Lake level and area variations are sensitive to regional climate changes and can be used to indirectly estimate water balances of lakes. In this study, 10 of the largest lakes in China,  $\sim 1000 \text{ km}^2$  or larger, are examined to determine changes in lake level and area derived respectively from ICESat and Landsat data recorded between 2003 and 2009. The time series of lake level and area of Selin Co, Nam Co, and Qinghai Lake in the Tibetan Plateau (TP) and Xingkai Lake in northeastern China exhibit an increasing trend, with Selin Co showing the fastest rise in lake level (0.69 m/a), area ( $32.59 \text{ km}^2/\text{a}$ ), and volume ( $1.25 \text{ km}^3/\text{a}$ ) among the 10 examined lakes. Bosten and Hulun lakes in the arid and semiarid region of northern China show a decline in both lake level and area, with Bosten Lake showing the largest decrease in lake level ( $-0.43 \text{ m/a}$ ) and Hulun Lake showing the largest area shrinkage ( $-35.56 \text{ km}^2/\text{a}$ ). However, Dongting, Poyang, Taihu, and Hongze lakes in the mid-lower reaches of the Yangtze River basin present seasonal variability without any apparent tendencies. The lake level and area show strong correlations for Selin Co, Nam Co, Qinghai, Poyang, Hulun, and Bosten lakes ( $R^2 > 0.80$ ) and for Taihu, Hongze, and Xingkai lakes ( $\sim 0.70$ ) and weak correlation for East Dongting Lake (0.37). The lake level changes and water volume changes are in very good agreement for all lakes ( $R^2 > 0.98$ ). Water balances of the 10 lakes are derived on the basis of both lake level and area changes, with Selin Co, Nam Co, Qinghai, and Xingkai lakes showing positive water budgets of 9.08, 4.07, 2.88, and  $1.09 \text{ km}^3$ , respectively. Bosten and Hulun lakes show negative budgets of  $-3.01$  and  $-4.73 \text{ km}^3$ , respectively, and the four lakes along the Yangtze River show no obvious variations. Possible explanations for the lake level and area changes in these four lakes are also discussed. This study suggests that satellite remote sensing could serve as a fast and effective tool for estimating lake water balance.

Lakes are not only water resources essential for life, but also sensitive indicators of climate change. Thus, they are of great importance for water assessment, climate modeling, and environmental and biodiversity studies. A global database of lakes and wetlands shows that the total lake area in China of those larger than  $1.0 \text{ km}^2$  is  $\sim 8 \times 10^4 \text{ km}^2$  [1], which accounts for  $\sim 0.8\%$  of China's land area. The Tibetan Plateau (TP) has the largest number of lakes, with 1055 lakes of

greater than  $1.0 \text{ km}^2$ , accounting for 39% and 51% of the total lake number and area in China [2], respectively, and is known as the “water tower of Asia”.

The physical properties of China's lakes have been strongly affected by climate changes and human activities during recent years. For example, shrinkage and vanishing of lakes in North China such as those in Xinjiang and Inner Mongolia occurred because of warming [3] and increased agriculture irrigation [4]. The decrease in lake area in South China is attributed to reclamation, lakeshore expansion, and

\*Corresponding author (email: guoqing.zhang2009@gmail.com)

enclosure associated with rapid economic growth [5]. A recent study of 74 lakes (56 saltwater lakes) in the TP indicated that the levels of 62 (84%) freshwater and 50 (89%) saltwater lakes increased from 2003 to 2009 [6], which is likely due to accelerated glacier melting and increased net precipitation over the TP [6–9]. This result is also consistent with the emergence of numerous new lakes and the increase in the areas of lakes in the region [5,10,11]. The interrelationship between the Yangtze River and Poyang Lake has been altered by local and regional climate and human activities, thus affecting the ecological system, wetland cover types, and economic benefits [12–14]. In particular, the operation of the Three Gorges Dam since 2003 shows a certain degree of influence on the hydrological process of Poyang Lake basin [12].

Lake volume variations can be calculated through water inputs such as precipitation over the lake, river inflow, and groundwater recharge and outputs such as evaporation from the lake, river outflow, and groundwater seepage. However, direct measurement of these parameters at hydrological stations is usually difficult. Moreover, the remoteness and harsh conditions of high-altitude lakes present further challenges. Remote sensing has proved to be a powerful and efficient tool for monitoring these lakes [15]. Water mass balance of a lake can be indirectly estimated by combining lake level and area changes. Satellite radar/laser altimeters such as TOPEX/POSEIDON, ENVISAT, JASON-1, and ICESat/GLAS have been successfully launched to monitor lake level changes [6,16–18]. Although ICESat/GLAS al-

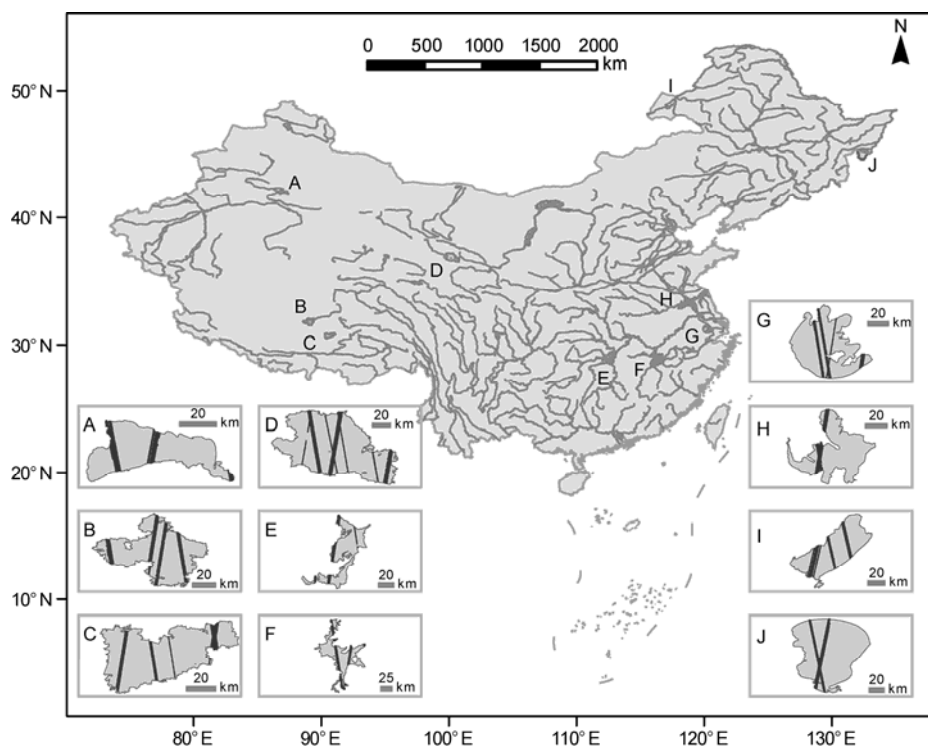

timetry shows high precision and accuracy [6,19–22], it is a sparse sampling scheme outside the polar regions and often excludes small lakes.

The 10 largest lakes in China, namely, Bosten, Selin Co, Nam Co, Qinghai, Dongting, Poyang, Taihu, Hongze, Hulun, and Xingkai (Figure 1), each with an area of  $\geq 1000$  km<sup>2</sup> and together covering an area of 22711.8 km<sup>2</sup> [2], present a representative spatial pattern distribution. These lakes are critical for China owing to the social, ecologic, and environmental benefits they provide to the country's 1.3 billion residents. However, the temporal variations in lake level and area as well as the water balance of these lakes under the conditions of rapid current climate changes and social and economic development remain unknown. In this study, we selected the 10 largest lakes in China and retrieved the lake levels by using ICESat data and areas using the Landsat Thematic Mapper (TM) and Enhanced Thematic Mapper (ETM+) data for the period 2003–2009. Finally, water volume for each lake was calculated from the lake level and area changes, and water balance was estimated.

## 1 Data and methodology

### 1.1 Characteristics of the 10 largest lakes

Figure 1 shows the spatial distribution of the 10 largest lakes, along with the largest river networks, in China. The physical characteristics of these lakes are summarized in Table 1.

**Figure 1** Locations of the 10 largest lakes in China. The insets indicate ICESat tracks passing through the lake surfaces. A represents Bosten Lake; B, Selin Co; C, Nam Co; D, Qinghai Lake; E, Dongting Lake; F, for Poyang Lake; G, Taihu Lake; H, for Hongze Lake; I, Hulun Lake; and J, Xingkai Lake.

**Table 1** Physical characteristics of the 10 largest lakes in China<sup>a)</sup>

Characteristics	Selin Co	Nam Co	Qinghai	Xingkai	Bosten	Hulun	Poyang	Taihu	Dongting	Hongze

a) S, for salt lake; F, for fresh lake.

Bosten Lake (A) is located in the Xinjiang Uygur Autonomous Region, northwest China. The lake lies on the southern slope of the Tianshan Mountains with a maximum water depth of 16 m and water volume of 8.8 km<sup>3</sup> [23] (Table 1). Selin Co (B), Nam Co (C), and Qinghai Lake (D) are the three largest lakes in the TP, and all are enclosed salt lakes. Selin Co and Nam Co in central TP are the highest lakes in the world with altitudes >4000 m. The lake basin of Selin Co has an area of 49895 km<sup>2</sup>, and the Zajia Zangbo River, the longest river in Tibet, flowing into this lake [24]. The

maximum water depth of Nam Co is approximately 98 m, and its multi-year mean water volume is 84.2 km<sup>3</sup> [25]. The Nam Co basin of 10857 km<sup>2</sup> is located in the northern Nyainqentanglha Range with abundant glacier coverage [24,26,27]. Qinghai Lake is the largest saltwater lake in China with an area of more than 4000 km<sup>2</sup> (Table 2). Its drainage basin covers an area of approximately 29660 km<sup>2</sup>. The combination of precipitation and glacier/snow melting in the basin provides a major water source to Qinghai Lake [20].

Dongting (E), Poyang (F), Taihu (G), and Hongze (H)

a) All lakes are grouped into three subgroups of lake level increase, decrease, and no obvious trend.

Lakes in the mid-lower reaches of the Yangtze River, originating from the TP, are located in the most populated region of southeastern China and are important sources of regional water and ecosystems. Hulun Lake (I) is located in a semiarid region of Inner Mongolia Autonomous Region, China, under a continental monsoon climate with an area of  $\sim 2000 \text{ km}^2$  and maximum depth of 5 m. It is now a closed lake with a pH of 9.2 and salinity of 2.5 g/L, as measured in 2009 [28]. A special lake in northeastern China, Xingkai Lake (J), stretches across the border of China and Russia.

## 1.2 Hydrological and meteorological data

The Nam Co Station for Multisphere Observation and Research (briefly, Nam Co Station), established in 2005 by the Institute of Tibetan Plateau Research, Chinese Academy of Sciences, provides hydrological and meteorological data. The station is located in the southeast region of lake at  $30^\circ 47' 18.24'' \text{N} / 90^\circ 58' 32.46'' \text{E}$  [6]. The monthly temperature, precipitation, and pan evaporation ( $E_{\text{pan}}$ ) data between 2003 and 2009 for the Hulun Lake basin were obtained from the China Meteorological Data Sharing Service System at <http://cdc.cma.gov.cn/>. Pan evaporation describes evaporation measured by open circular pans with a diameter of 20 cm, which is more representative of surface evaporation. The 84 meteorological stations from the Meteorological Bureau of Jiangxi Province recorded monthly temperature, precipitation, and  $E_{\text{pan}}$  of the Poyang Lake basin during 2003–2009. In addition, the daily water level measured at Duchang Hydrological Station at Poyang Lake was collected.

## 1.3 ICESat data

The ICESat mission, with the Geoscience Laser Altimeter System (GLAS) instrument, was launched in January 2003. The primary purpose of ICESat was to detect elevation changes of ice sheets in Greenland and the Antarctic, in addition to other scientific objectives such as global measurements of cloud and aerosol heights, land topography, and vegetation canopy heights [34,35]. The precision of ICESat measurement is  $\sim 2 \text{ cm}$  with footprints 70 m in diameter along 172-m interval tracks for monitoring polar ice sheets and sea ice [35,36]. Moreover, ICESat/GLA14 shows high accuracy for measuring inland lake levels and their changes [6,20,37]. ICESat/GLAS Release-31, covering the 10 lakes between 2003 and 2009, were acquired from the National Snow and Ice Data Center (NSIDC). The elevation and related information were extracted through the Interactive Data Language (IDL) code provided by NSIDC. The ICESat data is referenced to TOPEX/Poseidon (T/P) ellipsoid and the Earth Gravitational Model 2008 (EGM2008) Geoid in Release 531. The ICESat elevation was converted to the orthometric height with the EGM2008 Geoid provided with the original ICESat and WGS84 ellipsoid with an offset of 0.7 m relative to the T/P ellipsoid [20]. Studies have shown

that the accuracy of ICESat may be better than 10 cm in monitoring lake level changes [6,20,38].

For thousands of lakes, the ICESat footprints crossing the lake surface are generally selected by the boundary derived from MODIS data with a resolution of 250/500 m [6,19]. A pixel size of 250 m is still excessively coarse, as compared with the 70-m footprint of ICESat data. In this study, the lake boundaries derived from Landsat images (30 m in pixel size) are used to extract ICESat footprints. Therefore, a more accurate boundary is provided to remove the outliers from the water-land transition. In particular, this action is necessary for seasonal lakes with variable lake extents. A further step for removing outliers was also conducted in data processing with ICESat parameters such as waveform saturation, and instrument gain, and final standard deviation of footprints [20].

## 1.4 Landsat data and lake boundary derivation

The Landsat TM/ETM+ archives were downloaded through the United States Geological Survey (USGS) at <http://glovis.usgs.gov/>. A total of 130 Landsat scenes during 2003–2009 for the 10 lakes was used in this study. The Landsat ETM+ has shown a data gap of a 22% data loss per scene due to scan line corrector failure (SLC) since May 31, 2003. The Landsat ETM+gaps are filled with a local linear histogram-matching method developed by the USGS [39]. For some lakes such as Nam Co and Selin Co, a clear lake boundary can be identified from images and delineated with visual interpretation. The lake area of Nam Co on April 16, 2009, was determined in this study to be  $2014.02 \text{ km}^2$ , which is very close to  $2014.66 \text{ km}^2$  on the same date, as reported by Zhang et al. [25].

In other lakes, such as Poyang and Dongting, the water inundation extent shows large variability owing to rainfall and water exchange with the Yangtze River; therefore, a Modified Normalized Difference Water Index (MNDWI) (eq. (1)) was used to map these water bodies [40,41]. The mean of MNDWI for water is much higher than that for other land cover types such as bare land, residential areas, vegetation, and clouds. Density slicing with a mean threshold sampled from the lake surface was further performed to derive water body information [42,43]. The range of MNDWI threshold for the lakes in the Yangtze River basin is 0.32–0.45:

$$\text{MNDWI} = [\rho_{0.56} - \rho_{1.65}] / [\rho_{0.56} + \rho_{1.65}], \quad (1)$$

where  $\rho_{0.56}$  and  $\rho_{1.65}$  are bands 2 (green band) and 5 (middle infrared band) for Land TM/ETM+, respectively.

## 1.5 Water-balance derivation

A method for computing the water volume of lakes was proposed by Taube [44] as eq. (2). We used this formula to examine the water volume changes in lake area and differ-

ences in lake level:

$$\Delta V = \frac{1}{3}(H_2 - H_1) \times (A_1 + A_2 + \sqrt{A_1 \times A_2}), \quad (2)$$

where  $\Delta V$  denotes the lake volume change from lake level  $H_1$  with an area of  $A_1$  to  $H_2$  with  $A_2$ . The water volume change is achieved with two consecutive elevation and area values. The water balance can be estimated with total of all step values between 2003 and 2009.

## 2 Results

### 2.1 Lake level and area changes

Figure 2 shows the lake level derived from ICESat, area from Landsat TM/ETM+, and water volume changes during 2003–2009 for the 10 lakes. These lakes were grouped into the following three subgroups according to their lake levels and area changes, as shown in Table 2: lake level increase, decrease, and no trend. Four lakes, namely, Selin Co, Nam Co, and Qinghai Lake in the TP and Xingkai Lake in northeastern China, showed lake level and area increases. Selin Co had the fastest lake level and area increase rates from 2003 to 2009, with respective values of 0.69 m/a (4.37 m) and 32.59 km<sup>2</sup>/a (185.91 km<sup>2</sup>) against 0.23 m/a (2.03 m) and 2.89 km<sup>2</sup>/a (30.50 km<sup>2</sup>) for Nam Co and 0.11 m/a (0.70 m) and 11.70 km<sup>2</sup>/a (80.44 km<sup>2</sup>) for Qinghai Lake. In addition, Selin Co had an area of 2178.37 km<sup>2</sup> in 2009 and is currently the largest lake in Tibet; Nam Co, with an area of 2018.25 km<sup>2</sup>, previously held the title [45]. Detailed lake level changes and related snow cover/glacier changes for the three lakes were previously reported [6,20,24,46]. Xingkai Lake showed a slight increase in lake level and area with respective values of 0.07 m/a and 2.17 km<sup>2</sup>/a, or amounts of 0.27 m and 2.16 km<sup>2</sup> during 2003–2009.

Hulun and Bosten lakes showed both lake level and area decreases. Bosten Lake had the faster lake level drop with a rate (amount) of -0.43 m/a (-3.11 m) against -0.41 m/a (-2.42 m) for Hulun Lake. Hulun Lake indicates a greater area shrinkage with -35.56 km<sup>2</sup>/a (-216.03 km<sup>2</sup>) against -10.57 km<sup>2</sup>/a (-75.35 km<sup>2</sup>) for Bosten Lake.

The four lakes, namely, Dongting, Poyang, Taihu, and Hongze, located in the mid-lower reaches of the Yangtze River basin, showed intraseasonal variability in lake level and area and no trend at all. The area values were obtained with available data for dates nearest those available for lake level. For Dongting Lake, including east, south, and west sections, ICESat tracks are mainly covered in the east section, and only a few are available in the south section. Therefore, only East Dongting Lake is examined for its elevation and area changes in this study. East Dongting Lake is seasonal with mean and maximum elevations and areas of 24.67 m, 27.61 m, 447.76 km<sup>2</sup>, and 792.66 km<sup>2</sup>, respectively. Poyang Lake has an inundated area of more than 3000 km<sup>2</sup> during rainy seasons and less than 1500 km<sup>2</sup> during dry

seasons. Lake levels and area showed abrupt increases during April–June of 2005 and 2006 and abrupt decreases that remained low in 2007–2009. Taihu Lake showed the lowest altitude, between 0.4 and 1.0 m, among the 10 lakes and an area fluctuation of approximately 2300 km<sup>2</sup>. Hongze Lake presented a mean elevation of ~12.5 m and a mean area of ~1550 km<sup>2</sup> with some variations.

Of the 10 lakes, Selin Co showed the most rapid lake level and area increase between 2003 and 2009, while Bosten Lake showed the fastest lake level decrease, and Hulun Lake showed the greatest area shrinkage during this period.

### 2.2 Lake boundary changes

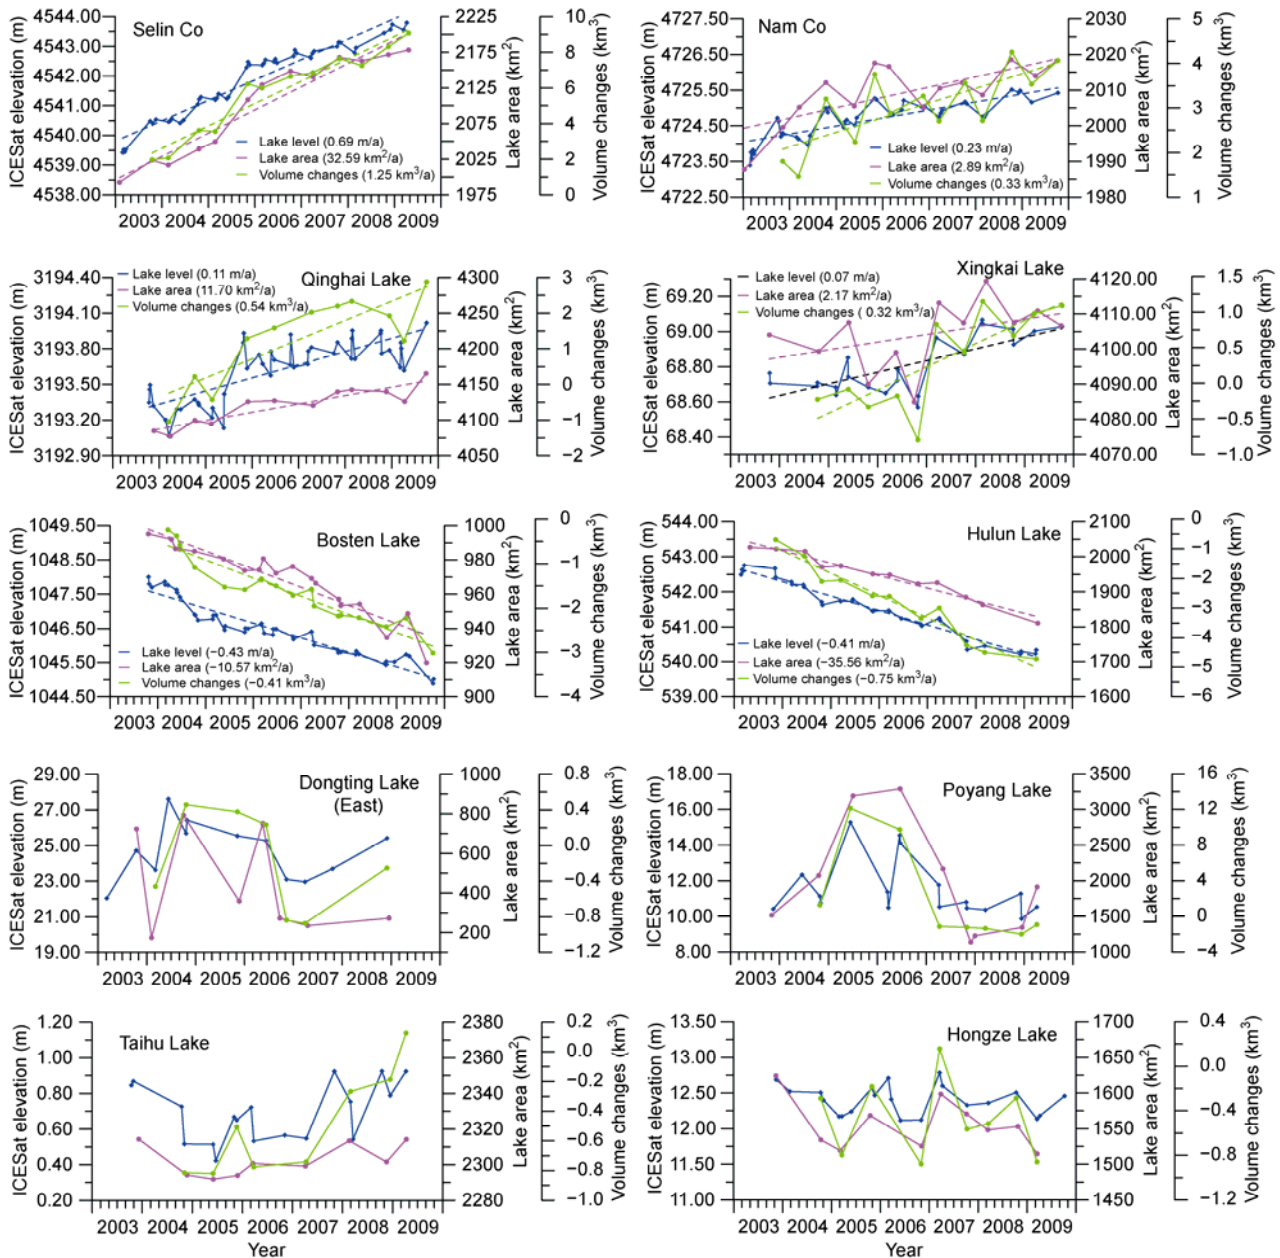

Figure 3 shows the boundary changes of the 10 lakes. An insert presents enlarged views of lake bank changes. Selin Co showed a sharp lake boundary extent between 2005 and 2006, which is consistent with lake level (1.69 m) and area (99.12 km<sup>2</sup>) increases in the two years (Figure 2). Nam Co had a greater expansion of shorelines toward west and east. Rapid bank enlargements occurred in 2004, 2005, and 2008, which correlates with lake level and area increases (Figure 2). Qinghai Lake showed greater shoreline enlargements in the eastern portion of the lake in 2005 and 2009. The lake level and area changes in the two years also presented higher peaks. The largest lake bank extent of Xingkai Lake appeared in 2008, which is consistent with lake level and area increases.

A retreating of shoreline of Hulun Lake mainly appeared in its southern region. The lake boundary showed apparent decreases in 2004, 2007, and 2009, which is consistent with the three valleys of lake level and area changes in these three years (Figure 2). Bosten Lake, with continuous decreases in lake level and area between 2003 and 2009, showed obvious bank shrinkage.

Dongting, Poyang, Taihu, and Hongze lakes have seasonal variability due to rich rainfall and water exchange with the Yangtze River; thus, lake boundary changes can occur rapidly and are usually marked by large inundations in the wet season that decline significantly in the dry season. For example, the extent of Dongting Lake was much larger in October 2004 than in November 2005, indicating a considerable decrease. Poyang Lake had a large area in June 2006, and a substantial decrease occurred during the dry period of November 2007. The shoreline changes of Taihu Lake occurred in its northeastern and southeastern regions and were accompanied by rapid industrialization and urbanization. Hongze Lake indicated clear boundary shrinkage in 2008–2009 around the lake, which is closely related to human regulations such as increased irrigation, reclamation of wetlands, and expansion of lakeside development.

### 2.3 Relationships between lake level, area, and volume

Figure 4 shows the correlation between corresponding (or

**Figure 2** ICESat-derived lake level time-series (blue lines), Landsat-derived lake area time-series (red lines), and water volume changes during 2003–2009.

the closest available) lake area and levels for the 10 lakes. The lakes located in arid-semiarid regions including Selin Co, Nam Co, Qinghai, Hulun, and Bosten showed strong correlations ( $R^2 = 0.83\text{--}0.96$ ), except for Xingkai Lake with a slightly smaller value of 0.76. The lakes in the mid-lower Yangtze River basin showed weaker correlations including 0.37 for East Dongting Lake, 0.70 for Taihu Lake, 0.71 for Hongze Lake, and 0.83 for Poyang Lake. The weaker relationship between lake level and area for these four lakes could be partly due to sparse ICESat data coverage, while frequent changes of water surface extent occur with weather changes.

A third-grade polynomial regression shows a high corre-

lation ( $R^2 > 0.98$ ) between water level changes and water volume changes for the 10 lakes (Figure 5).

## 2.4 Water balance estimation

Table 2 shows the water volume changes of the 10 lakes and their water balances between 2003 and 2009. Results show that the lakes in the TP (Selin Co, Nam Co, and Qinghai Lake) and Xingkai Lake had a positive balance. Selin Co showed a maximum volume increase of 9.08 km<sup>3</sup> with a rate of 1.25 km<sup>3</sup>/a. Bosten and Hulun lakes showed respective water volume decreases of -3.01 and -4.73 km<sup>3</sup> and change rates of -0.41 and -0.75 km<sup>3</sup>/a. The lakes in the

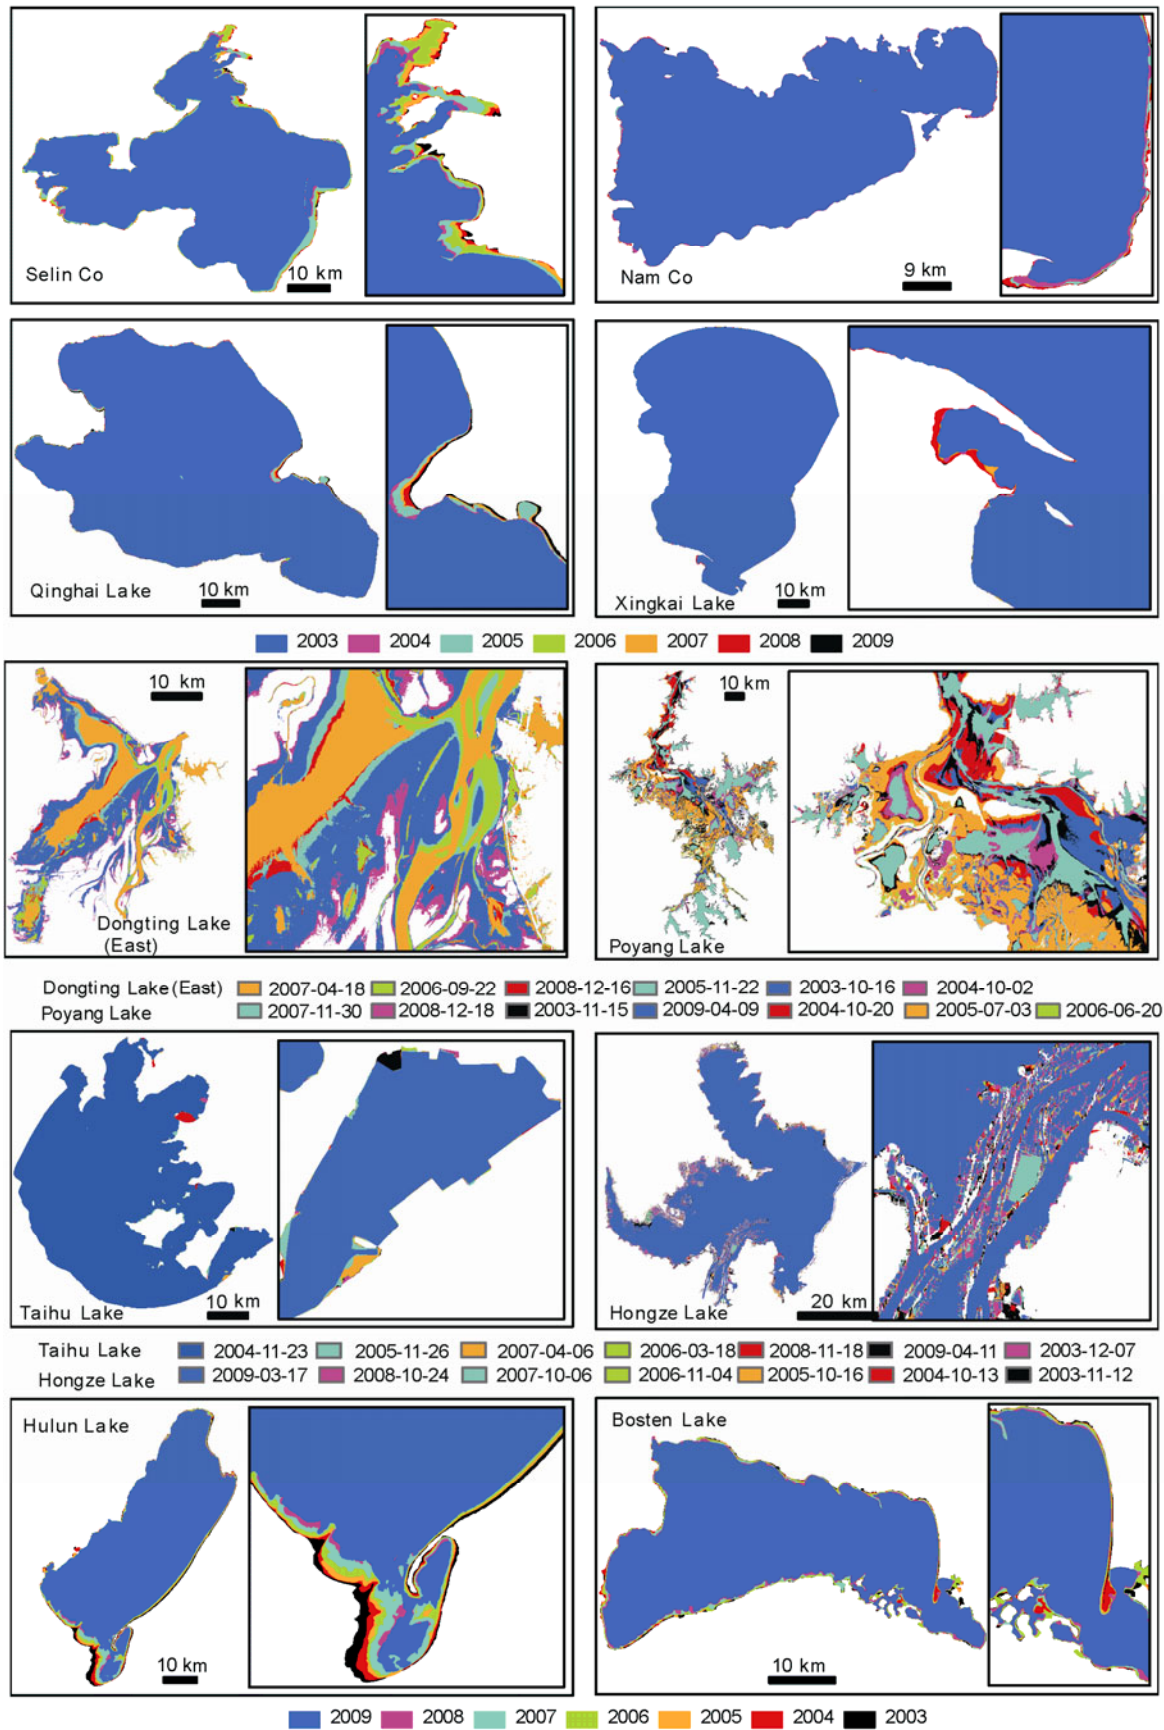

Figure 3 Lake boundaries delineated from Landsat imagery, with insets showing enlarged views of shoreline changes.

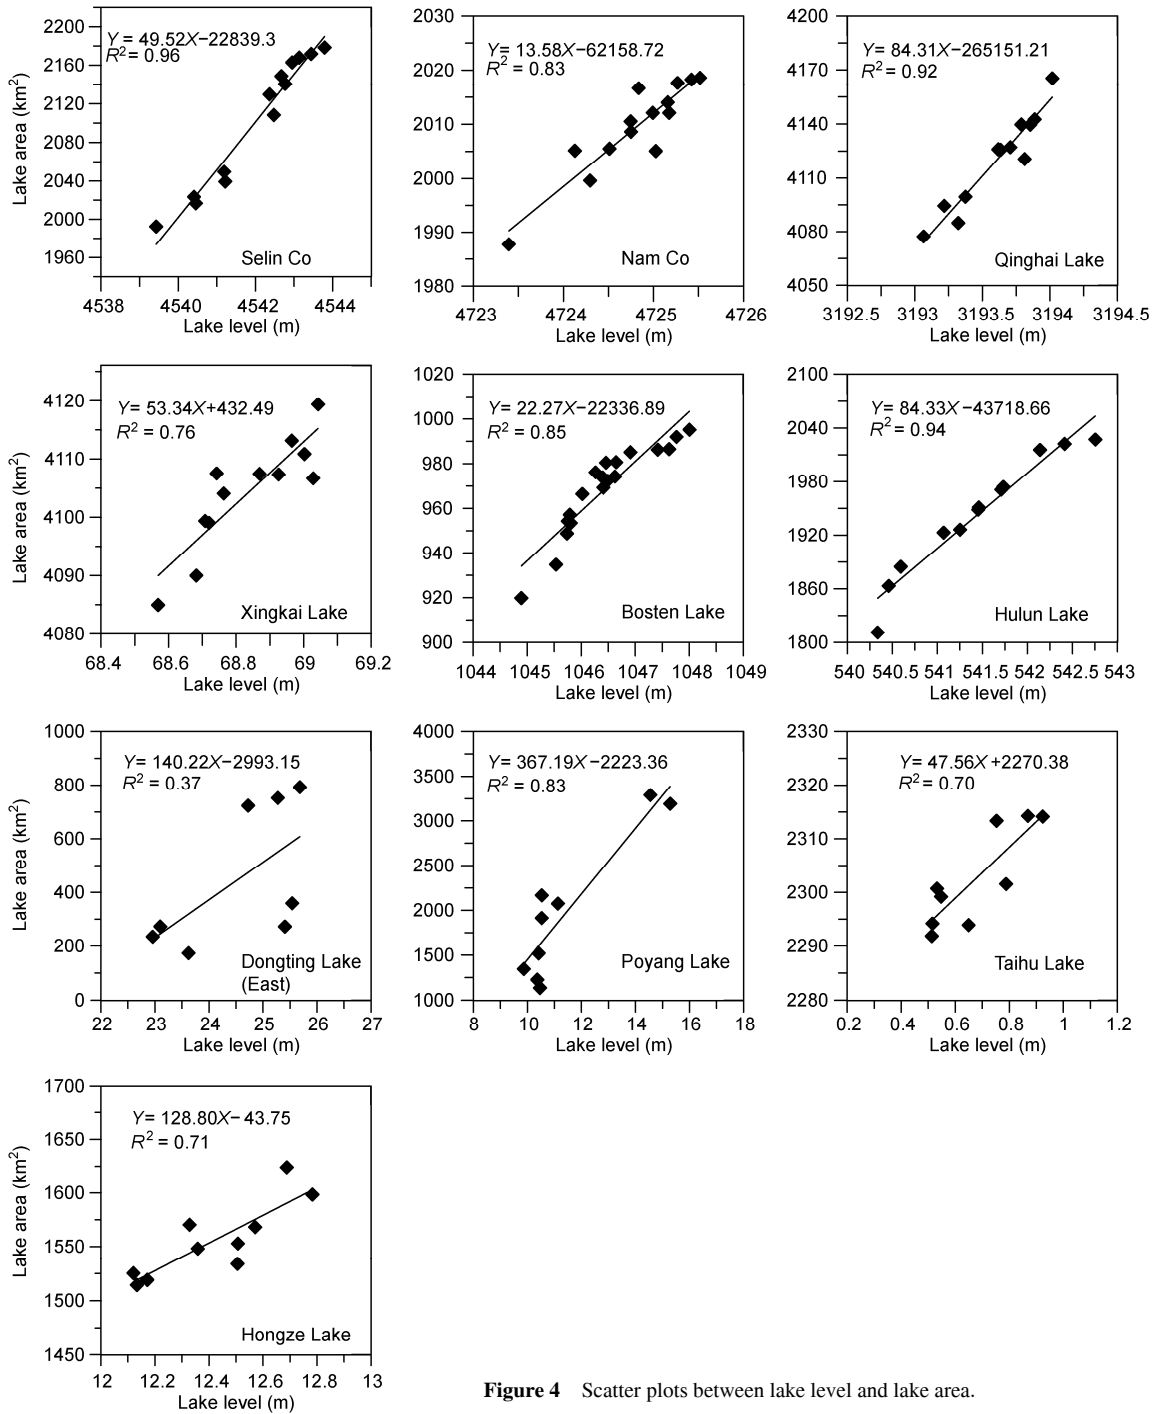

Figure 4 Scatter plots between lake level and lake area.

mid-lower reaches of the Yangtze River (Dongting, Poyang, Taihu, and Hongze) presented slight volume fluctuations of  $-0.25$ ,  $-0.90$ ,  $0.13$ , and  $-0.86$  km<sup>3</sup>, respectively.

### 3 Discussion

Lake level and area changes are closely related to precipitation and evaporation over lake surfaces and water recharge

and discharge of the rivers within the lake basins. Three representative lakes—Nam Co, with a lake level increase in the TP, and Hulun and Poyang, with a water level decrease, and no apparent trend, respectively, in the mid-lower reaches of the Yangtze River Basin—were selected to discuss the possible causes of lake level and area changes by using available meteorological data.

Figure 6 shows the daily precipitation and  $E_{pan}$  measured at Nam Co Station since 2006. The annual  $E_{pan}$  in 2008–

**Figure 5** Lake level changes vs. water volume changes with a third degree polynomial.

2010 was 1645.85, 2051.74, and 2007.50 mm, respectively. Rainfall in the lake basin is usually from April through October. The annual precipitation in 2006–2008 showed an increase, particularly in 2008, which is consistent with lake level, area, and volume variations recorded in the three years. The year 2009 presents a small precipitation while similar or slightly greater  $E_{pan}$ . But the lake level (area and volume) still increased. This suggests that in addition to precipitation and evaporation, snow cover and glaciers play

an important role in the water budget for the basin. As illustrated by recent studies, the rapid shrinking of glaciers in the Nyainqêntanglha Range play an important role in lake level and area changes of Nam Co [26,27,47,48]. Quantitative analyses of lake level changes and snow cover together with precipitation and  $E_{pan}$  for Nam Co and Selin Co have also been reported [24,49].

Reasons for level and area changes of Hulun Lake were examined by using the four nearest meteorology stations

**Figure 6** Daily precipitation and  $E_{\text{pan}}$  observed at station Nam Co during 2006–2010. The x-axis for each year is presented in the order of January, March, May, July, September, and November.

**Figure 7** Location of meteorological stations near Hulun Lake including Manzhouli (MZL), New Barag Youqi (NBY), New Barag Zuoqi (NBZ), and Duleng (DL).

Including Manzhouli (MZL), New Barag Youqi (NBY), New Barag Zuoqi (NBZ), and Duleng (DL) (Figure 7). The monthly and annual temperature, precipitation, and  $E_{\text{pan}}$  from 2003 to 2009 were used in this study. The monthly temperature at stations MZL, NBY, and NBZ showed seasonal variability and an overall increase in average annual temperature (Figure 8). The precipitation data from the three stations showed slight decreases in 2003–2005 followed by obvious increases in 2006–2009. Annual  $E_{\text{pan}}$  indicated no obvious trend with several fluctuations. The differences between average annual  $E_{\text{pan}}$  at station DL and precipitation from the three stations ( $E_{\text{pan}}$  minus precipitation) during 2003–2007 showed increases with slight decreases in 2006, which is consistent with general lake level, area, and volume declines with slight increases in 2006–2007 (Figure 2). Although these differences show decreases in 2008 and 2009, lake level and area changes are not clear in 2009 due to limited ICESat data. Overall, the negative difference between precipitation and  $E_{\text{pan}}$  play a key role in decreases of lake level, area, and volume. In addition, the degradation of seasonally frozen soil with warmer tempera-

ture and river closure of two tributaries upstream of Hulun Lake could partially contribute to the decrease in lake level [50,51].

Poyang Lake, located in the northern Jiangxi Province and south of the Yangtze River, is the largest freshwater lake in China with an area of  $\sim 3000 \text{ km}^2$ . The lake drainage area of  $162000 \text{ km}^2$ , which occupies approximately 97% of Jiangxi Province, has been an important habitat for wildlife and domestic water supply for more than 40 million populations [52]. Five major rivers including the Xiushui, Gangjiang, Fuhe, Xingjiang, and Raohe flow into Poyang Lake, and six hydrologic stations are located in its basin (Figure 9). Figure 10 shows the daily and mean annual lake levels derived from gauge measurements at Duchang station and available daily ICESat-derived water levels. Gauge measurements show clear seasonal variations with water level increases during March–August and decreases during September–February, in addition to overall decreases during 2003–2009. The ICESat water levels overlap with gauge-measured water levels with  $R^2 = 0.86$  between corresponding gauge and ICESat measurements.

Figure 11 shows monthly and average annual temperature, precipitation, and  $E_{\text{pan}}$  changes between 2002 and 2009 from 84 stations in the Poyang Lake basin, Jiangxi Province. The difference of annual precipitation and  $E_{\text{pan}}$  (precipitation minus  $E_{\text{pan}}$ ) showed a decrease, which could have contributed to the overall decrease of the lake level shown in Figure 10. However, differences were present the intra-annual pattern, particularly in 2003 and 2006. The mean lake level in 2003 was the highest, whereas the difference between precipitation and  $E_{\text{pan}}$  was low. These results are due to the highest difference between precipitation and  $E_{\text{pan}}$  of the previous year (2002). The difference between precipitation and  $E_{\text{pan}}$  in 2006 was high, while the mean lake level was low. Most of area in the upper reaches of the Yangtze River experienced extreme drought in the summer of 2006, and the runoff of the Yangtze River reached the lowest level among the last 50 years [53]. The extreme drought event has resulted in early onset and long duration of the dry season

**Figure 8** Monthly temperature and precipitation observed at meteorological stations Manzhouli (MZL), New Barag Youqi (NBY), New Barag Zuoqi (NBZ) and annual average from three stations and monthly  $E_{pan}$  at station Duleng (DL) during 2003–2009. The differences between the average annual precipitation of stations MZL, NBY and NBZ and  $E_{pan}$  from station DL ( $E_{pan}$  minus precipitation) during the same period are also presented.

for Poyang Lake (Figure 10). In addition, the lower runoff of the Yangtze River and impoundment of the Three Gorges Dam increased replenishment from lake and tributaries to the Yangtze River in 2006 [12,53]. These factors could have resulted in the decrease of lake level, although the precipitation in the Poyang Lake basin showed no obvious change.

The lakes in the mid–lower reaches of the Yangtze River basin could have experienced more influence from human activities than from climate effect. A stronger increase in annual precipitation and weaker warming rate were reported in the humid South China than those in the northeastern region [54, 55]. However, the number of vanished lakes in the mid–lower reaches of the Yangtze River basin account for approximately 40% of total loss of lakes in China. This result is mainly attributed to human activities such as reclamation, expansion of lakeside development, and enclosures [5].

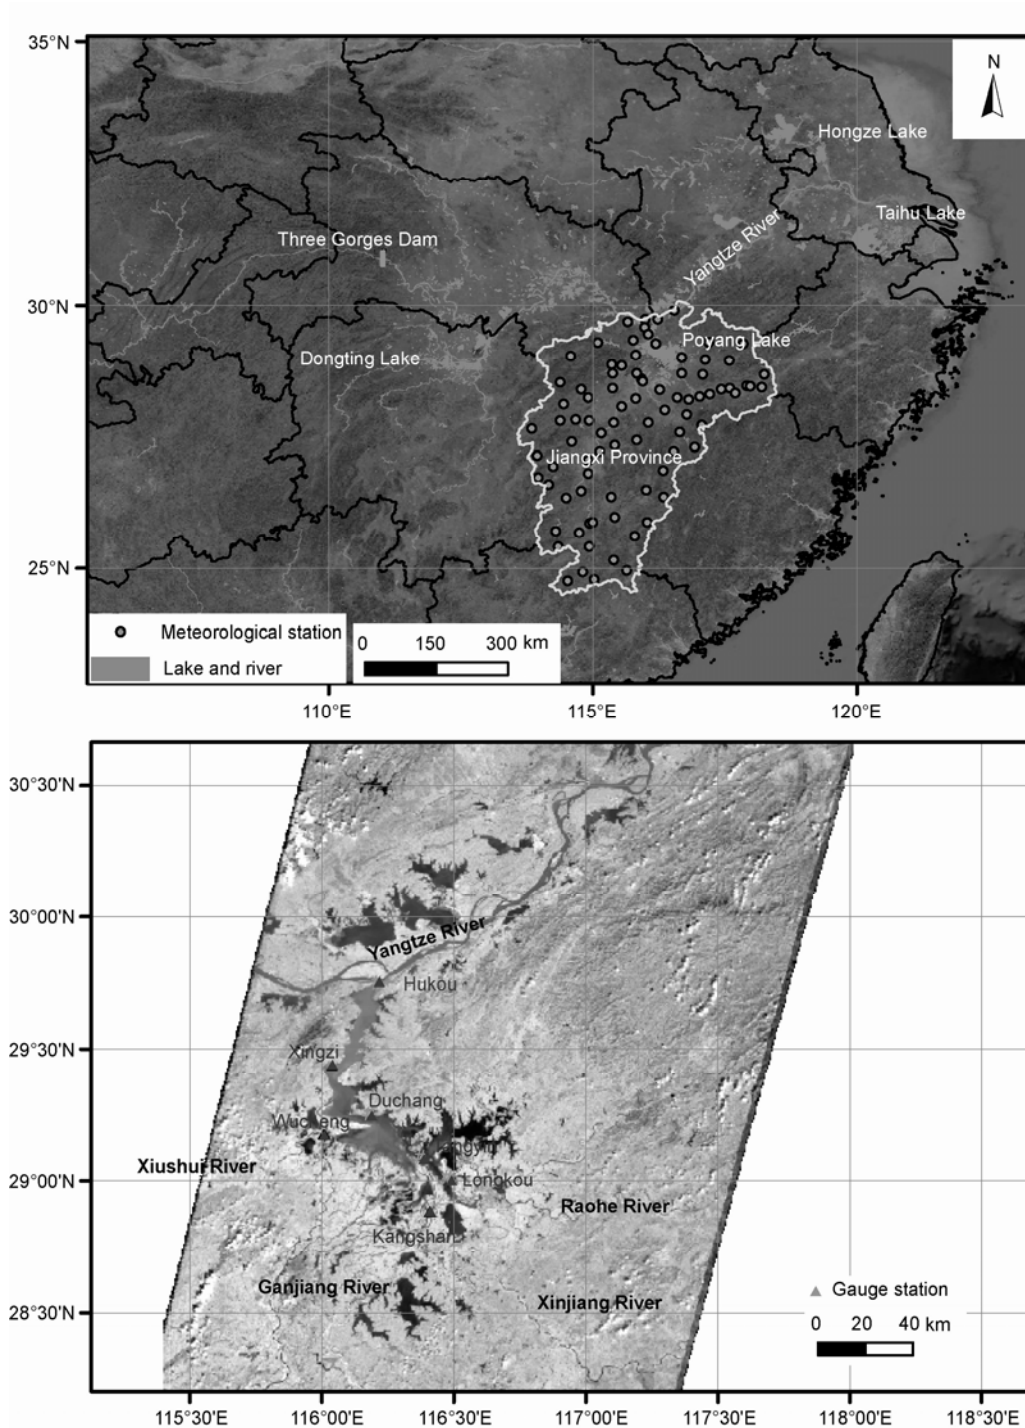

#### 4 Conclusions

In this study, we derived lake levels and area from ICESat

altimetry data and Landsat data, respectively. The water balances of the 10 largest lakes in China during 2003–2009 were estimated, and the lakes were grouped into three subgroups according to the lake level and area trends.

Selin Co, Nam Co, and Qinghai Lakes in the TP showed greater lake level and area increases. Selin Co showed the most rapid lake level (0.69 m/a) and area (32.59 km<sup>2</sup>/a) increase with a water balance of 9.08 km<sup>3</sup> and rate of 1.25 km<sup>3</sup>/a. The positive water balance of Nam Co and Qinghai Lake was 4.07 and 2.88 km<sup>3</sup>, respectively. In addition, Xingkai Lake, which crosses the border of China and Russia, showed slight lake level (0.07 m/a) and area (2.17 km<sup>2</sup>/a) increases with a water balance of 1.09 km<sup>3</sup>. Bosten and Hulun Lakes in arid and semiarid China showed substantial lake level, area, and volume decreases with respective rates of –0.43 m/a, –10.57 km<sup>2</sup>/a, and –0.41 km<sup>3</sup>/a and –0.41 m/a, –35.56 km<sup>2</sup>/a, and –0.75 km<sup>3</sup>/a; water balances were –3.01 and –4.73 km<sup>3</sup>, respectively. The area and water level changes of Dongting, Poyang, Taihu, and Hongze lakes in the mid–lower reaches of the Yangtze River basin showed seasonal variability.

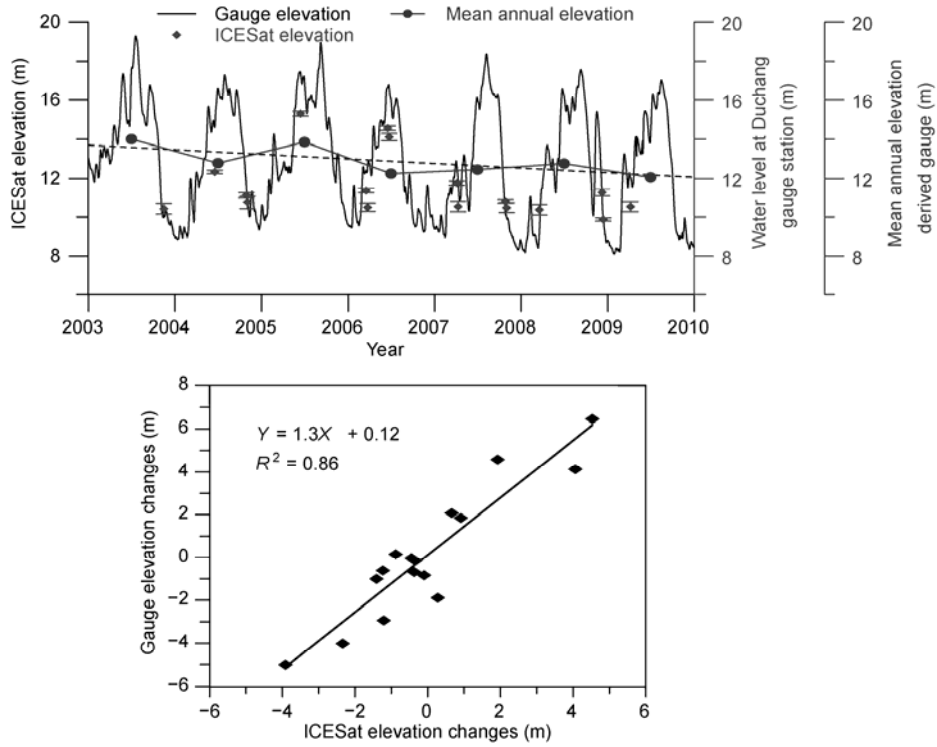

Three of the 10 lakes, one in each group, were selected to

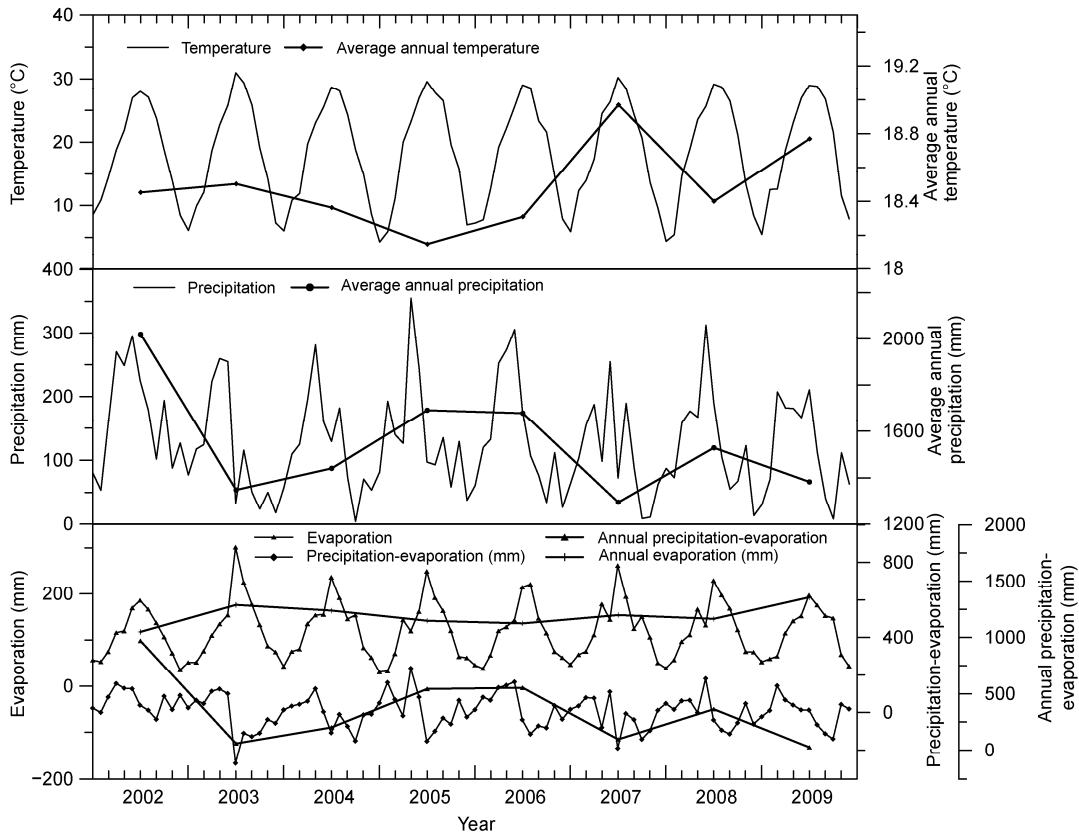

**Figure 9** Dongting, Poyang, Taihu, and Hongze lakes; Three Gorges Dam along the Yangtze River; and 84 meteorological stations in Jiangxi Province (top panel). Five major tributary rivers, Xiushui, Ganjiang, Fuhe, Xinjiang, and Raohe, discharge into Poyang Lake. Six hydrological stations are annotated (bottom panel).

discuss the possible causes of lake level and area changes. The increases in lake level and area in the TP are primarily caused by increased precipitation in addition to accelerated melting of snow cover and glaciers. The greater negative balance between precipitation and evaporation triggered lake level and area decreases in the arid and semiarid region such as Bosten and Hulun lakes. The lake level and area in

the mid–lower reaches of the Yangtze River basin has strong seasonal variations in wet and dry seasons. Poyang Lake is examined within the entire basin with rich meteorological data. A slight decrease in lake level was affected by regional climate changes coupled with anthropogenic activities. This study suggests that water balance of lakes can be estimated by combining satellite-derived lake area and level

**Figure 10** Lake levels derived from ICESat data with standard deviation for daily and annual water levels observed at Duchang Hydrological Station at Poyang Lake (top panel). The relationship between lake level changes derived from ICESat and gauges is also given (bottom panel).

**Figure 11** Monthly and average annual temperature, precipitation, and  $E_{pan}$  from 84 stations during 2002–2009 in the Poyang Lake basin, Jiangxi Province. The differences between precipitation and  $E_{pan}$  (precipitation minus  $E_{pan}$ ) from the same period are also shown.

changes. This study also provides a method for validating the estimation of water volume changes of lakes for hydrological modeling.
