Abstract The absence of laminin α2 chain causes muscle cell degeneration and peripheral dysmyelination in congenital muscular dystrophy patients and dy mice, suggesting its role in the maintenance of sarcolemmal architecture and peripheral myelinogenesis. Here we demonstrate the secretion of laminin α2 chain in cerebrospinal fluid (CSF). Laminin α2 chain was detected as a minor component of the total CSF proteins or glycoproteins. Laminin α2 chain was localized in the cytoplasm of epithelial cells of choroid plexus, suggesting active secretion. Our results suggest that immunochromatographic analysis of CSF laminin α2 chain could be useful as an aid for the diagnosis of congenital muscular dystrophy.

Key words: Laminin α2 chain; Laminin-2; Cerebrospinal fluid; Congenital muscular dystrophy; dy mouse

1. Introduction

Laminin, a heterotrimer made up of three chains of classes α, β, and γ, is a major component of the basal lamina (for review see [1,2]). Laminin has numerous biological functions in cell differentiation, adhesion, migration, and proliferation, in addition to being a true structural component of the basal lamina meshwork [2]. Each class of laminin chains has multiple isoforms and laminin exists in numerous trimeric isoforms in different tissues [1,2]. Laminin-2, comprised of the α2, β1 and γ1 chains, is expressed in the basal lamina of striated muscle cells, Schwann cells and trophoblasts [2–5]. Recently, the absence of laminin α2 chain was identified as the cause of muscle cell degeneration and peripheral dysmyelination in congenital muscular dystrophy (CMD) and its animal model dy mice [6–12]. Since laminin-2 is a ligand of dystroglycan in both striated muscle and Schwann cell membranes [5,7,13], these findings implicate the laminin-2–dystroglycan interaction in not only the maintenance of sarcolemmal architecture but also peripheral myelinogenesis. Thus far, it is unknown if laminin α2 chain is secreted into body fluids such as cerebrospinal fluid (CSF). If this is the case, immunochromatographic analysis of laminin α2 chain in body fluids could be useful as an aid for the diagnosis of CMD, because it is reasonable to suspect that laminin α2 chain is absent in the body fluids of CMD patients. We have addressed this issue in the present study.

2. Materials and methods

2.1. Immunochromatographic analysis of CSF proteins

CSF was obtained from several humans who had no abnormalities in the CSF composition as determined by routine laboratory analyses, including cell count and total protein concentration. After particulates were cleared by brief centrifugation, 2 ml of CSF from each individual was concentrated by centrifugal concentrator (Tomy CC-101). CSF concentrates were separated by 3−12% SDS-PAGE and analyzed by immunoblotting.

2.2. Isolation of wheat germ agglutinin (WGA)-binding glycoproteins from CSF

100 µl of WGA-Sepharose (Pharmacia) was equilibrated with buffer A (50 mM sodium phosphate pH 7.4, 0.5 M NaCl, 0.1 mM phenylmethylsulfonyl fluoride and 0.75 mM benzamidine) and then incubated, overnight at 4°C, with 2 ml of human CSF in the presence of 0.5 M NaCl. After extensive wash with buffer A, WGA-Sepharose was eluted with 300 µl of buffer A containing 0.3 M N-acetylglucosamine (GlcNAc). The eluates were separated by 3−12% SDS-PAGE and analyzed by immunoblotting.

2.3. SDS and EDTA extraction of proteins from choroid plexus and spinal roots

Bovine choroid plexus and spinal roots were obtained at a local abattoir and quick frozen in isopentane cooled in liquid nitrogen. For SDS extraction, cryosections from choroid plexus and spinal roots were homogenized in 20 vols. of SDS extraction buffer (10% SDS, 80 mM Tris-HCl pH 6.8, 115 mM sucrose, 1% β-mercaptoethanol, 1 mM phenylmethylsulfonyl fluoride and 1 mM benzamidine) and then incubated for 15 min at 60°C. For EDTA extraction, cryosections from choroid plexus and spinal roots were homogenized in 20 vols of EDTA extraction buffer (10 mM EDTA, 50 mM Tris-HCl pH 7.5, 150 mM NaCl, 1 mM phenylmethylsulfonyl fluoride and 0.75 mM benzamidine) and then incubated for 2 h at 4°C. After insoluble debris were cleared by brief centrifugation, supernatants were separated by 3−12% SDS-PAGE and analyzed by immunoblotting.

2.4. Others

Immunohistochemical analysis, 3−12% SDS-PAGE and immunoblotting were performed as previously described [5]. Monoclonal antibody 2D9 against the proximal portion of the G domain of human laminin α2 chain was characterized previously [14]. Antibody against mouse EHS sarcoma laminin was purchased from Sigma. Peroxidase-labeled WGA was purchased from Boehringer-Mannheim.

3. Results and discussion

Human CSF was analyzed by SDS-PAGE and immunoblotting. Antibody against mouse EHS sarcoma laminin detected two bands in the range of 200 kDa corresponding to laminin β1 and γ1 chains, but did not detect laminin α1 chain (Fig. 1). The results suggest that laminin α1 chain is not present in CSF. Although a possibility cannot be excluded that the antibody did not react with human laminin α1 chain. Instead, monoclonal
antibody 2D9 detected laminin α2 chain of 400 kDa (Fig. 1). The bands corresponding to laminin α2, β1 and γ1 chains could not be identified in the SDS gel stained with Coomassie blue (Fig. 1), indicating that these proteins were not major components of the total CSF proteins. The same results as shown in Fig. 1 were obtained for all the CSF samples tested.

To know the relative abundance of laminin α2 chain in the CSF glycoproteins, we isolated WGA-binding glycoproteins from human CSF by WGA chromatography. The GlcNAc eluates of WGA-Sepharose were analyzed by SDS-PAGE and immunoblotting. Although immunoblot analysis demonstrated that CSF laminin α2 chain was recovered in the GlcNAc eluates, the band corresponding to laminin α2 chain was not identified in the SDS gel stained with Coomassie blue or the nitrocellulose transfer stained with peroxidase-labeled WGA (Fig. 2), indicating that laminin α2 chain was not a major component of the total CSF glycoproteins.

To see if laminin α2 chain is secreted by choroid plexus, we performed immunohistochemical analysis. Immunoreactivity for laminin α2 chain was clearly detected in the cytoplasm of epithelial cells of choroid plexus (Fig. 3). To confirm the expression of laminin α2 chain in choroid plexus, we performed immunoblot analysis. Previously, laminin α2 chain was shown to be extracted from skeletal muscle by EDTA [7,9]. Similar to skeletal muscle, laminin α2 chain was detected in not only the SDS but also EDTA extracts of choroid plexus (Fig. 4). All together, these findings suggest that laminin α2 chain is actively secreted by choroid plexus.

It is unlikely that CSF laminin α2 chain originates from cells or connective tissue debris present in CSF for the following reasons: (1) CSF contains very few cells; (2) the vast majority of CSF cells are leukocytes which do not produce laminin α2 chain; and (3) immunoreactivity for laminin α2 chain was not detected in the leptomeninges and connective tissues surrounding subarachnoid space by immunohistochemistry (not shown). Although immunoreactivity for laminin α2 chain was detected in the basal lamina of Schwann cells of spinal roots (Fig. 3), the fact that leptomeninges and connective tissues densely surround bundles of spinal root nerve fibers in vivo makes it unlikely that Schwann cells secrete laminin α2 chain into CSF. Interestingly, the molecular weight of laminin α2 chain differed between choroid plexus and spinal roots (Fig. 4). Differential splicing of mRNA or protein glycosylation may be responsible for this finding. The latter possibility is of interest in view of the hypothesis that differential glycosylation of proteins may play a role in the sorting mechanism for apical or basolateral secretory pathway [15].
Laminin assembles to form a reversible polymer that contributes to the network structure of the basal lamina (for a review see [16]). Currently, the three-arm interaction model for laminin-network formation proposes that the N-terminal moieties of each of the short arms of laminin form the basic bond of laminin polymers [16]. Once incorporated into the basal lamina, laminin has numerous biological functions in cell differentiation, adhesion, migration and proliferation (for a review see [2]). In particular, laminin-2, comprised of the α2, β1 and γ1 chains, plays important roles in the maintenance of sarcolemmal architecture and peripheral myelinogenesis [3–13, 17, 18]. In the present study, we have demonstrated the secretion of laminin α2 chain, most likely in the form of laminin-2 heterotrimer, into CSF. Our results thus indicate that laminin also exists in a free form, not incorporated into polymers, in vivo. At present, the biological functions of laminin α2 chain secreted into body fluids such as CSF are unclear and their elucidation awaits future research. It would be interesting to see if secreted laminin α2 chain has inhibitory, and potentially regulatory, effects on the binding of basal lamina laminin-2 with cell surface receptors such as dystroglycan and integrins.

Recent evidence indicates that the absence of laminin α2 chain is the primary cause of CMD [9–12]. Thus, it is reasonable to suspect that laminin α2 chain is also absent in the CSF of CMD patients. Currently, definite diagnosis of CMD is possible only by immunochemical demonstration of the absence of laminin α2 chain in skeletal muscle obtained through biopsy [9–12], which is a stressful procedure for young children. Our results suggest that immunochemical analysis of CSF laminin α2 chain could be useful as a less stressful means of diagnosis of this devastating disease.
