## Abstract

**Background:** Bisphosphonates are a main component in the therapy of osteoporosis and other bone resorptive diseases. Previous studies have shown a positive effect of systemically applied bisphosphonates on fracture healing. Nevertheless high doses are related to side effects like osteonecrosis of the jaw, nephrotoxis and gastrointestinal symptoms. In this study we investigated the effect of locally applied pamidronate on fracture healing.

**Methods:** In a rodent model a simple femur fracture was set in female Wistar rats. We performed intramedullary fixation of the fracture and placed a collagen matrix around the fracture area. One group was treated with pamidronate, the other group with placebo via the matrix.

To investigate the volume and quality of the callus we used micro-CT ( $\mu$ CT) and histology after 14 and 28 days.

**Results:** Our results show a positive influence of local applied pamidronate on callus volume. After 14 days an insignificant increase of callus volume in the treated animals was seen. 28 days after trauma the increase of callus volume in the treatment group was significantly higher in comparison to the control group. Osteonecrosis was not seen.

**Conclusions:** Locally applied bisphosphonates increase the callus volume in fracture healing.

## Background

Osteoporosis is a major health problem of the elderly western society and gains economical importance [1, 2] besides its obvious impact on clinical practice. The risk of fractures is directly related to bone density [3]. In addition the incidence of falls and fall-related injuries rises with age [4]. Therefore fracture fixation in osteopenic bone has become a major task in modern orthopaedic surgery. Postoperative implant loosening is often observed, and 'cutting out' of implants in the femoral head is a common complication. In the elderly a rapid mobilisation after surgery is necessary to reduce the incidence of complications like pneumonia and venous thromboembolism as well as mental confusion.

Bisphosphonates are a main component of osteoporosis therapy and other diseases involving increased bone resorption. Osteoporosis is initially treated with oral calcium, vitamin D and Bisphosphonates [5]. Bisphosphonates reduce the activity of osteoclasts by binding hydroxyapatite crystals and impair the osteoclasts ability to resorb bone [6]. In the resorption lacuna with its exposed calcium ions on bone surface a high dose of the bisphosphonates accumulates. The agent is then resorbed by the active osteoclast. On a cellular level bisphosphonates inhibit steroid synthesis by inhibiting the farnesyl diphosphate synthase (FPPS) in the mevalonate pathway. Thereby the synthesis of essential lipid sidechains of membrane binding proteins is impaired. In absence of lipid sidechains it is impossible for proteins to bind to the cell membrane and they are functionless [7–9]. Subsequently the activity of the osteoblasts overweighs and bone resorption is reduced [10]. An emerging concept in modern

trauma surgery is therefore to develop biological augmentation techniques in order to promote fracture healing.

Previous studies have shown a positive effect of bisphosphonates on fracture healing [11]. In most of these studies bisphosphonates were given systemically. Based on the poor bioavailability of bisphosphonates high doses were necessary. These can cause side effects like osteonecrosis of the jaw, nephrotoxicity, gastrointestinal symptoms, etc. [12]. Wermelin et al. have studied the local effect of bisphosphonates on implant fixation [13]. The authors investigated the fixation of bisphosphonate-coated screws in rat tibias demonstrating improved screw pull out resistance when bisphosphonates were applied.

Greiner et al. [14] investigated locally applied zoledronic acid via coated implants in fractured rodent tibiae. Bending tests and review of plain radiographs revealed improved mechanical stability of the bones of animals treated with zoledronic acid but the results were not supported by histological or high-resolution radiological studies. Therefore we used  $\mu$ CT to image callus formation and callus volume. Histology was performed to investigate cellular processes.

Our rationale was to make use of the positive effects of bisphosphonates in fracture healing while reducing the side effects of systemically application by local application.

## Methods

### Animals

44 female Wistar-rats (mean weight  $200 \pm 10$ ) were obtained from the local service unit of the author's institution. The animals were kept one per cage with free access to water and maintenance diet. The rodents were allowed free movement about their cages. The lighting was maintained on a 12-hour light-dark cycle.

After surgery the animals received analgesia (100 mg/kg Metamizol sodium (Novalgin<sup>®</sup>, Hoechst, Unterschleissheim, Germany) with the drinking water. The animals were sacrificed on day 14 or 28 after the surgical procedure.

### Surgical procedure

The animals were randomized in two groups. The first group was treated with pamidronate (Pamifos<sup>®</sup> - Medac GmbH, Wedel) 0.6 mg/kg, the other group was treated with placebo (NaCl 0.9 % Fresenius Kabi AG, Bad Homburg). Anaesthesia was applied (Fentanyl 0.005 mg/kg, Midazolam 2.0 mg/kg und Medetomidin 0.15 mg/kg) intraperitoneally. First the intramedullary fixation through a median parapatellar insertion at the knee was performed as described by Gabet et al. [15]. A cannula was drilled into the fossa intercondylaris and advanced into the femur. Then the wound was closed and a standard trauma was applied to the right femur as described by Bonnarens [16]. Afterwards through a second surgical approach on the lateral femur, a sub vastus approach,

the collagen matrix (soaked with pamidronate or placebo) was laid around the fracture region and fixed with a suture. The wound was closed again and anaesthesia was antagonized by Naloxon 0.12 mg/kg, Flumazenil 0.2 mg/kg and Atipamezol 0.75 mg/kg.

### Micro CT analysis

The bones were scanned in a  $\mu$ CT Scanner (vivaCT 40, Scanco Medical AG, Bassersdorf, Switzerland) with 70 kVp, 114 mA and 1300 ms integration time at 10.5  $\mu$ m resolution in 1000 slices of the fracture region as described before [17]. During scanning, the femoral bones were placed in phosphate buffered saline. For quantitative analysis of the bone formation the  $\mu$ CT Evaluation Program Version 6.5-1 (Sanco Medical, Bassersdorf, Switzerland) was used to obtain the volume of interest. Based on histogram of attenuation distribution, tissue was segmented into highly mineralised tissue (270 – 400) and low mineralised tissue (180 – 269) in per mille of maximal image grey value [15].

### Preparation of specimens and histologic assessment

After the  $\mu$ CT scan bone histology was performed to investigate the micro-architecture of the callus.

For calcified histology the bones were fixed in 10 % neutral buffered formalin for 14 days at room temperature, dehydrated with ascending concentrations of ethanol and embedded in methylmethacrylate for 5 days at 4 °C.

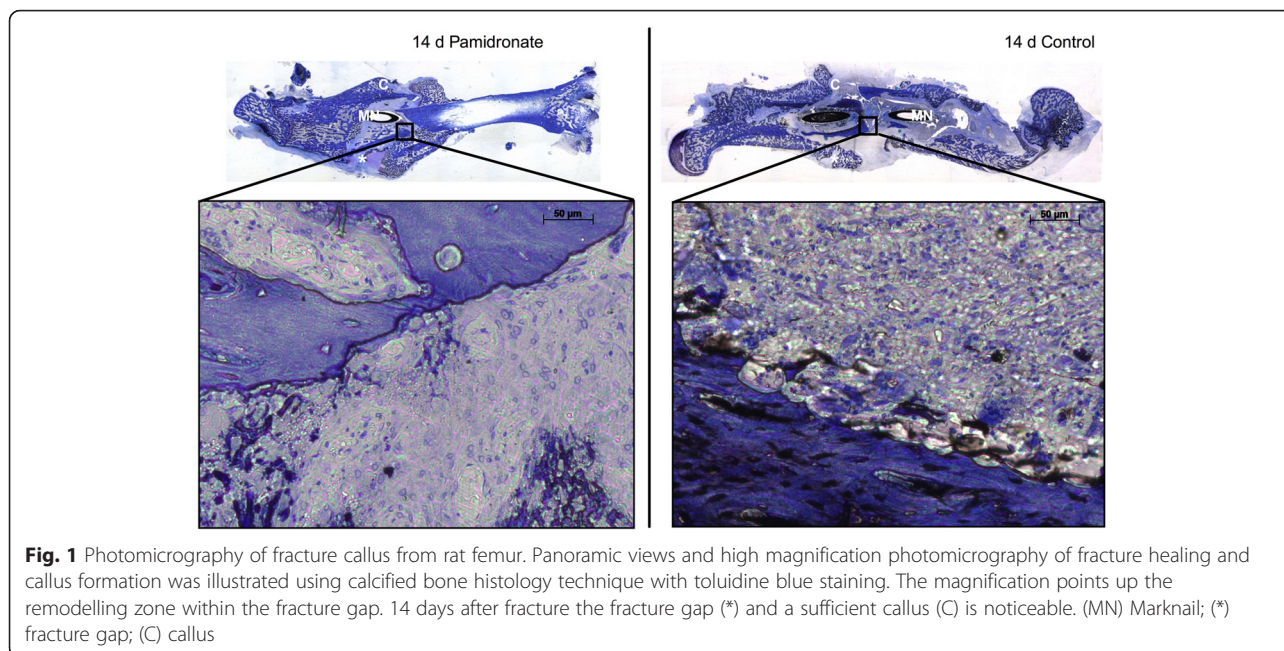

Afterwards the tissue was soaked in methyl methacrylat monomer, nonpylphenyl-polyethyleneglycol acetate and azoisobutyronitrile (all from Sigma-Aldrich, St. Louis, USA). The blocks were released from the glass vials and sections of 40  $\mu$ m were sawed and grinded using an EXAKT diamond saw system (Exakt, Norderstedt, Germany). The samples were lubricated with 0.1 % formic acid for 2 minutes and washed with water afterwards. The sections were submerged in 20 % methanol for one hour and stained with toluidine blue or haematoxylin and eosin.

### Statistical analysis

We used a standard statistical program (GraphPad Software Inc., La Jolla, CA USA) to perform a Kolmogorov-Smirnov normality test. Statistical significance was evaluated using the Mann-Whitney test. Volumes of were illustrated with box and whisker plots.

### Results

All animals recovered quickly after surgery and mobilized fully within one day. No signs of pain or dysfunction in physical motion were recognized after one day. Five animals died during anaesthesia. No animal had to be excluded because of implant dislocation or soft tissue infection. Six rodents were excluded because of multifragmentary fractures.

**Histology**

Callus formation and fracture healing were investigated by standard calcified bone histology. With this method we were able to illustrate the cellular and mineralised components of the callus and the new bone formation.

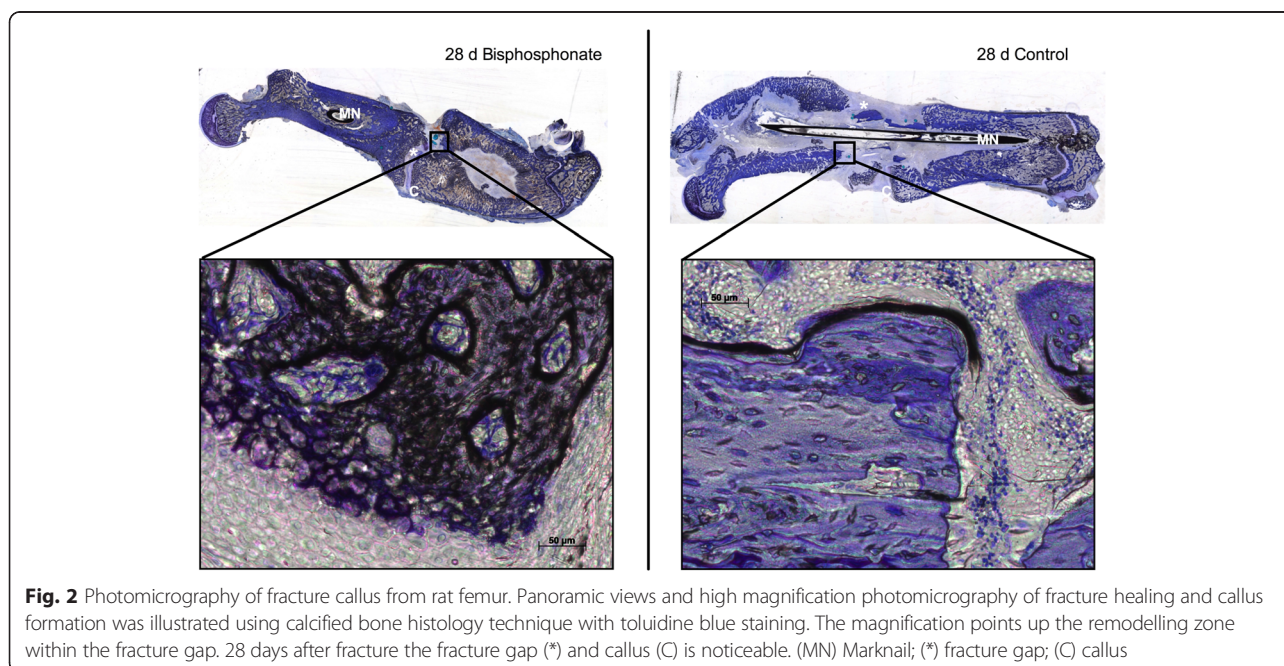

14 days after trauma the fracture gap was still visible. Toluidine blue staining showed the first connective tissue between the bone ends (Fig. 1).

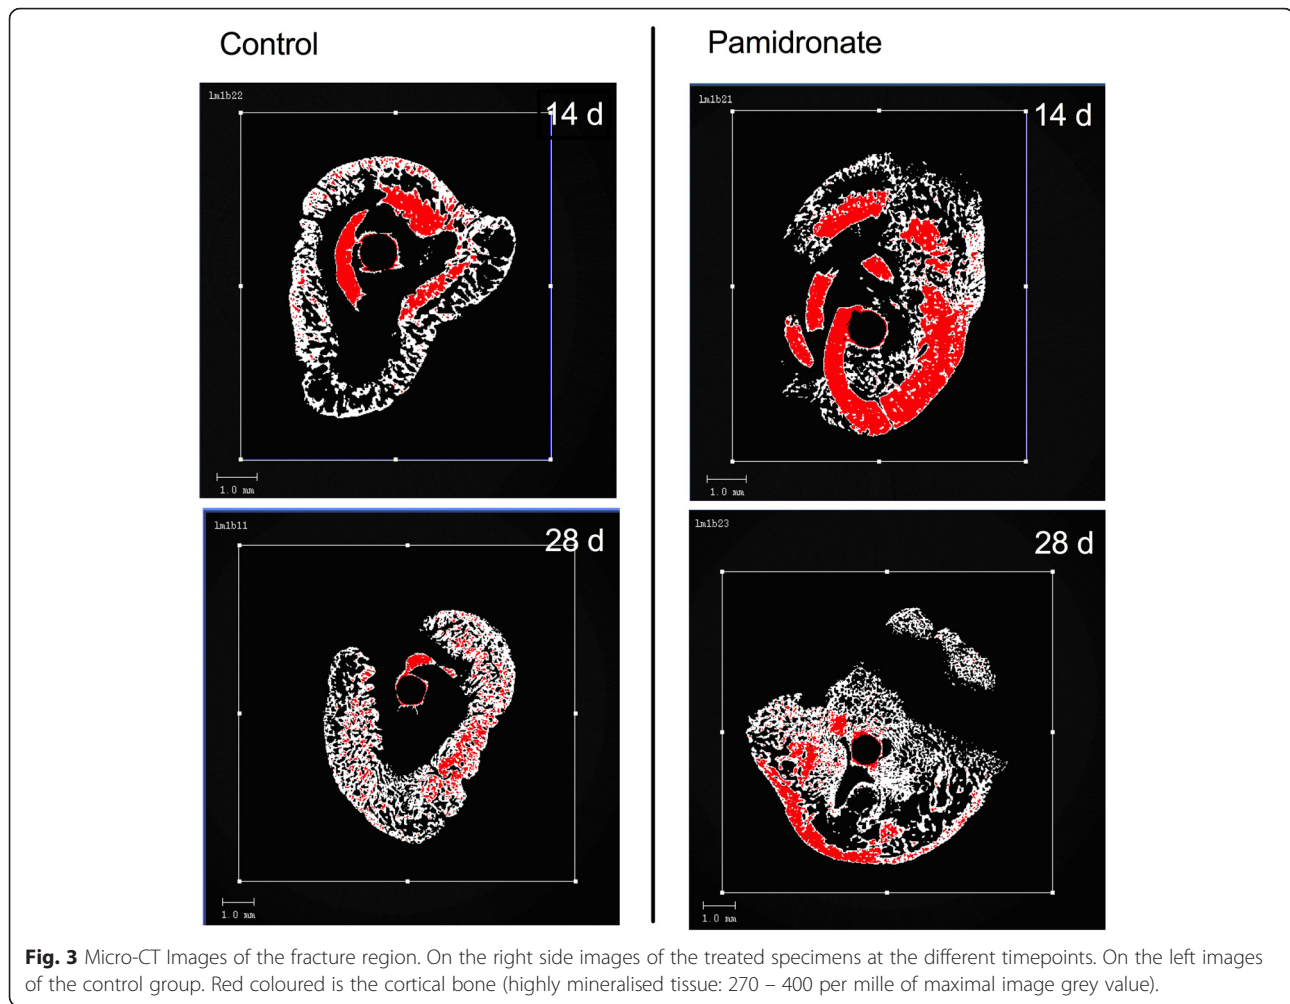

After 28 days the fracture healing was not complete. There was partial bony bridging of the fracture gap (Fig. 2)

and sufficient callus had arisen. No clear differences were determined between the two groups.

**Micro CT scans of the fracture zone**

The callus volume was determined in the fracture region (Fig. 3). After 14 days there was more callus in the animals treated with Bisphosphonates ( $60.94 \text{ mm}^3 \pm 11.28 \text{ mm}^3$ ;  $n = 12$ ) than in the control group ( $52.85 \text{ mm}^3 \pm 16.58 \text{ mm}^3$ ;  $n = 9$ ). But this increase was statistically not significant ( $p = 0.1264$ ) (Fig. 4a).

At this time the difference in cortical bone volume was similarly insignificant (BP:  $42.01 \text{ mm}^3 \pm 16.65 \text{ mm}^3$ ;  $n = 12$ ; control:  $28.14 \text{ mm}^3 \pm 10.71 \text{ mm}^3$ ;  $n = 9$ ;  $p = 0.0579$ ).

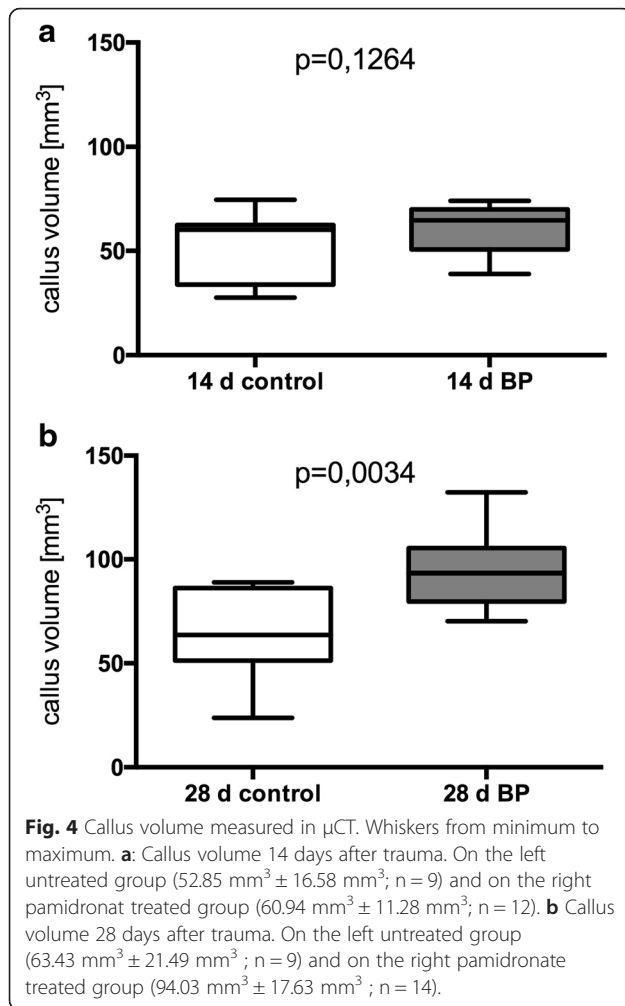

28 days after trauma the increase of the callus volume in the treated group ( $94.03 \text{ mm}^3 \pm 17.63 \text{ mm}^3$ ;  $n = 14$ ) was significantly higher ( $p = 0.0034$ ) in comparison to the control group ( $63.43 \text{ mm}^3 \pm 21.49 \text{ mm}^3$ ;  $n = 9$ ) (Fig. 4b). 28 days post trauma there was no statistical significant difference ( $p = 0.4004$ ) in bone volume of treated ( $60.52 \text{ mm}^3 \pm 25.08 \text{ mm}^3$ ;  $n = 14$ ) and untreated animals ( $61.94 \text{ mm}^3 \pm 20.95 \text{ mm}^3$ ;  $n = 9$ ).

## Discussion

In this study we have investigated the effect of local application of bisphosphonate via a bisphosphonate loaded collagen matrix in a well established fracture model.

Previous studies indicate an increase of callus volume in fracture healing under bisphosphonate application [18–20]. In these studies the agent was given systemically. Goodship et al. report that callus volume was increased under treatment with pamidronate in a sheep

model. Nyman and colleagues investigated the effect of high doses of subcutaneously injected clodronate on fracture healing in tibia fractures in rats. The results show that there is a higher calcium content in the callus when treated with clodronate [19]. Li et al. demonstrate that significantly larger callus arises when incadronate was injected before and after trauma [21]. Despite all favourable effects described in the literature side effects of the systemic treatment with bisphosphonates do still represent a major obstacle. The group around Villa investigated the bisphosphonate related osteonecrosis of the jaw (BRONJ) in female patients with postmenopausal osteoporosis. With continuous bisphosphonate therapy they report 9 % osteonecrosis of the jaw [22]. Perazella et al. described the nephrotoxicity of intravenous bisphosphonate therapy. The toxicity depends on the dose and the infusion time [23]. Hyldstrup et al. demonstrated in their study the poor bioavailability of oral applied pamidronate. The bioavailability depends on the oral dose and showed high intraindividual variations [24].

Locally applied bisphosphonates therefore offer the distinct advantages of a reduced dose that theoretically causes less side effects and while the local effective dose is increased. So far to our knowledge there is no study investigating the effect of locally applied bisphosphonate on fracture healing.

Skoglund et al. investigated the effect of local applied simvastatin in fracture healing. The group compared the continuous locally applied HMG-CoA reductase inhibitor to daily subcutaneous application. The locally applied simvastatin showed a positive effect on biomechanical properties of the newly formed callus [25].

Our results demonstrate a positive effect on fracture healing of locally applied bisphosphonate. After 14 days the callus volume was increased in the treated group. The difference became statistically significant after 28 days. In keeping with these results previous studies showed increased callus volume after systemically applied bisphosphonates [18, 20].

At no time point the bone volume was significantly increased in either group. After 14 days the bone volume

was slightly increased in the treated rodents. After 28 days the increase turned into a slight decrease and the control group showed slightly higher bone volume. A possible explanation for the phenomena is a delayed bone turnover under bisphosphonate therapy as described before [26]. On a cellular level histology does not reveal osteonecrosis, abnormal bone healing or inflammation.

The rodent fracture model we used is an established and commonly used model to investigate fracture healing. It is a cheap and easy to handle model in contrast to larger animals. Nevertheless certain aspects of rodent fracture healing may well be used to investigate basic mechanisms. The limited amount of animals in this study is due to ethical considerations. When all animals included in this study were analysed it seemed inappropriate to further increase the number tested as our results seemed convincing. Statistically there is less power of the cohort.

Limitations of the study presented here comprise lack of mechanical testing, which would be necessary to be investigated in further studies.

## Conclusions

Locally applied bisphosphonates increase the callus volume in fracture healing. There is no increased bone volume under the influence of bisphosphonate. Biomechanical testing will be necessary to investigate the mechanical abilities of the newly formed tissue. With local application lower doses of bisphosphonates may be effective which could lead to a reduction of side effects.

## Abbreviations

BRONJ, bisphosphonate related osteonecrosis of the jaw; FPPS, farnesyl-diphosphate-synthase; HMG-CoA 3-hydroxy-3-methylglutaryl-coenzyme A;  $\mu$ CT, micro computed tomography.

## Acknowledgements

We thank G. Neßenius for her excellent technical support with data acquisition.

## Funding

The work was funded by our own institutional funds.

## Availability of data and materials

All data supporting our findings are contained within the manuscript.

## Authors' contributions

LM drafted the manuscript, participated in its design and performed the surgery and the statistical analysis. MW carried out the surgical procedures and participated in its design and coordination. TK performed the statistical analysis. SB carried out the surgical procedures. PB conceived of the study and carried out the histologic assessment. SF-O carried out the histologic staining and participated in its design and coordination. DV participated in the micro-CT. NP performed and assessed micro-CT. CCG assessed the micro-CT. TP assessed the histology. AS conceived of the study and participated in its design. SL designed the study, participated in its coordination and helped to draft the manuscript. All authors read and approved the final manuscript.

## Competing interests

The authors declare that they have no competing interests.

## Consent to publish

Not applicable.

**Ethics approval and consent to participate**

Ethical approval was obtained from the regional ethics committee of Schleswig-Holstein, Germany (V 312-72241.121-9 (23-3/08)).
