ABSTRACT

Ultrafast fiber sources having short pulses, broad bandwidth, high energy, and low amplitude fluctuations have widespread applications. Stretched-pulse fiber lasers, incorporating segments of normal and anomalous dispersion fibers, are a preferred means to generate such pulses. We realize a stretched-pulse fiber laser based on a nanotube saturable absorber, with 113 fs pulses, 33.5 nm spectral width and ~0.07% amplitude fluctuation, outperforming current nanotube-based designs.

KEYWORDS

Nanotubes, fiber laser, saturable absorber, ultrafast pulse generation

1. Introduction

Passively mode-locked fiber lasers are attractive for many applications, such as optical communications [1], spectroscopy [2], and biomedical diagnostics [3], because of their simplicity, compactness, efficient heat dissipation, and ability to generate high-quality pulses [3–5]. The dominant mode-locking technology is based on semiconductor saturable mirrors (SESAMs) [6]. However, SESAMs are typically complex quantum wells, fabricated by molecular beam epitaxy on distributed Bragg reflectors [1, 3, 6], and ion implantation is normally required to reduce the recovery time [6]. Therefore, novel saturable absorbers with better performance, cheaper fabrication and easier integration are of great interest. Alternative saturable absorbers based on single wall carbon nanotubes (SWNTs) and graphene are at the centre of an intense research effort [7, 8], due to their broad operation range, low

saturation power, easy fabrication, mechanical and environmental robustness, and quick recovery times [7–28]. These have been used to mode-lock fiber [8–23], waveguide [24], solid-state [25–27], and semiconductor lasers [28]. Present mode-locking technology typically relies on soliton-like operation. In this regime, nonlinear effects due to strong mode confinement [5, 29, 30], and the long fibre required (typically ~10 m [5, 30]), distort the transform-limited soliton pulses, and limit the generation of high-energy pulses [5, 29, 30]. The resulting pulses normally have strong sidebands, in both frequency and time domains [5, 29, 30]. Indeed, the shortest pulse to date using a SWNT-based mode-locker at 1550 nm is ~115 fs, with traditional soliton-like operation [22], but with strong sidebands in the spectral and time domains [22] and random multiple pulses [5, 12, 22, 29, 30], limiting the achievement of ever shorter pulses, clean spectra, low amplitude fluctuations and higher energy.

Address correspondence to acf26@cam.ac.uk

To overcome these restrictions, a dispersion management design utilizing different types of fibers with alternating anomalous and normal group velocity dispersion (GVD) (i.e., group velocity decreasing and increasing, respectively, with decreasing optical frequency) has been proposed [5, 29, 30]. Dispersion plays a critical role in the propagation of ultrafast pulses within optical fibers, as different spectral components move at different speed. In principle, dispersion-induced pulse broadening could be compensated by an equal amount of dispersion of opposite sign. As indicated in Fig. 1, alternating normal and anomalous GVD allows periodic stretching and compression of the intracavity pulses in the resonator [5, 29, 30]. The average pulse width in one cavity round trip can increase by an order of magnitude or more [5, 29, 30]. This significantly decreases the intracavity average peak power, compared to soliton-like operation. Thus, nonlinear optical effects triggered by high intensity are mitigated. This allows high quality pulses with larger energy (up to nanojoules) to be achieved for a specific system-bearable nonlinearity [5, 29–31]. This configuration is known as the stretched-pulse design. Ultrafast high-energy fibre lasers enabled by the stretched-pulse design have a variety of potential applications, such as amplification, frequency doubling, and spectroscopy [4, 5, 32, 33].

Here, we demonstrate the stretched-pulse fiber design for a laser using a SWNT saturable absorber. We achieve 113 fs pulses at 1.56 μm , with 18.76 MHz

repetition rate, ~ 33.5 nm output spectral width, and $\sim 0.07\%$ fluctuation.

2. Experimental

2.1 Device fabrication and characterization

Pristine SWNTs cannot be stably dispersed in a highly polar solvent like water without functionalization [34]. Usually, surfactants [34–37] or water soluble polymers [37–39] are used to exfoliate SWNTs from their naturally occurring bundles. The most commonly used surfactants are sodium dodecyl sulfate (SDS) and sodium dodecyl benzenesulfonate (SDBS) [34–37]. Both are linear chain anionic surfactants with a hydrophobic tail and a hydrophilic head [35]. When SWNTs are isolated by the shear forces from the formation and collapse of cavities generated by ultrasounds [40], surfactants—at concentrations above the critical micelle concentration—form micelles around individual SWNTs and small SWNT bundles, preventing their re-aggregation [34].

To make our polyvinyl alcohol (PVA)–SWNT saturable absorber composite, we use SDBS due to its efficiency in dispersing large amounts of SWNTs [35–37]. Importantly, it disperses SWNTs with a larger diameter range compared to bile salts, the latter being more effective with small diameter tubes [7]. The amounts of SWNTs and dispersant used to prepare solutions vary according to the SWNT purity. For the PVA–SWNT composites, we use SWNTs grown by laser ablation, as described in Ref. [41], and purified as reported in Ref. [42]. The mean diameter (1.3 nm) of the SWNTs used here ensures that the semiconducting SWNTs in the sample have an absorption band at around 1500 nm. We dispersed 2 mg of SWNTs in 14 mL of deionized water with 40 mg of SDBS for 2–3 h at 10–12 $^{\circ}\text{C}$ using a Bioruptor (Diagenode) sonicator system operating at 20 kHz with a power of 270 W. This resulted in a dark dispersion with no visible SWNT aggregates, Fig. 2(a). Note that the actual power delivered to the sample is substantially lower than 270 W due to the non-contact operation of this ultrasonicator. The residual bundles and impurities were removed by ultracentrifugation at $\sim 80\,000$ g for 1 h by using a fixed angle MLA-80 rotor in an

Optima-Max-E ultracentrifuge (Beckman Coulter). The supernatant was then decanted. The absorption of the SWNT dispersion at ~ 1550 nm was 0.15 for a 10 mm absorption path length. The dispersion was then mixed with a 20 wt% aqueous PVA solution. Ultrasonication of the mixture resulted in a uniform solution which was then drop-cast on a Petri dish. Slow evaporation (1–2 weeks) under ambient temperature and pressure in a desiccator gave a free standing SWNT–PVA composite, 50 μm thick with homogeneously dispersed tubes [7, 11, 13]. The film was then dried at 45 °C. Figure 2(b) shows a micrograph of the composite, confirming the homogeneous nanotube dispersion. Approximately 2 mm² of the composite were used between fiber connectors for our transmissive-type device configuration, Fig. 2(c).

The SWNT films were characterized by Raman spectroscopy (Fig. 3) and absorption spectrophotometry (Fig. 4). In the 1550–1590 cm⁻¹ region, the Raman spectra of SWNTs have two distinct features, the so-called G⁺ and G⁻ peaks. These originate from the tangential (TO) and the longitudinal (LO) modes resulting from the splitting of the doubly degenerate E_{2g} phonon of graphene [43]. In metallic tubes, the LO mode is affected by a Kohn anomaly (KA) [43, 44], which causes the softening of this phonon [43, 44]. Since KA are not present in semiconducting SWNTs, the G⁺, G⁻ assignment in metallic SWNTs is the opposite of semiconducting tubes [43]. In semiconducting tubes, both the G⁺ and G⁻ bands appear as sharp Lorentzian peaks. The G⁺ is usually more intense than the G⁻, and its position is nearly independent of tube diameter, whereas the G⁻ position decreases with decreasing tube diameter. On the other hand, in

Figure 2 Preparation and integration of the SWNT–PVA composite: (a) photograph of the SWNT dispersion after ultrasonication; (b) optical micrograph of the SWNT–PVA composite showing no aggregation; (c) integration of ~ 2 mm² of the composite to a fiber connector

metallic tubes the G⁻ peak is usually rather intense, very broad, and downshifted with respect to its counterpart in semiconducting tubes [43]. The other prominent features in the Raman spectrum of SWNTs are the radial breathing modes (RBM). These are associated with a symmetric movement of carbon atoms in the radial direction, whose energy is inversely related to the tube diameter. The SWNT diameter, d , can be derived from the RBM frequency, ω_{RBM} , by means of the expression $d = C_1/(\omega_{\text{RBM}} - C_2)$, combined with the Kataura plot and the known excitation energy [45–47]. A variety of different values of C_1 and C_2 have been proposed [45–47] but their precise value is only critical for chirality assignment [45–47], which is not an issue here, since we are interested only in the diameter. The shapes of the G peaks at the two excitation energies, shown in Fig. 3, imply the presence of both metallic and semiconducting tubes. The RBMs indicate a diameter distribution of 1–1.4 nm, implying a band gap of 0.7–1.1 eV [48]. We target this range to cover the gain bandwidth of our erbium fiber at 1550 nm. This is verified by the absorption spectrum, Fig. 4, which has a maximum at ~ 1600 nm with a bandwidth of ~ 340 nm.

After packaging (Fig. 2(c)), the nonlinear absorption of the film is characterized by power-dependent absorbance performed with a pulsed erbium-doped fiber (EDF) laser at 1550 nm. This gives a saturation intensity of ~ 18.9 MW/cm² and modulation depth

Figure 3 Raman spectra of pure PVA and SWNT–PVA composite measured with excitation wavelengths of 633 and 785 nm

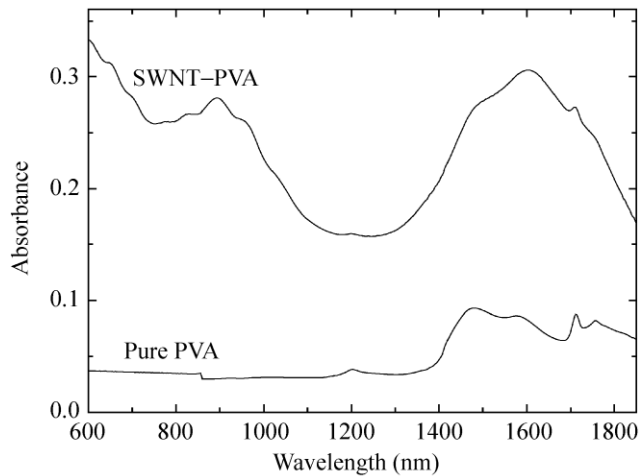

Figure 4 Absorption spectra of the SWNT-PVA composite and pure PVA film

of ~16.9% (Fig. 5), sufficient to provide strong pulse shaping, reliable self-starting and stabilized pulse generation [6].

2.2 Laser setup

The packaged SWNT-PVA composite was inserted in a fiber laser cavity. The laser was in a ring configuration. A 3.6 m EDF (Fibercore Ltd.) was forward pumped by a 980 nm diode laser through a fused wavelength division multiplexer to provide gain. To realize the stretched-pulse design at ~1.5 μm , the EDF was selected with normal dispersion at our operating wavelength, while the other fibers were chosen with anomalous dispersion to set the total intracavity GVD close to zero

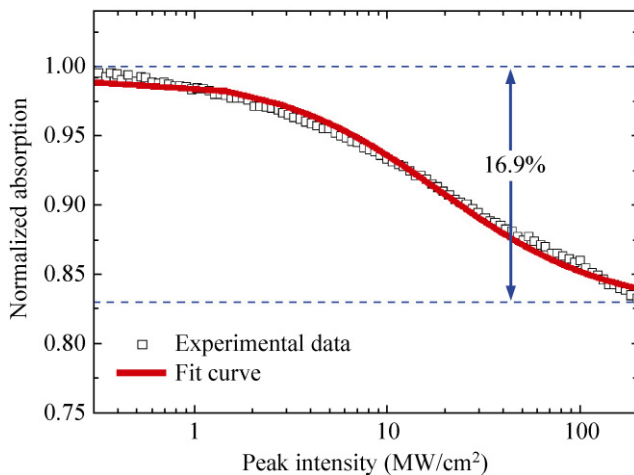

Figure 5 Nonlinear power-dependent absorbance of SWNT-PVA

[4, 5, 29–33]. The GVD was measured by inserting the same EDF into a home-made soliton-like fiber laser. We evaluated the EDF dispersion by measuring the wavelength shift ($\Delta\lambda$) between sidebands and central wavelength of the soliton pulse spectrum [49]. We obtained a GVD coefficient $\beta_2 \sim 36 \text{ ps}^2/\text{km}$. The rest of the laser was constructed from Flex 1060 and Corning SMF-28 fibers, with anomalous dispersion. The total length of Flex 1060 ($\beta_2 = -7 \text{ ps}^2/\text{km}$) was ~1.83 m, while for SMF-28 ($\beta_2 = -22 \text{ ps}^2/\text{km}$) we used ~5.74 m, providing an intracavity GVD $\sim -0.008 \text{ ps}^2 \pm 0.005 \text{ ps}^2$. The total cavity length was ~11.17 m. A polarization-independent optical isolator ensured unidirectional operation. For mode-locking optimization, we adjusted the polarization using two intracavity polarization controllers. A fused 20/80 output coupler was utilized. The 20% port extracted the pulses from the cavity. The pump and average output power were monitored by a photodiode power meter (Ophir PD300-IR). A spectrum analyzer (HP 86140A) with 0.1 nm resolution and a second harmonic generation (SHG) autocorrelator (Inrad 5-14-LDA) with ~5 fs resolution were used to measure the output spectrum and pulse duration.

3. Results and discussion

Continuous wave operation starts at ~7.5 mW pump power. Self-starting single-pulse mode-locking is observed at ~12.8 mW. Figure 6 shows a typical output pulse spectrum. The full width at half maximum (FWHM) bandwidth is ~33.5 nm. To the best of our knowledge, this is the widest spectrum achieved thus far from an EDF laser mode-locked by SWNTs. No sidebands are observed. Figure 7 shows a plot of a typical output SHG autocorrelation trace, including Gaussian and sech² fits. A sech² pulse profile is typically expected for soliton fiber lasers. However, a Gaussian also fits well our experimental data, as expected for stretched-pulse lasers [30]. The autocorrelation FWHM is ~160 fs. Assuming a Gaussian profile, the data deconvolution gives a pulse duration of ~113 fs, the shortest reported to date from an EDF laser mode-locked by SWNTs. The time-bandwidth product (TBP) of the output pulses is ~0.467, with a minor deviation from the value of 0.44 expected for

Figure 6 Typical output spectrum, with bandwidth ~ 33.5 nm

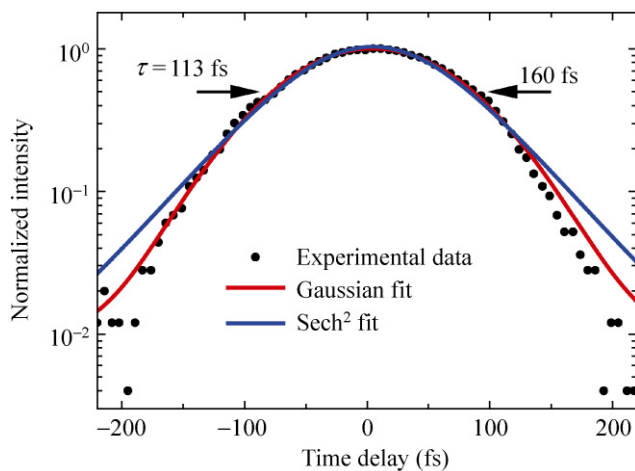

Figure 7 Autocorrelation trace, with Gaussian and sech² fits

transform-limited Gaussian pulses [50]. This could be caused by uncompensated third-order dispersion, distorting the intracavity pulse [31] and also limiting the minimum achievable pulse width [51, 52]. Another limitation to shorter pulses could be spectral filtering effects introduced by the erbium gain medium [5, 29]. Using a ~ -0.03 ps² fiber patchcord (1.37 m SMF-28), the FWHM of the fitted autocorrelation trace is ~ 1.358 ps, corresponding to ~ 961 fs for a Gaussian temporal profile. This shows that the output pulse stretches ~ 8 times after passing a fiber with ~ 0.033 ps² GVD. The pulse evolution and the ~ -0.096 ps² GVD of the intracavity fibers (3.78 m SMF-28 and 1.83 m Flexcor 1060) confirm the stretched-pulse design of our laser.

The operating stability is characterized from radio-frequency (RF) spectrum measurements of the output

intensity [53]. The repetition rate is ~ 18.76 MHz, corresponding to a ~ 53.3 ns round-trip time, Fig. 8(a). No spectrum modulation is observed over 1.5 GHz (Fig. 8(b)), with no Q-switching instabilities. Figure 9(a) shows a plot of the RF spectrum around the fundamental cavity round-trip frequency. A signal-to-noise ratio $\Delta P = \sim 77$ dB ($10^{7.7}$ contrast) is observed, highlighting the low-amplitude fluctuation $\Delta E/E$ of the laser. From $\frac{\Delta E}{E} = \sqrt{\Delta P \times \frac{\Delta f}{\Delta f_{\text{res}}}}$, where Δf and Δf_{res} are frequency jitter bandwidth and resolution respectively [53], we estimate an amplitude fluctuation $\Delta E/E \approx 7 \times 10^{-4}$. Figure 9(b) shows a plot of the RF spectrum around the tenth harmonic. A ~ 60 dB peak-to-background ratio is measured, indicating low timing jitter and good mode-locking stability [53].

Compared with previous SWNT mode-locked EDF lasers [9, 20, 22], our system provides shorter durations, wider and cleaner spectra, and lower amplitude noise fluctuations, thanks to our dispersion-managed stretched-pulse configuration realized by using fibers

Figure 8 (a) Oscilloscope trace. (b) RF spectrum up to 1.5 GHz

Figure 9 RF spectra around (a) the fundamental repetition rate ($f_1 = 18.76$ MHz), and (b) the 10th harmonic repetition rate ($f_{10} = 187.6$ MHz)

with relatively large normal and anomalous dispersions. In previous pulsed laser designs, the intracavity GVD was typically set as negative with a large absolute value to favour soliton-like pulses [5, 10, 20, 22]. With this design, the width and quality of the output pulses are limited by overdriven nonlinearities and instabilities [5, 29, 49]. In contrast, in our case, nonlinearities significantly decrease, as a result of stretching and compressing the intracavity pulse. Even shorter pulse duration, greater spectral width and higher output power could be achieved by further improvement of the cavity design, employing evanescent field interaction with SWNT saturable absorbers [12, 21].

4. Conclusions

We demonstrated a stretched-pulse erbium-doped fiber laser using a SWNT-based saturable absorber, generating 113-fs pulses at 1.56 μm . The output spectral width is 33.5 nm. This can lead to novel light sources

meeting the pulse length, quality and energy requirements for many applications, such as micro-machining and optical tomography, opening new opportunities in metrology, spectroscopy and biomedical diagnostics.
