Abstract

Purpose: It is still technically difficult to collect high purity cancer cells from tumor tissues, which contain noncancerous cells. We hypothesized that xenograft models of NOG mice expressing enhanced green fluorescent protein (eGFP), referred to as NOG-EGFP mice, may be useful for obtaining such high purity cancer cells for detailed molecular and cellular analyses.

Methods: Pancreato-biliary cancer cell lines were implanted subcutaneously to compare the tumorigenicity between NOG-EGFP mice and nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mice. To obtain high purity cancer cells, the subcutaneous tumors were harvested from the mice and enzymatically dissociated into single-cell suspensions. Then, the cells were sorted by fluorescence-activated cell sorting (FACS) for separation of the host cells and the cancer cells. Thereafter, the contamination rate of host cells in collected cancer cells was quantified by using FACS analysis. The viability of cancer cells after FACS sorting was evaluated by cell culture and subsequent subcutaneous reimplantation in NOG-EGFP mice.

Results: The tumorigenicity of NOG-EGFP mice was significantly better than that of NOD/SCID mice in all of the analyzed cell lines ($p < 0.01$). Sorting procedures enabled an almost pure collection of cancer cells with only slight contamination by host cells. Reimplantation of the sorted cancer cells formed tumors again, which demonstrated that cell viability after sorting was well maintained.

Conclusions: This method provides a novel cancer sampling system for molecular and cellular analysis with high accuracy and should contribute to the development of personalized medicine.

Keywords: NOG-EGFP mouse, Xenograft, Cancer, Stromal cell, Separation

Introduction

Cancer xenograft models of immunodeficient mice are widely applied in various cancer research areas. Recently, xenografted human tumors are commonly used for pre-clinical drug testing, including biomarker discovery. [1,2] It has been reported that there is a close correlation between the effects in xenografts and clinical outcomes, in terms of both drug resistance and sensitivity. [3] An eventual goal of such preclinical studies using mouse

xenograft models is the realization of personalized medicine. Molecular analyses using clinical specimens or xenografted tumors are essential in research for personalized medicine, and high purity samples of sufficient volume are necessary for precise analyses. In general, mouse xenografts are superior to clinical specimens because of the abundance and renewability of the tumor samples.

Tumors consist of two components, i.e. cancer cells and stroma. Stromal cells derived from murine cells within the xenografted tumors. Even though tumor tissue acquired from patients is transplanted, human stromal cells are ultimately replaced by murine stromal cells [4].

Accordingly, contamination by stromal cells hinders precise analyses of cancer cells using tumor tissue. Although stromal cells need to be removed from tumor tissue as much as possible to obtain accurate results, it is still technically difficult to collect high purity cancer cells without contamination by stromal cells. As technologies of comprehensive analyses (e.g., high-resolution microarray, next-generation sequencing and proteomics) are progressing rapidly, high purity samples uncontaminated by stromal cells are necessary for such advanced technology. Therefore, it is very important to establish a method of separating cancer cells and stromal cells clearly and collecting cancer cells uncontaminated by stromal cells.

On the other hand, athymic nude mice, nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mice or NOD.Cg-*Prkdc^{scid} Il2rg^{tm1Sug}/ShiJic* (NOG) mice are routinely used for mouse xenograft models of cancer. Among these types of mice, NOG mice show the most severe immunodeficient state. Machida and colleagues have reported that NOG mice have higher susceptibility to xenografted tumors than other immunodeficient mice [5]. Thus, NOG mice are very useful for the transplantation of tumor tissue.

In 2008, Niclou and colleagues reported that NOD/SCID mice with ubiquitous expression of enhanced green fluorescent protein (eGFP) were useful for the clear separation of tumor cells and mouse stromal cells in subcutaneous xenografted tumors by fluorescence activated cell sorting (FACS), and demonstrated that the contamination by stromal cells after the removal of eGFP-expressing cells was slight. [6] Meanwhile, Suezumi et al. generated NOG mice expressing eGFP ubiquitously (NOG-EGFP) and clarified that NOG and NOG-EGFP mice have equivalent immunodeficient states. [7] However, there are no reports to study cancer xenograft of NOG-EGFP mice.

In this study, we hypothesized that NOG-EGFP mice are potentially useful for the collection of cancer cells without contamination by stromal cells and would also have the advantage of easy engraftment. Here we compare the tumorigenicity between NOG-EGFP and NOD/SCID mice and show the degree of contamination by stromal cells after removal of eGFP-expressing cells in the xenografted tumors of NOG-EGFP mice by FACS. Furthermore, we demonstrate the viability of the collected cancer cells by cell culture and subsequent inoculation.

Materials & methods

Ethics

All animal experiments conformed to the guidelines of the Institutional Animal Care and Use Committee of Tohoku University and were performed in accordance with the Guide for the Care and Use of Laboratory

Animals of Tohoku University. The protocol was approved by the Ethics Review Committee of Tohoku University.

Animals

6 week-old female NOG-EGFP (formally, NOD.Cg-*Prkdc^{scid} Il2rg^{tm1Sug}Tg* (Act-eGFP) C14-Y01-FM1310sb/ShiJic) mice and NOG mice were kindly provided by Central Institute for Experimental Animals (Kawasaki, Japan). NOD/SCID mice were purchased from CLEA Japan, Inc. (Tokyo, Japan). Female heterozygous NOG-EGFP mice were mated with male NOG mice in order to breed the NOG-EGFP mice under the permission of Central Institute for Experimental Animals. Since their offspring were NOG mice or NOG-EGFP mice, the fluorescence of NOG-EGFP mice was confirmed by a hand-held UV lamp (COSMO BIO, Tokyo, Japan). Thereafter, NOG-EGFP mice were used in the experiments. The animals were housed under pathogen-free conditions on a 12-hour light cycle and with free access to food and water.

Cell culture

Human pancreatic cancer cell lines (MIA PaCa2 and AsPC-1) and human cholangiocarcinoma cell lines (HuCCT1 and TFK-1) were obtained from the Cell Resource Center for Biomedical Research of Tohoku University. HuCCT1, TFK-1 and AsPC-1 were cultured in RPMI-1640 media (Sigma-Aldrich, MO, USA) with 10% heat-inactivated fetal bovine serum (FBS) (SAFC Biosciences, MO, USA) and 1% penicillin/streptomycin (P/S) (Gibco/Life Technologies, CA, USA) at 37°C in an atmosphere of 5% CO₂ and 95% air. Dulbecco modified Eagle medium (DMEM) (Gibco/Life Technologies) was used for culture of MIA PaCa2 cells.

Image acquisition

We confirmed that organs and cells obtained from NOG-EGFP mice could be fluorescently visualized. In detail, after euthanizing NOG-EGFP mice, internal organs were placed on a tray and imaged using an IVIS[®] Spectrum system (Caliper Life Sciences, MA, USA). Skin fibroblasts of NOG-eGFP mice were cultured in RPMI-1640 media with 10% FBS and 1% P/S. Subsequently, cultured fibroblasts on dishes were visualized using a Keyence BZ-9000 fluorescence microscope (Keyence Corporation, Osaka, Japan).

Cell transplantation in NOG-EGFP and NOD/SCID mice

5×10^5 cells in a total volume of 100 μ l media were injected subcutaneously into each side of the lower back of 6-8-week-old NOG-EGFP mice and NOD/SCID mice. Tumor size was measured with digital calipers (A&D,

Tokyo, Japan) twice a week. Tumor volume was determined using the following formula [8]:

$$\text{tumor volume} = [\text{length} \times \text{width}^2] / 2$$

Patient-derived cancer xenografts

Resected specimens of pancreatic cancer tissue were cut into 2–3mm³ pieces in antibiotic-containing RPMI-1640 media. Under anesthesia with pentobarbital (Abbott Laboratories, IL, USA), and sevoflurane (Maruishi Pharmaceutical, Osaka, Japan), the pieces of the tumors were implanted subcutaneously into each side of the lower back in 6–8-week-old female NOG-EGFP mice. Tumors were harvested upon reaching a volume of 1,500 mm³ and provided for immunohistochemistry.

Immunohistochemistry

Subcutaneous tumors of NOG-EGFP xenografts were fixed in 10% formalin before embedded in paraffin. After blocking, immunohistochemistry for eGFP was performed using a rabbit anti-GFP (ab290, Abcam, MA USA) at a dilution of 1:1000 incubated for 1 hour at 25°C. A horseradish peroxidase (HRP)-conjugated goat anti-rabbit IgG (Nichirei Biosciences, Tokyo, Japan) was used as the secondary antibody. Peroxidase visualization was done using 3,3'-Diaminobenzidine (DAB). All techniques including H&E staining were performed by Animal Pathology Platform, Biomedical Research Core of Tohoku University Graduate School of Medicine.

Cell sorting and phenotyping of murine stromal cells

TFK-1 xenografts were used in this experiment. Freshly isolated subcutaneous tumors of NOG-EGFP mice were

dissociated by mincing the tissue with scalpels, followed by incubation in RPMI-1640 media containing collagenase (Worthington Biochemical, NJ, USA) for 30 min at 37°C. After incubation, the cell suspension was filtered through a 100- μ m cell strainer. The cells were resuspended in phosphate buffered saline (PBS) and sorted on a fluorescence-activated cell sorter (FACS Aria™ II Cell Sorter, BD Biosciences, Erembodegem, Belgium) on the basis of single-cell viability and the presence of GFP. For immunophenotyping, cells were incubated for 30 min at room temperature with conjugated antibodies against mouse CD31, CD90, CD49b, CD14, CD11c (CD31: 561410, CD90: 553007, CD49b: 553858, CD14: 560636 and CD11c: 560583, BD Biosciences) or conjugated isotype controls (APC-Cy™7 (Rat IgG1, κ)-560534, Alexa-Fluor700 (Hamster IgG, λ 1): 560555, APC (Rat IgG2a, κ): 53932, PE (Rat IgM, κ): 553943, PE-Cy™7 (Rat IgG2a, κ): 552867, BD Biosciences), as previously reported [6]. Analyses were performed on a FACS Aria™ II Cell Sorter (BD Biosciences).

Viability of sorted cancer cells

Xenografted tumors of TFK-1 cells in NOG-EGFP mice were harvested and separated into cancer cells and

stromal cells by FACS as described above. Collected TFK-1 cells were cultured on dishes and subsequently reimplanted in NOG-EGFP mice. In order to confirm the effect of removal of eGFP-expressing cells, the subcutaneous tumors of TFK-1 cells were provided for primary cell culture without FACS sorting as a control.

Statistical analysis

Data were presented as the mean \pm S.E. Statistical significance was determined by Mann-Whitney *U* test performing using GraphPad Prism for Windows version 5.02. Differences between experimental groups were considered significant when the *p*-value was <0.05 .

Results

Confirmation of eGFP expression in NOG-EGFP mice

Green fluorescence was detected in the NOG-EGFP mice by a hand-held UV lamp (Figure 1A). Almost all internal organs showed green fluorescence in the imaging instrument (Figure 1B). The fluorescence of skin fibroblasts was visible using a fluorescence microscope (Figure 1C). Histological findings revealed eGFP-expressing cells (shown as DAB-positive cells in Figure

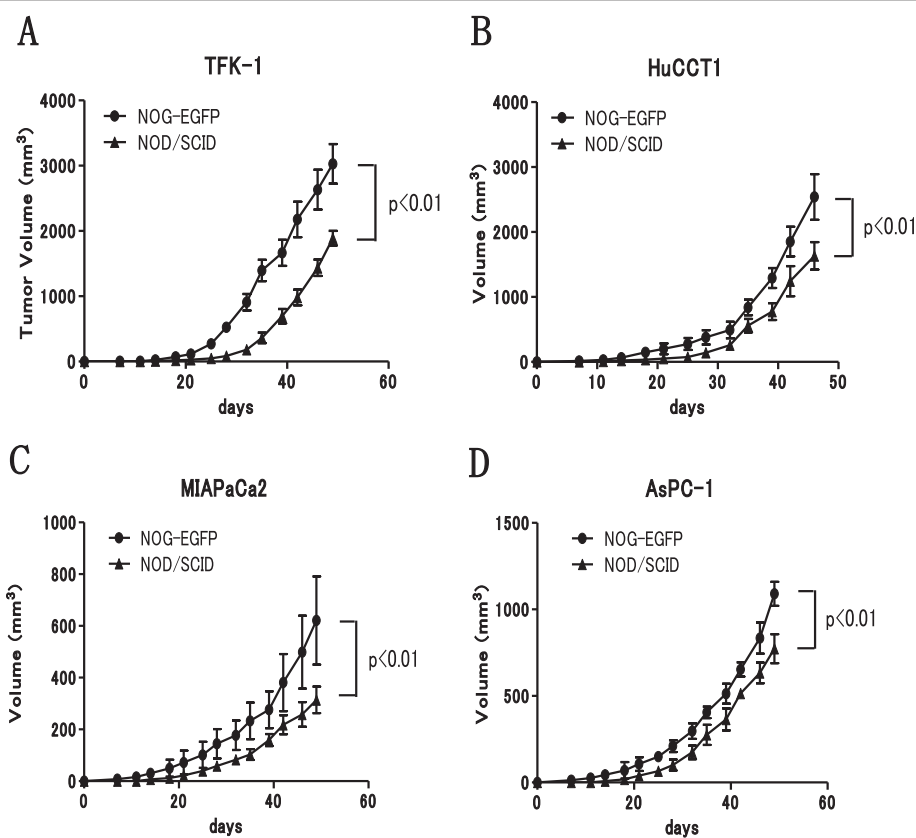

Figure 2 Tumorigenicity was compared between NOG-EGFP mice and NOD/SCID mice using the pancreato-biliary cancer cell lines.

A) TFK-1, B) HuCCT1, C) MIAPaCa2 and D) AsPC-1. A total of 5.0×10^5 cells was injected into each mouse ($n = 6$). ** denotes $P < 0.01$. NOG-EGFP mice showed a significantly higher tumorigenic potential than that of NOD/SCID mice in all cell lines ($p < 0.01$).

1Db and fluorescent cells in Figure 1Dc) in the stroma of the xenografted tumors, whereas cancer cells did not show eGFP expression (Figure 1Db-c). Based on the findings mentioned above, expression of eGFP on NOG-EGFP mice was confirmed.

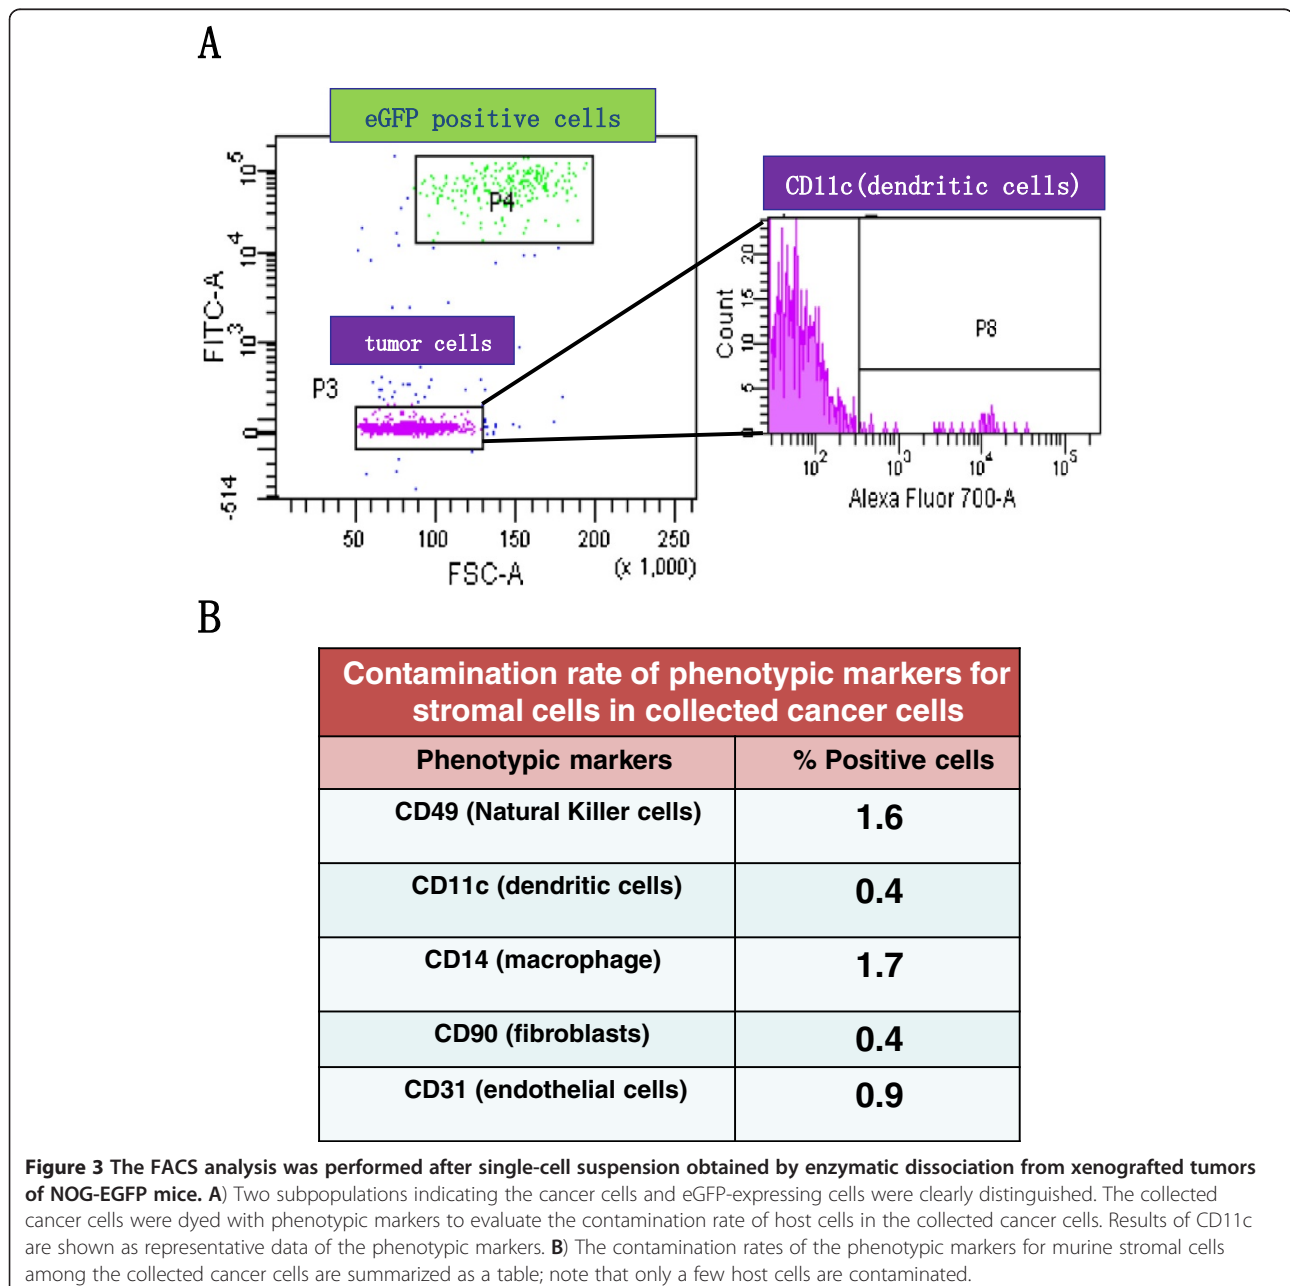

Comparison of tumorigenic potential between NOG-EGFP and NOD/SCID mice

Human pancreatic cancer cell lines (MIA PaCa2 and AsPC-1) and human cholangiocarcinoma cell lines (TFK-1 and HuCCT1) were inoculated into NOG-EGFP mice and NOD/SCID mice for comparison of the tumorigenic

potential. The tumorigenic potential of the NOG-EGFP mice was significantly superior ($p < 0.01$) to that of the NOD/SCID mice in all cell lines (Figure 2A-D).

Separation of cancer cells and stromal cells

A single-cell suspension was obtained by enzymatic dissociation from the xenografted tumors of TFK-1 cells. The cancer cells and the GFP-expressing cells were sorted using FACS. FACS analysis showed two subpopulations clearly enabling us to separate the cancer cells and the GFP-expressing cells (Figure 3A). Then, the subpopulation of cancer cells was collected for phenotyping

of murine stromal cells. CD31, CD90, CD49b, CD14 and CD11c are specific markers suggesting the existence of endothelial cells, fibroblasts, natural killer cells, macrophage and dendritic cells, respectively. The percentages of mouse CD31, CD90, CD49b, CD14 and CD11c positive cells in the subpopulation of the cancer cells were almost below the detection level (0.9%: CD31; 0.4%: CD90; 1.6%: CD49b; 1.7%: CD14 and 0.4%: CD11c (Figure 3B). These results demonstrated that the accuracy of the separation of the cancer cells and the host cells in this study was the same as in the previous report [6].

Cell viability after FACS sorting

Cancer cells collected from TFK-1 xenografts of NOG-EGFP mice by FACS were able to grow on the dishes (Figure 4A). Few fluorescent cells were detectable among

the collected cancer cells (experimental) on the dishes, whereas the unsorted cancer cells (control) showed a mixture of fluorescent and non-fluorescent cells (Figure 4A). These results demonstrated that FACS sorting could completely separate cancer cells and stromal cells. Subsequent reimplantation after cell culture showed that the sorted cancer cells had tumorigenic ability (Figure 4B). Since the period from inoculation to beginning of growth was longer in the sorted TFK-1 cells than in the unsorted TFK-1 cells (Figure 4B), the viability of the sorted cells might have been lower than that of the unsorted cells.

Discussion

The aim of the present study was to develop methods for separating mice-xenografted human cancer cells

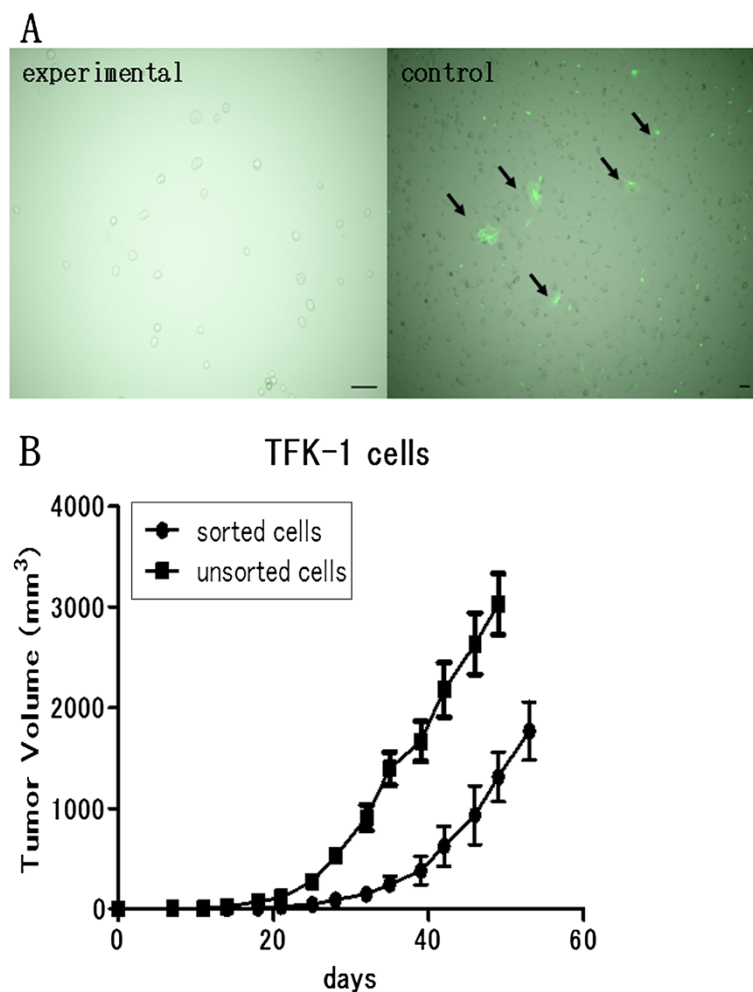

Figure 4 In order to determine the cell viability, the cancer cells were cultured on dishes after FACS sorting and subsequently reimplanted into NOG-EGFP mice. **A)** Left panel (experimental): The fluorescent cells were invisible among the collected cancer cells cultured on the dishes under the fluorescent microscope. Right panel (control): Directly cultured cells from the xenografted TFK-1 tumors. Fluorescent cells were detectable in some areas under the fluorescent microscope. Black arrows indicate eGFP-expressing cells. **B)** TFK-1 cells cultured after FACS sorting were able to grow in the NOG-EGFP mice. Tumorigenicity of the sorted TFK-1 cells was directly compared with that of the unsorted TFK-1 cells shown in Figure 2A. A total amount of 5.0×10^5 cells was injected into each mouse ($n = 6$).

from host cells by FACS with minimal amount of contamination and also to maintain the cell viability for subsequent analyses. For this purpose, we have developed techniques that employ NOG-EGFP mice.

To date, fluorescent immunodeficient mice, i.e. GFP nude mice [9], NOD/SCID EGFP mice [6] and NOG-EGFP mice [7], have been established. The previous reports showed that fluorescent mice were very useful to study the details of tumor-stroma interaction [10-12]. Recently, Niclou and colleagues reported the almost complete separation of cancer cells and host cells using xenografted tumors of a glioma cell line in NOD/SCID EGFP mice. Based on this report, we evaluated the contamination rate of murine stromal cells among each cell type collected cancer cells. Our results showed similar contamination rates to those of the previous report and suggest that fluorescent mice would be very useful for the separation of cancer cells from host cells. However, the purity of the separation might be different in tumor type and implantation site since content rate of stromal cells varies in them. Further studies including orthotopic models of several organs and use of other tumor types are needed to evaluate the purity of separation. We also demonstrated that that sorted cancer cells were able to grow *in vitro* and *in vivo*. One of the advantages is that the tumor cells start to grow significantly earlier in NOG-EGFP mice than in NOD/SCID mice. Our present results provide a novel way of employing of collected cancer cells for to various subsequent analyses. In the report of the NOD/SCID EGFP xenografts, cancer cells labeled with another type of fluorescence were used for the separation study [6]. The present study suggests that fluorescent labeling of cancer cells is not necessary for the separation of cancer cells and host cells.

On the other hand, this method is applicable for the collection of not only cancer cells but also stromal cells. The methodology using fluorescent mouse xenografts might usefully contribute to studies of cancer stromal cells.

In conclusion, NOG-EGFP has high potential utility for complete separation of cancer cells and stromal cells with minimal contamination, if any, from xenografted tumors. Further studies are needed to establish a solid methodology for the separation and collection of stromal/cancer cells, and the use of NOG-EGFP mice for this is very promising.

Competing of interests

All of the authors declare no potential conflicts of interest.

Authors' contributions

KS, MM and NO designed research. KS performed the research. YK technically supported the experiments of the flow cytometry. NI contributed to the animal experiments. KS, MM, HH, KN, TO and NS analyzed data. KS and MM wrote the paper. MM and NS edited the manuscript. FM, TR, YK, SE, NI AH

and MU reviewed the manuscript. MU integrated the entire study. All authors read and approved the final manuscript.
