16. Abstract

An 8.5-inch (21.59-cm) model was used with aerodynamically positioned tertiary inlet doors and secondary flaps. The flaps and doors were stable at all power settings and free-stream Mach numbers. Nozzle efficiencies of 0.98 were obtained at takeoff with a nozzle pressure ratio near 3.0, and 0.971 at Mach 2.0 with a nozzle pressure ratio near the design value of 29.0. At subsonic cruise both the nozzle performance and the floating flap position was sensitive to nozzle pressure ratio. For example, at Mach 0.9 increasing pressure ratio from 3.27 to 4.20 increased nozzle efficiency from 0.868 to 0.888 and reduced the nozzle area ratio from 2.93 to 2.38.

PERFORMANCE OF AN AERODYNAMICALLY POSITIONED AUXILIARY

INLET EJECTOR NOZZLE AT MACH NUMBERS FROM 0 TO 2.0

by Donald L. Bresnahan

Lewis Research Center

SUMMARY

An experimental investigation was conducted in the Lewis Research Center's 8- by 6-Foot Supersonic Wind Tunnel to determine the performance characteristics of a cold flow 8.5-inch (21.59-cm) diameter auxiliary inlet ejector with aerodynamically positioned tertiary inlet doors and secondary flaps. The design pressure ratio of the nozzle was 29.0. Two primary nozzles were tested: a small nozzle with a throat to nacelle area ratio of 0.185 to simulate operation at subsonic and supersonic cruise and nonafterburning acceleration, and a large nozzle with an area ratio of 0.261 to simulate afterburning takeoff and acceleration and also idle descent.

The flaps (which could reduce the exit area by 38 percent) and the inlet doors were stable at all power settings and free-stream Mach numbers. For a typical trajectory, the flaps were closed at takeoff and during subsonic acceleration. The flaps began to open at Mach 1.0 and were fully open at Mach numbers of 1.47 and above. The auxiliary inlets were full open at takeoff and partially open at subsonic cruise. During acceleration the inlets were closed at speeds above Mach 0.8.

Nozzle efficiencies of 0.98 were obtained at takeoff with a nozzle pressure ratio near 3.0 and 0.971 at Mach 2.0 with a nozzle pressure ratio of 27.6. At subsonic cruise both nozzle performance and floating flap position were sensitive to nozzle pressure ratio. For example, at Mach 0.90 increasing pressure ratio from 3.27 to 4.20 increased nozzle efficiency about 2 percent to 0.888 and reduced the nozzle area ratio from 2.93 to 2.38.

INTRODUCTION

The Lewis Research Center is evaluating various nozzle concepts appropriate for supersonic cruise applications. These nozzles must operate efficiently over a wide

range of flight conditions and engine power settings, necessitating extensive geometric variations. The performance of a low-angle plug nozzle and a variable-flap ejector nozzle designed for a supersonic cruise aircraft are reported in references 1 and 2, respectively. Another nozzle type of interest is the auxiliary inlet ejector. At the supersonic cruise point, this nozzle is similar to the variable-flap ejector. However, at takeoff and subsonic flight conditions, auxiliary inlets open to admit tertiary air to minimize primary flow overexpansion. This tertiary air fills part of the shroud, reducing the amount of exit-area variation required with an associated reduction in boattail area. Internal performance for an auxiliary inlet ejector nozzle with fixed geometry has been reported in reference 3. An ejector nozzle with free-floating doors and fixed shroud exit areas is reported in reference 4. However, experimental results on auxiliary inlet ejector nozzles with fully floating components are not generally available. The present investigation, therefore, was conducted to determine the performance of an aerodynamically positioned auxiliary inlet ejector nozzle over a range of free-stream Mach numbers from 0 to 2.0. Two primary nozzles were tested: a small nozzle to simulate a configuration for nonafterburning acceleration and for subsonic and supersonic cruise, and a large nozzle to simulate a configuration for afterburning takeoff and acceleration and for idle descent.

APPARATUS AND INSTRUMENTATION

Installation in 8- by 6-Foot Supersonic Wind Tunnel

A schematic drawing of the model support system in the 8- by 6-Foot Supersonic Wind Tunnel showing the internal geometry and thrust-measuring system is shown in figure 1 with a photograph of the model installation in figure 2. The grounded portion of the model was supported from the tunnel ceiling by a vertical strut. The floating portion was supported by the primary and secondary air bottles cantilevered by flow tubes from external supply manifolds. The primary air bottle was guided by front and rear bearings. The secondary air passed through hollow crossover struts at station 100.66 to the annulus formed between the primary nozzle and the shroud. Since the primary and secondary flows enter the floating portion of the model support system normal to the force measurement axis, the entry momentum of the internal flows can be neglected in the cal-

culation of thrust. Therefore the load cell measured only the internal nozzle forces, the external pressure and viscous forces downstream of the skin break, and a tare force.

A static calibration of the thrust-measuring system was obtained by applying known forces to the nozzle and measuring the output of the load cell. A water-cooled jacket surrounded the load cell and maintained a constant temperature of 90° F (305.6 K) to eliminate errors in the calibration due to variations in temperature from aerodynamic heating.

The tertiary door and secondary flap positions were determined by measuring the angles from movies taken during the test runs.

Nozzle Configurations

Two basic variable nozzle configurations were tested, differing only in primary nozzle area. The small nozzle provided a throat to nacelle area ratio of 0.185 and simulated nonafterburning operation for subsonic acceleration and subsonic and supersonic cruise. The large nozzle had an area ratio of 0.261 and simulated afterburner-on operation for takeoff and transonic and supersonic acceleration and simulated low power operation for idle descent.

Each primary nozzle had 16 tabs that are used during reverse thrust operation. In practice the primary nozzle translates downstream to seal against the secondary nozzle and the primary leaves and tabs close to block the primary flow thereby directing it upstream through the tertiary doors. During forward thrust operation the tabs are in a position to provide some guidance to the flow expansion. An air guide is provided in the secondary annulus to direct some of the cooling flow over the leaves of the primary nozzle.

The ejector shroud had 16 single hinge auxiliary inlet doors on the 3° 23-minute fixed boattail portion of the model and 16 floating secondary flaps. The three doors at the 2, 6, and 10 o'clock locations were fixed in the closed position to simulate an installed condition within a wing structure, and the remaining 13 unsynchronized doors were free to float to admit tertiary air. The secondary flaps could reduce the exit area by 38 percent and were made up of leaves and seals which were free to float for the aerodynamic adjustment of exit area with pressure ratio. The juncture radius of the flaps was approximately 0.029 of the maximum model diameter. In figure 3 the flaps are shown in the open and closed positions. Figure 4 shows the auxiliary inlet area variation as a function of the tertiary door angle. With the 13 doors fully open, the auxiliary inlet area to small primary throat area ratio was 0.935.

Between the tertiary doors are hollow support beams which duct a portion of the secondary flow into the secondary flap cavity. This flow simulated that required for

film cooling of the shroud and exited through two internal annular slots on the flaps with exit areas that were 1.94 and 0.86 percent of the maximum model area. At low pressure ratios it was anticipated that this flow would pressurize this cavity to aid in closing the flaps. Basic nozzle dimensions, contour coordinates and static pressure instrumentation are shown in figures 5(a) to (h) and the variation of nozzle area ratio with boattail angle for the two primary throat areas is shown in figure 5(i).

In an effort to improve subsonic cruise performance, the small primary configuration was modified and retested at increased secondary flow rates in an attempt to force the flaps closed, thereby reducing the overexpansion losses. These modifications are shown in the following sketch.

(1) Plugged actuator link slots
(2) Plugged air guide holes previously open for door movement
(3) Door stops now on air guide
(4) Capability of fixing doors maximum open
(5) Capability of plugging air guide slot (all secondary flow through beams and secondary nozzle)
Configuration	Modifications
Nonafterburning 1	1, 2, and 3
Nonafterburning 2	1 to 4
Nonafterburning 3	1, 2, 3, and 5

Configuration 1 had the actuator link slots and the air guide holes plugged to prevent leakage and to direct more of the secondary flow through the beams into the secondary flap cavity where it could only exit through the annular cooling slots. If this higher flow rate increased the cavity pressure, it would tend to close the flaps. Configuration 2 was the same as configuration 1 but also had the tertiary doors fixed in the maximum open position. Configuration 3 was the same as configuration 1, but the air guide annulus was also plugged to force all the secondary flow through the beams and into the secondary flap cavity.

Nozzle Instrumentation

The model instrumentation is shown in parts of figure 5 and in figure 6(a). The primary and secondary total pressures were obtained by the use of total pressure probes as shown. The average primary total pressure was calculated from the integrated average pressure of each rake. Typical profiles are shown in figures 6(b) and (c).

Procedure

Nozzle performance was obtained over a range of pressure ratios and Mach numbers. The schedule shown in figure 7 was used as a guide for setting pressure ratio over the range of Mach numbers from 0 to 2.0 for each power setting. At each Mach number, data were taken at several nozzle pressure ratios near the values shown on the schedule. Since tunnel static pressure was fixed at a given Mach number, the nozzle pressure ratio was varied by changing the nozzle-inlet pressure. The maximum pressure ratio at each Mach number was restricted due to the limitations of the primary air supply. At each pressure ratio, corrected secondary weight flow ratio was varied up to a maximum of 0.06 of the primary flow for all power settings with the exception of idle descent where the corrected secondary weight flow ratio was set at approximately 0.14.

Data Reduction

Both primary and secondary flow rates were measured by means of standard ASME flowmetering orifices located in the external supply lines and the primary orifice was calibrated with an ASME nozzle of known discharge coefficient. Thrust-minus-drag measurements were obtained from a load cell readout of the axial forces acting on the floating portion of the model. Internal tare forces, determined by internal areas and measured pressures located as shown in figure 1, were accounted for in the thrust

calculation.

The only external friction drag charged to the nozzle was that downstream of station 136.90 shown in figure 1. That force acting on the portion of the nozzle between station 93.65 and 136.90 was also measured on the load cell, but was not considered to be part of the nozzle drag. Its magnitude was estimated using the semi-empirical flat-plate mean skin friction coefficient given in figure 6 of reference 5 as a function of free-stream Mach number and Reynolds number. The coefficient accounts for variations in boundary-layer thickness and profile with Reynolds number. Previous measurements of the boundary-layer characteristics at the aft end of this jet exit model in the 8- by 6-Foot Supersonic Wind Tunnel (fig. 5 in ref. 6), indicated that the profile and thickness were essentially the same as that computed for a flat plate of equal length. It also showed that the average momentum thickness to model diameter ratio was 0.019 for the range of Mach numbers investigated. The strut wake appeared to affect only a localized region near the top of the model and resulted in a slightly lower local free-stream velocity than measured on the side and bottom of the model. Therefore, the results of reference 5 were used without correction for three-dimensional flow effects or strut interference effects. The resulting correction was applied to the load-cell force.

The ideal gross thrust for each of the primary and secondary flows was calculated from the measured mass flow rate expanded from their measured total pressures to p_0. Provision was made to equate the ideal thrust of the secondary flow to zero if the total pressure was less than p_0. Nozzle efficiency is defined then as the ratio of the gross thrust-minus-drag to the ideal gross thrust of both primary and secondary flows:

$$\text{Nozzle efficiency} = \frac{F - D}{F_{ip} + F_{is}}$$

In addition, nozzle gross thrust coefficients, $(F - D)/F_{ip}$, are also presented.

RESULTS AND DISCUSSION

Nozzle Performance for Typical Flight Pressure Ratio Schedule

The auxiliary inlet ejector nozzle was tested with two primary nozzles to simulate afterburning and nonafterburning operation. Each configuration was tested over a range of nozzle pressure ratios and Mach numbers corresponding to a typical schedule for a supersonic turbojet engine (fig. 7). A summary of the performance characteristics over a range of free-stream Mach numbers at several simulated power settings is shown in figure 8. The corrected secondary weight flow ratio of 0.04 was selected as a basis for

comparison at all flight Mach numbers except at supersonic cruise where a flow ratio of 0.02 was selected.

The band of tunnel interference shown in the figures was a result of the terminal shock movement over the model. In free flight the flow field near the front of an ogive cylinder creates a terminal shock that moves aft rapidly with increasing flight speed and disappears downstream at speeds slightly above Mach 1. In a tunnel installation, however, large models retard the aft movement of the terminal shock. Therefore, the resultant boattail pressure drag can be influenced by tunnel installation effects particularly at speeds where the terminal shock is near the boattail. A more detailed discussion of this phenomenon is covered in reference 7.

At takeoff conditions it can be seen in figure 8(a) that high efficiencies of 0.980 and 0.982 were obtained with the large and small primary nozzles, respectively. In figures 8(b) and (c) it can be seen that the flaps were fully closed at this condition and the doors were fully open. As indicated in figure 8(d) secondary flow pumping was marginal at afterburning conditions since a secondary pressure equal to free-stream pressure was needed for a corrected secondary flow ratio of 0.04. Later figures show that corrected secondary flow ratios of 0.02 and 0 are obtained with secondary total pressures equal to 96.5 and 95 percent of the ambient pressure. For the nonafterburning condition a corrected secondary flow ratio of 0.04 was obtained with a secondary total pressure equal to 96.7 percent of the ambient pressure.

For afterburning acceleration, figure 8(c) shows that the doors were closed at speeds above Mach number 0.85, and figure 8(b) shows that the flaps were fully open at speeds above Mach 1.5. This permitted the nozzle to operate near the fully expanded condition, and figure 8(a) shows that the nozzle efficiency was high throughout the acceleration speed range. The efficiency was lowest in the transonic range where the flaps were still partially closed and the boattail drag was high.

For the small primary configuration, figure 8(a) indicates that performance was very sensitive to nozzle pressure ratio as it was reduced from the acceleration value to typical subsonic cruise values. For example at Mach 0.85 or 0.90, reducing the pressure ratio from 5 or more, typical of acceleration, to about 4.2 caused about a 3-percent loss in efficiency. A further drop in pressure ratio to about 3.2 reduced the efficiency by an additional 2 to 3 percent to a value of about 87 percent. Figure 8(b) shows that the flaps tended to float further open at lower pressure ratios. As the pressure ratio was reduced from 4.20 to 3.27, the nozzle area ratio increased from 2.38 to 2.93. This increased the internal expansion and probably contributed to the reduction in efficiency. Figure 8(c) indicates that the tertiary doors were only slightly more than half open at a pressure ratio of 4.2. When the pressure ratio was reduced to 3.2 they opened further at a Mach number of 0.85, but remained at the same position at Mach 0.90. At these same conditions the secondary total pressure was a little less than ambient pressure

indicating that internal drag forces existed. This also would provide easy pumping of the secondary flow.

The small primary was also operated at Mach 2.0, the maximum wind tunnel speed, and near the design pressure ratio of 29.0 to obtain an approximate indication of supersonic cruise operation. With the difference in external flow effects between Mach 2.0 and 2.7 being relatively minor, the data are shown in the summary figure at Mach 2.7 the supersonic cruise Mach number. A nozzle efficiency of 0.971 was obtained at this condition with a pressure ratio of 27.6.

Floating Flap Position

The variation of boattail angle with nozzle pressure ratio over a range of Mach numbers is shown in figure 9. For the nonafterburning configuration (fig. 9(a)) the boattail angle was sensitive to free-stream Mach number and nozzle pressure ratio. At pressure ratios below 4.5, the flaps showed a stronger tendency to open as the free-stream Mach number increased from 0 to 0.9. This was probably responsible for the performance degradation at subsonic cruise conditions. With the doors and flaps closed the fully expanded nozzle pressure ratio is about 13.0. At subsonic Mach numbers, the boattail was closed at pressure ratios from 4.5 up to the maximum value tested of 7.0. However, at the supersonic Mach numbers, the flaps began opening between pressure ratios of 6 and 7 and were fully open at pressure ratios greater than 20.0. Supersonic flow over the boattail apparently reduced boattail pressures which resulted in an opening moment in spite of the internal overexpansion of the flow.

With the afterburning configuration (fig. 9(b)), the design pressure ratio with the flaps closed was about 7.0. The flaps began opening at pressure ratios near 6.0 for the supersonic Mach numbers and were fully open at nozzle pressure ratios greater than 10.5. At the subsonic Mach numbers the flaps opened at pressure ratios less than 2.5 and remained closed to the maximum pressure ratio tested (6.5). In addition to being sensitive to free-stream Mach number and nozzle pressure ratio, this configuration was also affected by the variations in corrected secondary flow rates up to 0.06 as indicated by the data band at a given Mach number and pressure ratio. In general, this occurred only at the transonic Mach numbers where the flaps were between the stops. Increases in secondary flow tended to close the flaps by pressurizing the cavity between the internal and external surfaces.

The flaps were stable at all simulated power settings and free-stream Mach numbers. The flaps had no friction built into their design other than that inherent in the linkage, and it was quite small.

Tertiary Door Position

The variation of tertiary door position with pressure ratio and Mach number is shown in figure 10. For the nonafterburning configuration (fig. 10(a)) the doors were generally closed at pressure ratios greater than 6.0. For the afterburning configuration (fig. 10(b)), they were closed at pressure ratios greater than 4.0. As will be seen in later figures, these pressure ratios correspond to the nozzle pumping characteristics providing secondary total pressures about equal to free-stream static pressure.

Small Primary Nozzle Performance

Nozzle efficiency and pumping characteristics at various Mach numbers from 0 to 1.97 and for a range of pressure ratios are shown in figure 11 for the nonafterburning configuration. Also presented on the figure is the boattail angle (when available) and whether the tertiary doors were full open (open symbols), in-travel (half-solid symbols) or closed (solid symbols). Tails on the performance points indicate that the secondary total pressure was less than free-stream static pressure ($P_s < p_0$) and, therefore, the secondary stream ideal thrust was set to zero. At conditions where the nozzle was charged with the ideal thrust of the secondary flow ($P_s > p_0$), peak efficiency generally occurred at a corrected secondary weight flow ratio of about 0.04; otherwise, the efficiency increased with secondary flow until P_s became larger than p_0, and the nozzle was then charged with the ideal secondary thrust.

At takeoff (fig. 11(a)) the nozzle operated with the doors full open and the flaps fully closed and obtained a relatively high efficiency at all pressure ratios. However, with subsonic external flow (figs. 11(b) to (f)) the performance was reduced below these high values. Typical nozzle operation with external flow can be seen in figure 11(e) at Mach 0.85. The tertiary doors never fully opened, even at a pressure ratio of 2.14. By comparing the solid symbols (doors closed) with the tailed symbols ($P_s < p_0$) it can be seen that the doors closed whenever the secondary total pressure became slightly larger than free-stream static pressure. Thus the doors closed at a pressure ratio of 6 to 7 which was about 1/2 the fully expanded pressure ratio with the boattail closed. At pressure ratios appropriate for subsonic cruise (3.20 and 4.25), secondary total pressure was less than the free-stream static value as indicated by the tailed symbols, and this caused low pressures in the region of the primary nozzle base.

These low internal pressures can be seen in table I which presents listings of the static pressures at various conditions from Mach 0 to 0.9. At Mach numbers 0.85 and 0.9, and with subsonic cruise pressure ratios, the internal nozzle static pressures in the primary base region averaged about 5 percent less than free-stream static pressure,

indicating relatively high drag forces. Pressures on the 3° fixed boattail indicated that little drag existed in this region, but static pressures on the floating boattail indicated drag on the outer portion of it. However, the 3° boattail pressures may be somewhat misleading since the orifice was located directly downstream of a tertiary door and may not be representative of the average boattail pressure. At a higher pressure ratio (7.29) when the doors are closed (table I(c)) the 3° boattail statics indicated a lower pressure and thus a higher drag. These lower pressures could also exist in between doors when the doors are open. At this same nozzle pressure ratio, table I(c) also shows internal pressures in the primary nozzle base region which were above free-stream static pressure indicating internal thrust at this condition.

A limited amount of data were taken for the nonafterburning configuration at Mach numbers 1.20 and 1.47. These efficiencies are shown in figure 12 as a function of nozzle pressure ratio for a corrected secondary weight flow ratio of 0.06. A summary of the effect of nozzle pressure ratio on nozzle efficiency for a constant corrected secondary weight flow ratio of 0.04 is shown in figure 13 for various Mach numbers. The nozzle gross thrust coefficients for various Mach numbers and nozzle pressure ratios are shown in figure 14.

Large Primary Nozzle Performance

The nozzle efficiency and pumping characteristics at various Mach numbers and pressure ratios are given in figure 15 for the afterburning primary nozzle. The nozzle efficiency generally peaked between 0.04 and 0.06 corrected secondary weight flow ratio. The nozzle efficiency was generally 3 percent better than the nonafterburning configuration due to a reduction in overexpansion losses. In addition the primary thrust was larger thereby reducing the relative effect of boattail drag on performance.

Because of the small number of data points taken at the idle descent power setting and because of the random variations in secondary flow at this power setting, the idle descent performance is listed separately in table II.

The effect of nozzle pressure ratio on nozzle efficiency for a constant corrected secondary weight flow ratio of 0.04 is shown in figure 16 for various Mach numbers. The nozzle gross thrust coefficients for various Mach numbers and nozzle pressure ratios are shown in figure 17.

Nozzle Pumping Characteristics

The pressure recovery requirements for the secondary system are shown in figure 18. At subsonic cruise power settings (fig. 18(a)), the secondary total pressure

required for a corrected secondary weight flow ratio of 0.04 was only 0.55 of the free-stream total pressure at Mach 0.9. At subsonic speeds with higher power settings the pressure recovery became a little more critical. For example, with the nonafterburning acceleration power setting at Mach 0.41 (fig. 18(b)), a secondary total pressure of 0.88 of free-stream total pressure was required for a corrected secondary weight flow ratio of 0.04. These pumping curves were relatively flat and reduced secondary flow rates would not affect the pressure recovery requirements appreciably. For the afterburning acceleration power setting at Mach 0.9 (fig. 18(c)), a secondary total pressure of 0.70 of free-stream total pressure was required for a corrected secondary weight flow ratio of 0.04. At takeoff, secondary flow pumping was marginal. A secondary pressure equal to free-stream pressure was needed to pump a secondary flow ratio of 0.04. Corrected secondary weight flow ratios of 0.02 and 0 were obtained with secondary total pressures equal to 96.5 and 95 percent of the ambient pressure. Results obtained at Mach 1.97 are shown in figure 18(d).

Nozzle Modification

As discussed earlier the nonafterburning configuration was modified and tested at increased corrected secondary flow rates of up to 0.16 in an attempt to force the flaps closed at subsonic cruise conditions, thereby reducing the overexpansion losses. The resulting boattail angles as a function of nozzle pressure ratio are presented in figure 19. Comparing the solid and open symbols in figure 19, it can be seen that the configuration changes did not significantly affect the boattail angle. At the subsonic cruise Mach numbers the flaps were still partially open at pressure ratios below approximately 4.5.

The nozzle efficiency and pumping characteristics for the three modified configurations are shown in figures 20 to 22 for the Mach numbers investigated. In general, configurations 1 and 2 performed in a similar manner. At Mach 0.4 nozzle efficiency was improved from 1 to 2 percent. At the subsonic cruise Mach numbers the efficiency was the same or less than the unmodified nonafterburning configuration. Configuration 3 had much lower nozzle efficiency at all three Mach numbers. This configuration, with the annular air guide slot plugged, was tested primarily to determine whether directing all of the secondary flow into the secondary flap cavity would pressurize the cavity enough to close the flaps at subsonic cruise. However, there was no appreciable change in the flap position.

SUMMARY OF RESULTS

An experimental investigation was conducted to determine the performance charac-
teristics of an auxiliary inlet ejector with aerodynamically positioned tertiary doors and
secondary flaps at Mach numbers from 0 to 2.0. Two primary nozzles were tested: a
small nozzle with a throat to nacelle area ratio of 0.185 to simulate a configuration for
subsonic and supersonic cruise and nonafterburning acceleration, and a large nozzle
with a throat to nacelle area ratio of 0.261 to simulate a configuration for afterburning
takeoff and acceleration and for idle descent. The following general trends were indi-
cated:

1. At takeoff nozzle efficiencies of 0.980 and 0.982 were obtained with the large and
small primary nozzles at pressure ratios near 3.0. The flaps were fully closed and the
doors fully open. Secondary flow pumping was marginal for the large primary since a
secondary pressure equal to free-stream pressure was needed to pump a corrected sec-
ondary weight flow ratio of 0.04.

2. At subsonic cruise both nozzle performance and floating flap position were sensi-
tive to nozzle pressure ratio. At Mach 0.9 increasing pressure ratio from 3.27 to 4.20
increased nozzle efficiency about 2 percent to 0.888 and decreased the nozzle area ratio
from 2.93 to 2.38.

3. At Mach 2.0 and with a nozzle pressure ratio of 27.6, the small primary nozzle
had an efficiency of 0.971 with the flaps fully open and the doors fully closed.

4. The aerodynamically positioned flaps (which could reduce the exit area by 38 per-
cent) were stable at all simulated power settings and free-stream Mach numbers. The
flaps were fully open at pressure ratios greater than 20 for the small primary and at
pressure ratios greater than 10.5 for the large primary. At lower pressure ratios the
floating position was sensitive to free-stream Mach number and to secondary flow.
Free-stream effects were most prominent at subsonic speeds at pressure ratios less
than 4.0.

5. For a typical trajectory the flaps would be closed at takeoff and during subsonic
acceleration. The flaps begin to open at Mach 1.0 and are fully opened at Mach numbers
of 1.47 and above.

6. The auxiliary inlets were open at takeoff and partially open at subsonic cruise.
During acceleration the inlets were closed at speeds above Mach 0.8.

Corrected secondary weight flow ratio, $\omega \sqrt{\tau}$

(d) Free-stream Mach number, 0.9.

(e) Free-stream Mach number, 1.0. Signifi-cant tunnel disturbances present.

(f) Free-stream Mach number, 1.09. Signifi-cant tunnel disturbances present.

Figure 15. – Continued.

(g) Free-stream Mach number, 1.20.

(h) Free-stream Mach number, 1.47.

(i) Free-stream Mach number, 1.77.

Figure 15. - Concluded.

41

Figure 16. – Nozzle efficiency of afterburning configuration as function of nozzle pressure ratio for corrected secondary weight flow ratio of 0.04.

(a) Free-stream Mach number, 0.

(b) Free-stream Mach number, 0.4.

(c) Free-stream Mach number, 0.85.

(d) Free-stream Mach number, 0.90.

(e) Free-stream Mach number, 1.0. (Significant tunnel disturbances.)

(f) Free-stream Mach number, 1.09. (Significant tunnel disturbances.)

(g) Free-stream Mach number, 1.20.

(h) Free-stream Mach number, 1.47.

(i) Free-stream Mach number, 1.77.

Figure 17. - Nozzle gross thrust coefficient as function of corrected secondary weight flow ratio for large primary.

43
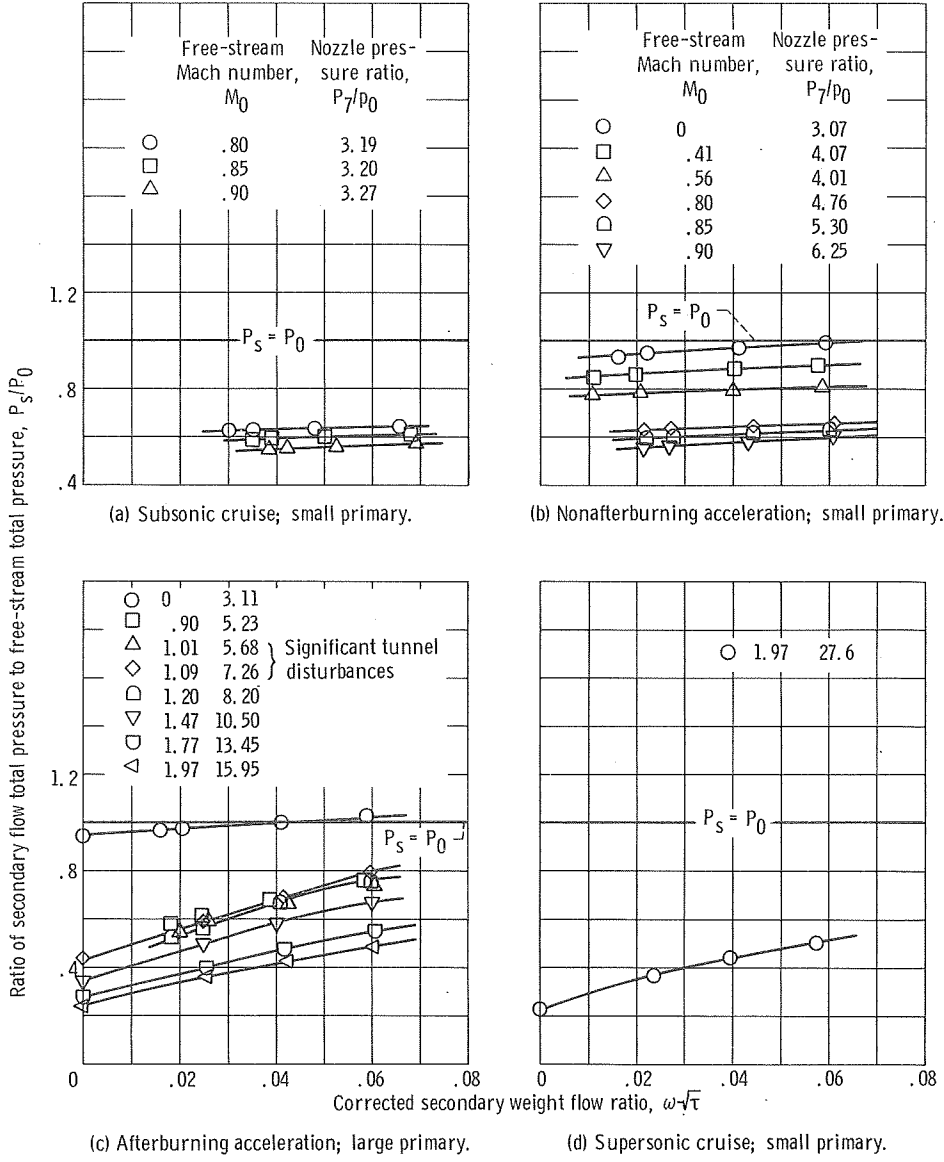

Figure 18. - Secondary flow pressure recovery requirement for various free-stream Mach numbers.

Free-stream
Mach number,
M_0

□ 0.40
◁ .85
◇ .90

Open symbols denote modi-
fied configuration
Solid symbols denote orig-
inal configuration
(a) Configuration 1.

(b) Configuration 2.

(c) Configuration 3.

Nozzle pressure ratio, P_7/p_0

Boattail angle, β, deg

Figure 19. – Variation of boattail angle with nozzle pressure ratio for modified nonafterburning configurations.

Figure 20. - Nozzle efficiency and pumping characteristics as function of corrected secondary weight flow ratio for modified nonafterburning configuration 1. Doors fully open.
(a) Free-stream Mach number, 0.40.

(b) Free-stream Mach number, 0.85.
(c) Free-stream Mach number, 0.9.

Figure 21. - Nozzle efficiency and pumping characteristics as function of corrected secondary weight flow ratio for modified nonafterburning configuration 2. Doors fully open.

47

Figure 22. - Nozzle efficiency and pumping characteristics as function of corrected secondary weight flow ratio for modified nonafterburning configuration 3. Doors fully open.

FIRST CLASS MAIL

*"The aeronautical and space activities of the United States shall be
conducted so as to contribute . . . to the expansion of human knowl-
edge of phenomena in the atmosphere and space. The Administration
shall provide for the widest practicable and appropriate dissemination
of information concerning its activities and the results thereof."*

— NATIONAL AERONAUTICS AND SPACE ACT OF 1958

NASA SCIENTIFIC AND TECHNICAL PUBLICATIONS

TECHNICAL REPORTS: Scientific and
technical information considered important,
complete, and a lasting contribution to existing
knowledge.

TECHNICAL NOTES: Information less broad
in scope but nevertheless of importance as a
contribution to existing knowledge.

TECHNICAL MEMORANDUMS:
Information receiving limited distribution
because of preliminary data, security classifica-
tion, or other reasons.

CONTRACTOR REPORTS: Scientific and
technical information generated under a NASA
contract or grant and considered an important
contribution to existing knowledge.

TECHNICAL TRANSLATIONS: Information
published in a foreign language considered
to merit NASA distribution in English.

SPECIAL PUBLICATIONS: Information
derived from or of value to NASA activities.
Publications include conference proceedings,
monographs, data compilations, handbooks,
sourcebooks, and special bibliographies.

**TECHNOLOGY UTILIZATION
PUBLICATIONS:** Information on technology
used by NASA that may be of particular
interest in commercial and other non-aerospace
applications. Publications include Tech Briefs,
Technology Utilization Reports and Notes,
and Technology Surveys.

Details on the availability of these publications may be obtained from:
