is attempted, buckling usually results and cracks form due to high localized stresses.

It has been shown that bending tests can be used to generate useful strain-range-against-life information (refs. 8 and 9). A fully reversed bending test was therefore employed in this investigation. The surface strain ranges experienced by the sheet specimens were calculated from a strain and deflection calibration procedure. Along with these cyclic tests, conventional elevated-temperature tensile and creep-rupture data were generated for the three materials.

Comparison was made of the cyclic lives obtained for the three materials investigated. Correlations were obtained between cyclic lives and predictions from theory by using tensile and creep-rupture data. A metallurgical investigation of the failed specimens was made to assist in understanding the observed cyclic behavior (transgranular or intergranular modes of cracking).

## MATERIALS AND SPECIMENS

### Materials

The sheet materials used in this investigation were a thoria-dispersion-strengthened nickel-chromium alloy (TD-NiCr), a thoria-dispersion-strengthened nickel alloy (TD-Ni), and a conventional nickel-chromium alloy (NiCr). The TD-Ni and NiCr alloys were 0.51 millimeter thick, while the TD-NiCr was 0.38 millimeter thick. These materials were commercially available. The chemical analysis for each alloy is listed in table I.

## Specimens

Two types of sheet specimens were used in this investigation. Reduced-section, pin-loaded specimens were used for the tensile and creep-rupture tests (fig. 1(a)). Simple strip specimens were sheared for the fatigue tests (fig. 1(b)). These strips were then formed at room temperature into semicircular arcs as shown in figure 1(c). This was accomplished without introducing surface cracking, since the materials of interest all had good room-temperature ductilities. Test specimens of TD-NiCr and TD-Ni were cut from the sheet stock in directions parallel and transverse to the rolling directions because of known processing anisotropy. The NiCr specimens were all taken from the sheet stock parallel to the rolling direction since this material was known to be isotropic.

## APPARATUS

### Cyclic Tests

Servocontrolled electrohydraulic fatigue-testing equipment was used for the flexural testing of the sheet specimens. This equipment has been extensively used in the past for axial fatigue investigations of both solid and rigid tubular specimens and is described in detail in reference 3. Some modifications to this equipment were necessary to permit flexural testing of thin sheet at temperatures as high as 1200 C. These modifications are described in the following paragraphs with the aid of figure 2.

Specimen gripping. - The preformed sheet specimens were bolted into the machine between the two water-cooled electrical connectors. The bolts pass through these connectors and into the ends of the loading rods. The specimens were clamped between the bolt face and the inside surface of the connectors.

Specimen heating. - An electro-optical temperature sensor was used to control specimen temperature. It was aimed at the center of the test specimen and its electrical output was fed into a temperature controller. This output was, in turn, fed into a conventional silicon controlled rectifier that regulated the power for specimen heating. The equipment was the same as that previously used for heating tubular specimens and is described in reference 3, with the exception that the thermocouple was replaced in this case by the optical temperature sensor. In order to use this system for the direct resistance heating of sheet specimens, an additional transformer had to be placed between the power regulator and the specimen. This transformer delivered the high current at low voltage required for obtaining the desired specimen temperature.

This closed-loop heating system, using thin sheet specimens, an optical temperature sensor, and direct resistance heating, was stable and had a very high response rate. Since the optical sensor was somewhat sensitive to specimen surface condition, a

separate hot-wire optical pyrometer was used to monitor the test section temperature. On the basis of periodic measurements, minor corrections in the temperature servosystem were made, resulting in specimen test section temperatures that varied by no more than  $\pm 10$  C from the desired 1200 C.

Another modification was made to the heating arrangement described in reference 3. The upper loading rod was electrically insulated from the upper portion of the testing machine frame by using flanges separated by a thin mica disk (fig. 2). This modification eliminated the parallel current path through the frame of the machine and most efficiently used the available power for specimen heating.

## Tensile and Creep-Rupture Tests

Conventional testing machines were used. The tensile tests were performed on a screw-driven testing machine, while the creep-rupture tests were performed on a deadweight-type loading machine. Specimens of the type shown in figure 1(a) were used with double universal joints inserted into the loading train. Specimens were heated by radiation in a vacuum furnace. A vacuum of  $10^{-7}$  torr or better was maintained throughout the tests. Temperature was controlled by a servosystem using tungsten/tungsten-rhenium thermocouples wired to the surface of the specimens. For tensile testing, the crosshead speed was maintained constant throughout a test.

## EXPERIMENTAL PROCEDURE

### Cyclic Flexural Tests

The cyclic flexural tests were conducted under closed-loop stroke control, with the stroke sensor being a linear variable differential transformer (LVDT). The command input signal to this system was a square-wave signal of 0.05 hertz. Specimens were inserted into the machine with an opening between the copper electrical connectors controlled at 38 millimeters. Before any cyclic displacements were applied, the servo-heating system was adjusted to the required 1200 C; and residual stresses induced when forming the specimen's arc were relieved by holding under these conditions for approximately 10 minutes. The displacement cycling was performed about this mean opening.

A dial indicator was used to measure the imposed vertical displacement range  $\Delta V$  (fig. 2). The dial indicator for reading the horizontal displacement range  $\Delta H$  was used only during the calibration procedure, as described in the section Strain Calibration.

A record of the imposed  $\Delta V$ , temperature, and cycles to failure was kept for each specimen. Failure for these tests was defined as separation of a specimen into two parts.

When this occurred, the electrical continuity through the specimen was interrupted and the testing machine was automatically shut down. In all cases, failure occurred in the mid-section of the specimen. It should be noted that under test conditions other than those used in this investigation, failures might possibly occur near the grips and necessitate a redesign of the specimen. A simple necked-down section, similar to the tensile and creep-rupture specimens in figure 1(a), could be used to ensure that failure would occur at the desired location.

## Tensile and Creep-Rupture Tests

The theory to be used to analyze the cyclic data in this investigation requires both tensile and creep-rupture data. These data were generated in vacuum at 1200 C. The test conditions and results are listed in table II for the three materials investigated.

## Strain Calibration

The objective of this investigation was to generate strain-range-against-life information for the three sheet materials at 1200 C. The flexural-type test employed does not, however, lend itself to a direct measurement of the required surface strain range at this very high temperature. A calibration procedure was devised which results in an estimate of the surface strain range for any given imposed displacement range.

The calibration method is based on the assumption that the surface strain range is proportional to the horizontal displacement range  $\Delta H$  rather than to  $\Delta V$ , as would be the more conventional assumption. In a sense, this assumes that  $\Delta H$  is a better indicator of changes in surface curvature at the test section than is  $\Delta V$ , and that we have "elastic strain invariance" (ref. 2, p. 194) based on the horizontal displacement range. A more detailed description of the calibration procedure is presented in the appendix.

## Metallography

Metallographic studies were made of representative test specimens of all materials to determine general microstructure, mode of cracking, and oxidation characteristics. The metallographic techniques utilized included optical microscopy, scanning electron microscopy, X-ray diffraction, and X-ray microanalysis. Metallographic specimens were etched with the solutions indicated in the following table:

Alloy	Etchant
TD-NiCr	100 ml H <sub>2</sub> O, 10 ml H <sub>2</sub> SO <sub>4</sub> , 2 g CrO <sub>3</sub>
NiCr	92 ml HCl, 5 ml H <sub>2</sub> SO <sub>4</sub> , 3 ml HNO <sub>3</sub>
TD-Ni	45 ml lactic acid, 45 ml ethanol, 10 ml HCl

## ANALYTICAL PROCEDURE

The general theory used to analyze the data in this study is described in detail in reference 10. This theory considers both low-cycle fatigue and cyclic creep as possible failure mechanisms. Low-cycle fatigue is considered to be a cycle-dependent mode of failure characterized by transgranular cracking. On the other hand, cyclic creep is considered to be a time-dependent mode of failure characterized by intergranular cracking.

In the present investigation, the theory was used to indicate the most likely mode of failure for each of the three materials. If an accurate knowledge of basic mechanical material properties and imposed stresses had been available, this theory could also have been used for predicting life.

### Low-Cycle Fatigue Failure

Failure by low-cycle fatigue was analyzed by using the Method of Universal Slopes (ref. 11). This method uses a formula that relates total mechanical strain range, cycles to fatigue failure, and conventional tensile properties, as follows:

$$\Delta\epsilon_t = 3.5 \frac{\text{UTS}}{E} N_f^{-0.12} + D_t^{0.6} N_f^{-0.6} \quad (1)$$

in which

- $\Delta\epsilon_t$  total strain range
- UTS ultimate tensile strength
- E Young's modulus of elasticity
- $N_f$  cycles to fatigue failure
- $D_t$  tensile ductility (true strain at failure)

The tensile properties used in equation (1) should be those obtained at the test temperature.

## Cyclic-Creep Failure

Failure by cyclic creep was analyzed by using the method of life fractions. Life fractions were calculated by either a stress-time or a strain-cycle approach, whichever was more suitable to a particular alloy. For example, the tensile stress amplitudes were assumed constant and could be estimated for both the TD-NiCr and TD-Ni because they behaved in a quasi-elastic manner. For these two alloys, failure would theoretically occur when the accumulated time under tensile stress equaled the conventional creep-rupture time at that same stress, or

$$N_c \Delta t = t_r \quad (2)$$

in which

$N_c$  cycles to creep failure

$\Delta t$  tension time for one square-wave cycle (for 0.05 Hz,  $\Delta t = 1/6$  min)

$t_r$  time to rupture at stress, equal to square-wave stress amplitude

This approach is called an exhaustion of creep-rupture life.

For the relatively weak NiCr, creep strain per cycle could be estimated more accurately than the stress amplitude. This material might be classified as quasi-plastic. Failure would theoretically occur when the accumulated creep strain in tension equaled the conventional creep ductility, or

$$N_c \Delta \epsilon_c = D_c \quad (3)$$

in which

$\Delta \epsilon_c$  creep strain per cycle

$D_c$  creep ductility (true strain at rupture)

This approach is called a linear exhaustion of creep ductility.

## RESULTS AND DISCUSSION

### Tensile and Creep-Rupture Test Results

The tensile and creep-rupture test results for the three materials in this investigation are all listed in table II and plotted in figure 3. In this figure, the ultimate tensile strength was arbitrarily plotted at one-fourth of the total time taken to perform the tensile test. When this procedure was used, the tensile data seemed to correlate well with the short-time creep-rupture data.

There are obviously very large differences in the short-time creep-rupture behavior of these three materials, the TD-Ni being by far the strongest and the NiCr the weakest. The anisotropy of the TD-NiCr and TD-Ni show up consistently for both the tensile and creep-rupture results. Although the tensile and creep ductilities for these two materials could not be accurately measured, it was estimated that they were in the vicinity of 1 percent or less. The measured creep ductility for the NiCr material was 24 percent. For the purpose of analysis, it was assumed that the tensile and creep ductilities were equal for any given alloy.

## Strain-Range-Against-Life Relations

The results of all the cyclic flexural tests are listed in table III. The total strain range associated with each test was calculated as described in detail in the appendix. The strain-range-against-life curves are also plotted in figure 4.

The relative trends observed from these curves are as would be expected from a general knowledge of low-cyclic-life behavior. Both the TD-NiCr and TD-Ni materials have relatively high strength and low ductility at 1200 C. The NiCr, on the other hand, has low strength and high ductility at 1200 C. It would be expected, therefore, that for the life range covered the TD-NiCr and the TD-Ni would have curves of shallower slopes than that of the NiCr. It would also be expected that the curves would tend to approach strain ranges at one cycle that have values of the order of material ductility. The anisotropy noted from the tensile and creep-rupture tests also affects the cyclic behavior, as would be expected from the theory. For a strain range of approximately 0.3 percent, the three materials all have lives of approximately 1000 cycles. For strain-ranges above 0.3 percent, the ductile NiCr has the greatest cyclic resistance to failure and the TD-NiCr in the transverse direction, the least. For strain ranges below 0.3 percent, the low-strength NiCr is least resistant to failure and the TD-NiCr and TD-Ni appear to be about equal.

## Analysis of Data

TD-NiCr. - From a general observation of all the tests performed on this material at 1200 C, it appears that TD-NiCr could be classified as a quasi-elastic material. It would be expected, therefore, that the stresses calculated from a knowledge of the elastic strains would not be too far from the actual stresses in the material. In order to calculate these stresses, however, it was necessary to know the elastic modulus at the test temperature. The values reported in the literature ranged from about 25 to 50 GN/m<sup>2</sup>.

This was far too great a spread to be useful in this analysis. It was found that an excellent correlation between the cyclic data and the tensile and creep-rupture data could be obtained if the modulus were assumed to be equal to  $31 \text{ GN/m}^2$ . It should be noted that this assumed value is within the range reported in the literature. Using this modulus, the elastic strains were used to calculate the stresses (see table IV). These values are plotted in figure 5(a) along with the tensile and creep-rupture data. The stresses computed for the cyclic data are plotted at the total tensile time to failure (eq. (2)). This extremely good correlation between cyclic and monotonic creep-rupture data for both the longitudinal and transverse specimens leads to the conclusion that these cyclically loaded test specimens failed as a result of the exhaustion of creep-rupture life.

TD-Ni. - The TD-Ni specimens failed in a quasi-elastic fashion similar to the TD-NiCr. The stresses were calculated by assuming the material had the same modulus as the TD-NiCr, and the results are plotted in figure 5(b). In this case, the cyclic data do not correlate with the monotonic creep-rupture data. The large spread between the longitudinal and transverse rupture curves does not appear in the cyclic data. The TD-Ni specimens failed long before they would have failed based on the exhaustion of creep-rupture life.

It should be recalled that the creep-rupture and tensile data were run in vacuum, while the cyclic tests were run in air. Since the TD-Ni oxidizes severely in air, one might expect that, in cyclic tests conducted in air, failure would occur sooner than in creep-rupture tests run in vacuum, providing the cyclic tests resulted in pure creep-rupture failures. However, the differences between the cyclic and monotonic curves of figure 5(b) appear to be much too great (2 orders of magnitude in time) to be explained on the basis of oxidation. The conclusion is that the TD-Ni failed by a low-cycle fatigue (cycle dependent) mechanism rather than by a cyclic creep-rupture (time dependent) mechanism.

Further indication that the TD-Ni failed by a cycle-dependent mechanism is seen from figure 6. Here, the TD-Ni cyclic data are plotted as total strain range against cycles to failure. Life predictions based on equation (1) are also plotted in this figure. Calculations are based on both longitudinal and transverse material properties. Applying the 10-percent rule, as proposed by Manson in reference 12, to the Method of Universal Slopes (eq. (1)) moves these curves to the left by one decade and appears to represent the cyclic data reasonably well. This approach predicts a small anisotropic effect which was, in fact, the case.

The fact that the 10-percent rule seems to fit the data may be explained on the basis of oxidation initiating grain boundary cracks. In reference 12, it was assumed that most of the crack initiation period would be bypassed as a result of creep-initiated grain boundary cracking during elevated-temperature cycling. It is also quite reasonable to assume that grain boundary oxidation could have the same effect on life and that the

10-percent rule would also be expected to apply. A more detailed discussion of oxidation and grain boundary cracking is given in the section Metallography.

NiCr. - Figure 7 is a plot of the calculated inelastic strain range per cycle against the measured number of cycles to failure. There are two lines included in this figure that represent a linear exhaustion of ductility (eq. (3)) in which the product of the number of cycles to failure and the inelastic strain range per cycle equals a constant. The lower line assumes this constant to be equal to the measured creep ductility of 24 percent as listed in table II. The upper line is a fit of the data which implies that the creep ductility should be 54 percent rather than the measured 24 percent. This analysis based on the exhaustion of creep ductility requires the knowledge of the creep strain. For these data, it was not possible to separate the total inelastic strain range into its creep and plastic flow components. If it were assumed that about one-half of the inelastic strain range calculated for each data point were creep strain, the data would fall on the expected curve for the measured 24-percent ductility. In any case, the data follow the general form of equation (3) and are shifted in the direction that is consistent with the fact that the calculated inelastic strain range must be greater than the creep strain range. These results lead to the conclusion that the NiCr material failed as a result of a linear exhaustion of creep ductility (a time-dependent failure).

## Metallographic Observations

The results of the metallographic investigation of the materials tested, TD-NiCr, TD-Ni, and NiCr, are presented. Photomicrographs of representative specimens are shown in figures 8 to 11.

General microstructure. - Both the TD-NiCr and TD-Ni materials had elongated grains in the direction of sheet rolling. The NiCr material, on the other hand, had generally equiaxed grains. These differences are also apparent in the micrographs of tested specimens as seen in figures 8 and 9.

Mode of cracking. - The two chromium-containing materials exhibited primarily intergranular cracking in both fatigue and creep-rupture tests (figs. 8(a) and (b) and 9(a) and (b)). The creep-rupture-tested specimens of these materials displayed classical grain boundary void formation in the portion of the boundaries normal to the loading direction (figs. 9(a) and (b)). The fatigue-tested chromium-bearing materials showed both intergranular and transgranular cracks emanating from specimen surfaces with intergranular cracks of the type shown in figures 8(a) and (b) generally predominant.

TD-Ni exhibited transgranular cracking in both creep rupture and fatigue (figs. 8(c) and 9(c)). The highly elongated shape of these grains was probably the controlling factor in the observed mode of cracking. These elongated grains provided very few grain

boundaries transverse to the loading direction, making it all but impossible for a crack to propagate intergranularly.

The observed cyclic test lives for the TD-Ni material were correlated with fatigue theory (cycle-dependent failure) and, on this basis, transgranular cracking would be expected. On the other hand, as previously noted, transgranular cracking was also observed for this material in the creep-rupture tests; and therefore, the observed mode of cracking would be expected for either cycle- or time-dependent failures. For the TD-NiCr and NiCr materials, the observed intergranular cracking was expected since the cyclic test lives were correlated with cyclic creep-rupture theory (time-dependent failure).

In fatigue-tested specimens the main crack that caused fracture always started at a specimen edge and propagated across the specimen width. In all materials there was a tendency for fatigue cracks to initiate at various sites on the surface of the sheet, as shown in figure 10, which is a photograph of the entire width of a TD-NiCr specimen. As the fatigue test progressed, these cracks became larger and the ones that were favorably oriented linked together and became part of the main crack. This type of cracking was particularly evident in specimens tested at relatively high strains.

Oxidation. - Based on scale thickness considerations of specimens tested in air, TD-NiCr was the most oxidation resistant of the three materials tested, followed by NiCr and TD-Ni, respectively, as may be seen in figure 8. The scale buildup on the surface of TD-NiCr and NiCr occurred early in the test and increased very little in thickness during the remainder of the test. The TD-Ni, however, oxidized rapidly and scale thickness continued to build up throughout the test. These observations, based on a limited examination of the oxidation characteristics of fatigue-tested specimens, are in agreement with the results published by Lowell, Deadmore, Grisaffe, and Drell in reference 13. These investigators showed that TD-NiCr has excellent oxidation resistance in static air. Since a complete oxidation study was not a primary objective of the present investigation, measurements such as weight change and metal thickness change were not performed. It was observed that oxide spalling was not a major problem in these tests, and therefore oxide thickness measurements probably provide a good comparison of oxidation resistance of these materials tested under the existing conditions. With regard to the possible effects of oxidation on the measured cyclic lives, it would appear that this may have been a problem with the TD-Ni material. It is suspected that the correlation of cyclic life with the 10-percent rule for this material is due to the high oxidation rate, which could easily cause premature cracking.

The composition of the scale found on TD-NiCr and NiCr was shown by the electron probe to be rich in chromium and low in nickel. The composition is presumed to be  $\text{Cr}_2\text{O}_3$ . The TD-NiCr showed some chromium depletion in the region immediately beneath the scale to about 16 percent from the nominal 20-percent level. There was evidence of thoria buildup in the scale at the outer surface. Within the scale, however, the

thoria content was low. Figure 11 shows the surface morphology of a tested TD-NiCr fatigue specimen. The angular particles protruding from the specimen surface were analyzed by X-ray to be  $\text{Cr}_2\text{O}_3$  single crystals. They were probably formed by redeposition of  $\text{Cr}_2\text{O}_3$  vapors that evaporated from the specimen surface during the test. The formation of these single crystals was typical of most of the fatigue-tested TD-NiCr specimens but was not observed on NiCr specimens. NiO was also observed on the surface of TD-NiCr specimens near the specimen corners and the area immediately surrounding many cracks. Many of the secondary cracks in the specimen of figure 10 are surrounded by small regions of NiO. It is probable that NiO formed after the chromium was depleted in these previously cracked regions of the specimen. The oxide inside the fatigue cracks was shown by the electron probe to be high in chromium and is probably  $\text{Cr}_2\text{O}_3$ . Nickel content of the oxide in the cracks was low.

The oxide formed on the surface of TD-Ni specimens was shown by the electron probe to be high in nickel and tended to fill all surface cracks. The electron probe also revealed a buildup of thoria in the scale-metal interface region. This may be the result of oxidation of the nickel at the specimen surface, leaving thoria behind at a higher concentration than in the virgin material.

## CONCLUDING REMARKS

We have presented testing and calibration procedures which make it possible to generate strain-range-against-life data from very simple, thin, sheet specimens subjected to cyclic flexure at elevated temperature. These procedures also have potential application to other types of investigations such as evaluating (1) the cyclic behavior of different sheet materials, (2) the effects of varying temperature on any one material, (3) surface coatings and their effects (e.g., bonding and cracking) on material behavior, (4) the effects of changes in material processing (e.g., rolling) on life, and (5) theories for predicting cyclic life.

With regard to the TD-NiCr material tested in this investigation, it would appear that, for Space Shuttle application, this alloy could be considered "well behaved." The cyclic flexural failures obtained were determined to be of the time-dependent type and could be predicted if the tensile and creep-rupture properties of the material were known.

## SUMMARY OF RESULTS

An investigation was conducted to determine the cyclic flexural resistance of three nickel-base sheet materials tested at 1200 C in air. These materials were TD-NiCr, TD-Ni, and NiCr. The following major results were obtained:

1. A relatively simple cyclic flexural test was developed and used to obtain strain-range-against-life information for thin sheet materials at elevated temperature.

2. The TD-NiCr and NiCr materials failed due to time-dependent cyclic creep and exhibited intergranular cracking. The TD-Ni material failed due to cycle-dependent fatigue and exhibited transgranular cracking.

3. The failure lives and modes of cracking for the three materials were correlated, by means of theories, with tensile and creep-rupture data.

4. As expected, the TD-NiCr had the best oxidation resistance of the three alloys tested, while the TD-Ni had the poorest. The TD-NiCr formed both  $\text{Cr}_2\text{O}_3$  and NiO oxides. The high oxidation rate of TD-Ni may have resulted in premature cracking of the surface, thereby reducing the fatigue life to that predicted by the 10 percent rule.

## APPENDIX - STRAIN AND DEFLECTION CALIBRATION

The calibration method is based on the assumption that the surface strain range is proportional to the horizontal displacement range. Since it is more convenient to measure vertical displacement range during an actual test rather than the horizontal displacement range, the adopted procedure is as follows:

(1) Obtain an elastic calibration of vertical-against-horizontal displacement range. For convenience, this is performed at room temperature.

(2) Obtain a calibration of horizontal displacement range against surface strain range at room temperature.

(3) Obtain a calibration of vertical-against-horizontal displacement range for the desired temperature and loading wave shape.

These calibrations can then be used to obtain the elastic and inelastic strain ranges for a given vertical displacement range at elevated temperature. The following illustrates this calibration procedure.

The results of the elastic measurements at room temperature (step (1) listed above) of the horizontal-against-vertical displacement ranges for the three materials are shown in figure 12(a) and can be represented by the equation

$$\Delta H_e = 0.385 \Delta V \quad (4)$$

where

$\Delta V$  imposed vertical displacement range

$\Delta H_e$  resultant elastic horizontal displacement range

A sheet specimen instrumented with conventional foil-type resistance strain gages provided a calibration of surface strain range against horizontal displacement range (step (2) listed above). Since we were dealing with thin sheet in bending and the gage thickness was an appreciable percentage of the specimen thickness, the measured strains were corrected to give true surface strains. This calibration was performed by using a TD-NiCr specimen of 0.38 millimeter thickness and resulted in the following relationship:

$$\Delta \epsilon_e / h = 0.00405 \Delta H_e \quad (5)$$

where

$\Delta \epsilon_e$  elastically measured surface strain range

$h$  thickness of sheet material

Furthermore, since we are dealing with the elastic portion of the calibration procedure, equation (5) is applicable to all three materials. This relationship is also included in figure 12(a) by adding the  $\Delta\epsilon_e/h$  scale that is 0.00405 times the  $\Delta H_e$  scale. These experimentally determined coefficients are approximately 10 percent greater than idealized theory (ref. 14) would predict.

The final portion of the calibration procedure involves the elevated-temperature displacement measurements (step (3) listed above). Figure 12(b) is an example of such a calibration obtained for the NiCr material in which the elevated-temperature horizontal displacement range is plotted against the imposed vertical displacement range. Included in this figure is the previously obtained elastic calibration line (eq. (4)). Subtracting this elastic  $\Delta H_e$  from the measured total horizontal displacement range  $\Delta H_t$  for a given  $\Delta V$  results in the inelastic value  $\Delta H_i$  which is also plotted in this figure.

By using equation (5), the strain scale can also be included in figure 12(b). For the NiCr, with a sheet thickness of 0.51 millimeter, the strain scale is 0.00207 times the  $\Delta H$  scale. The placing of this strain scale on the elevated-temperature deflection calibration plot is, in essence, the assumption of "elastic strain invariance," in which the strain range is linearly related to the horizontal deflection range.

A specific example of how these calibration curves were used follows. To determine the strain ranges associated with the NiCr specimen listed in row 4 of table III, use was made of figure 12(b). This specimen was subjected to a vertical displacement range  $\Delta V$  of 5.08 millimeters. By entering figure 12(b) at this value of the abscissa, the left-hand ordinate scale was used to obtain the total, elastic, and inelastic horizontal displacement ranges. These values were 2.63, 1.96, and 0.67 millimeter, respectively. The right-hand ordinate scale of strain range was also used to obtain the total, elastic, and inelastic strain ranges of 0.544, 0.406, and 0.139 percent, respectively. The  $\Delta H$  and  $\Delta\epsilon$  values for all the other specimens were obtained in this same manner and are listed in table IV.

## NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

**TECHNICAL REPORTS:** Scientific and technical information considered important, complete, and a lasting contribution to existing knowledge.

**TECHNICAL NOTES:** Information less broad in scope but nevertheless of importance as a contribution to existing knowledge.

**TECHNICAL MEMORANDUMS:** Information receiving limited distribution because of preliminary data, security classification, or other reasons.

**CONTRACTOR REPORTS:** Scientific and technical information generated under a NASA contract or grant and considered an important contribution to existing knowledge.

**TECHNICAL TRANSLATIONS:** Information published in a foreign language considered to merit NASA distribution in English.

**SPECIAL PUBLICATIONS:** Information derived from or of value to NASA activities. Publications include conference proceedings, monographs, data compilations, handbooks, sourcebooks, and special bibliographies.

**TECHNOLOGY UTILIZATION PUBLICATIONS:** Information on technology used by NASA that may be of particular interest in commercial and other non-aerospace applications. Publications include Tech Briefs, Technology Utilization Reports and Technology Surveys.

*Details on the availability of these publications may be obtained from:*
