During gastrulation, cells in the dorsal marginal zone polarize, elongate, align and intercalate to establish the physical body axis of the developing embryo. Here we demonstrate that the bifunctional channel-kinase TRPM7 is specifically required for vertebrate gastrulation. TRPM7 is temporally expressed maternally and throughout development, and is spatially enriched in tissues undergoing convergent extension during gastrulation. Functional studies reveal that TRPM7's ion channel, but not its kinase domain, specifically affects cell polarity and convergent extension movements during gastrulation, independent of mesodermal specification. During gastrulation, the non-canonical Wnt pathway via Dishevelled (Dvl) orchestrates the activities of the GTPases Rho and Rac to control convergent extension movements. We find that TRPM7 functions synergistically with non-canonical Wnt signaling to regulate Rac activity. The phenotype caused by depletion of the Ca2+- and Mg2+-permeant TRPM7 is suppressed by expression of a dominant negative form of Rac, as well as by Mg2+ supplementation or by expression of the Mg2+-transporter SLC41A2. Together, these studies demonstrate an essential role for the ion channel TRPM7 and Mg2+ in Rac-dependent polarized cell movements during vertebrate gastrulation.

Introduction

Vertebrate gastrulation is comprised of a series of dynamic cell shape changes that result in part via modulation of the actin cytoskeleton (Keller, 2002). A key breakthrough in our understanding of the molecular mechanisms regulating gastrulation was the seminal findings that components of the non-canonical Wnt signaling pathway regulate this process (Wallingford et al., 2002; Yin et al., 2009). Understanding the molecular, cellular, and biochemical mechanisms that regulate gastrulation continues to remain a central focus of developmental studies. To date, a number of signaling pathways including Wnt, FGF, and BMP have been implicated in this process (Roscio et al., 2009).

Non-canonical Wnt signaling is currently loosely applied to a number of intracellular branches that function to regulate cell polarization and motility through modification of the actin cytoskeleton. This pathway appears to be independent of transcription and the well-elucidated canonical or β-catenin-dependent pathway (Semenov et al., 2007). The Wnt signal is mediated through the Frizzled (Fz) receptor and the LRP5/6 co-receptor, leading to activation of the cytoplasmic phosphoprotein Dishevelled (Dvl) (Wallingford and Habas, 2005). Of a number of branches downstream of Dvl, the activation of the small GTPases Rho and Rac plays central roles during gastrulation (Komiya and Habas, 2008). Activation of Rho occurs through the molecule Daam1, which complexes with Dvl in response to Wnt stimulation (Habas et al., 2001). This Rho pathway is coupled to the activation of the Rho associated kinase Rock that subsequently functions to regulate cytoskeletal changes through phosphorylation of myosin's light chains (Marlow et al., 2002; Veeman et al., 2003; Wallingford et al., 2002). Activation of Rac occurs downstream of Dvl, which in turn stimulates JNK activity to also cause cytoskeletal changes (Habas et al., 2003; Li et al., 1999; Yamanaka et al., 2002). The mechanism of action of a host of identified factors including Strabismus, Prickle, and Diversin, among others, and their integration to subsequently govern cell polarization for directional cell migration remains unresolved (Semenov et al., 2007).

Interestingly, a number of studies have pointed to a non-canonical Wnt/Ca2+ pathway in which Wnt stimulation leads to an increase in intracellular Ca2+ levels (Kohn and Moon, 2005). This Ca2+ pathway has been shown to function during vertebrate gastrulation, and Ca2+ is a potent divalent second messenger that can further negatively influence canonical Wnt signaling (Slusarski and Pelegri, 2007). Indeed, while many studies have uncovered changes in Ca2+ levels in
cells undergoing gastrulation, it appears that much of these intracellular fluxes are due to the release of Ca\(^{2+}\) from intracellular stores (Susarla and Pelegri, 2007). The identity of calcium channels that may be expressed on the plasma membrane and functionally traffic extracellular Ca\(^{2+}\) into cells during early stages of development remains unknown. Moreover, whether other ion channels or divalent cations such as Mg\(^{2+}\) play any functional roles during gastrulation remains an understudied area of investigation.

The Transient Receptor Potential (TRP) superfamily is composed of cation-permeant ion channels that have varied, but poorly understood functions, ranging from thermosensation, chemosensation, and visual transduction (Clapham, 2003). Unique among ion channels, the ubiquitously expressed TRPM7 was discovered as the first ion channel to possess its own kinase domain (Nadler et al., 2001; Runnels et al., 2001). While most divalent cations block ion fluxes through Ca\(^{2+}\)-permeable ion channels, TRPM7 exhibits high permeation of Ca\(^{2+}\) as well as other essential divalent cations, including Mg\(^{2+}\) and Zn\(^{2+}\) (Monteil-Zoller et al., 2003). Consequently, an array of functions has been assigned to TRPM7, presumably owing to the diversity of cations permeated by the channel. Loss of TRPM7 has been reported to cause skeletal, pigmentation, and kidney defects in zebrafish (Elizondo et al., 2005). More recently, it was found that deletion of TRPM7 in mice disrupted embryonic development, resulting in lethality between E 6.5 and 7.5, although the reason for this lethality remains unknown (Dorovkov et al., 2005; Jin et al., 2006).

In this study, we report the cloning and functional analysis of TRPM7 in the Xenopus embryo. We show that XTRPM7 plays a previously undefined role in convergent extension movements during gastrulation. Importantly, our studies point to a key role of the channel, but not the kinase domain of this protein, and for the Mg\(^{2+}\) cation in regulating polarized cell movements during gastrulation, independent of mesodermal specification. Additionally, we show that XTRPM7 regulates gastrulation via its ability to modulate the activation levels of the small GTPase Rac and not Rho. These studies underscore a key role for this ion channel in regulating gastrulation, and furthermore uncover a central role for Mg\(^{2+}\) in this crucial embryonic process.

**Materials and methods**

**Embryo manipulations**

Embryo manipulations and convergent extension assays in embryos were performed as described (Khadka et al., 2009; Sato et al., 2006). Embryo injections were performed using in vitro transcribed RNAs, cDNAs, or Morpholino oligonucleotides (MO). Microinjection and microdissection of Xenopus embryos were performed as described (Khadka et al., 2009; Liu et al., 2008). Briefly, RNAs (500 pg) encoding GFP-CAAX and membrane-tethered Cherry were microinjected separately into dorsal blastomeres of four-cell stage embryos, alone or with RNAs encoding TRPM7 (2 ng) or XTRPM7 MOs (75 ng). “Shaved” Keller explants and analysis of cell shape and alignment were performed as described (Khadka et al., 2009; Liu et al., 2008). Detection of activated Rho and Rac was accomplished using a modified GST-pulldown purification assay (Habas et al., 2001). The relative level of activated GTase was calculated by comparing the total amount of activated protein in each band to the total amount of the protein in the lysate, and then normalizing this number to the amount of activated protein captured in the GST-pulldown assay from un.injected embryos.

**Plasmids and oligonucleotides**

To obtain the complete Xenopus TRPM7 (XTRPM7) sequence (accession number: GQ304750), we employed a PCR based approach to amplify and clone this cDNA from a stage 10.5 Xenopus library. Details are available upon request. pBS–SV40–TRPM7 containing full length Mus musculus TRPM7 was generated by subcloning a KpnI/NotI fragment containing the TRPM7 ORF from pTracerCMV2–TRP–PLIK (Runnels et al., 2001) into pB–SV40. pB–SV40 contains the SV40 polyadenylation sequence from pCS2+, which was introduced by PCR subcloning an amplified 220 bp PCR fragment into the NotI/SacII sites of pBS using the following primers: 5′–GCC GCG CCC TAG ATC CAG ACA TGA GAT ACA TTG ATG AGT TTG G–3′ and 5′–GCC GCG CAT TGA GAT ATG TGT G–3′ and 5′–GCC GCG CAT TAA AAA ACC TCC ACC TAC CCC–3′. To create the “kinase-inactive” mutant of TRPM7 containing G1618D, we employed QuikChange (Stratagene) using the primers previously described (Su et al., 2006). The pOG1 vector encoding human TRPM6x was kindly provided by Dr. Vladimir Chubanov (Philippines Universität Marburg) (Chubanov et al., 2007). The Mg\(^{2+}\) transporter SLC41A2 was subcloned into pCS2+ from the FLAG–SLC41A2/pcDNA4/T0 vector, generously donated by Dr. Andrew Scharenberg (University of Washington) (Sahni et al., 2007). pCS2+ containing C-Daam1, ΔDIX–Dvl, ΔDEP–Dvl, and Xdd1 have been previously described (Habas et al., 2001) as has pCS2+ containing Rho and Rac derived constructs (Habas et al., 2003).

**Results**

**XTRPM7 is temporally and spatially expressed in embryonic tissues undergoing morphogenesis**

To investigate the role of TRPM7 during early embryogenesis, we first cloned Xenopus laevis TRPM7 (XTRPM7), a protein that shares a sequence identity greater than 77% with the human protein. XTRPM7 possesses a domain architecture similar to that of its vertebrate orthologues, exhibiting high sequence identity within its NH2-terminal TRP homology region, its pore domain, and its COOH-terminal kinase domain (Supplementary Figs. 1A–C). We then examined the temporal and spatial expression patterns of XTRPM7 mRNA during Xenopus development. Two primer sets were designed to amplify fragments from the 5′ UTR and the 3′ UTR regions of the XTRPM7 mRNA, and RT–PCR analysis revealed expression of XTRPM7 maternally to the tadpole stage (Supplementary Fig. 2A). In situ hybridization demonstrated a relatively low level of XTRPM7 maternally through the gastrula stages of the developing embryo (Fig. 1A). During the gastrula stage, XTRPM7 RNA was most highly expressed in the dorsal ectodermal and mesodermal regions. By the neurula stage, XTRPM7 expression became restricted to the developing brain, kidney, heart, and notochord (Fig. 1A). This expression pattern is suggestive of a broad role for XTRPM7 during development.

**Dorsal expression of TRPM7 disrupts Xenopus gastrulation**

To determine the function of TRPM7 in vivo, we first expressed TRPM7 to elucidate its effect during Xenopus development. Injection of murine TRPM7 RNA into the ventral marginal zones of the four–cell embryo had no effect on Xenopus development. However, injection of TRPM7 RNA into the dorsal marginal zones of the four–cell embryo resulted in severe gastrulation defects in a dose–dependent manner, while injection of a similar dose of β-galactosidase (β-gal) RNA had no significant effect (Figs. 1B–C). In the TRPM7–injected embryos, the resulting gastrulation defect phenotypes were classified into two classes: severe and mild. In the severe class, anterior structures, including the head, eyes and cement glands, were reduced or absent; in addition, axial extension was impaired resulting in a severe dorsal–flexure in the embryos, and the blastopore and neural folds failed to close. In the mild class, there was a reduction in the size of the head,
eyes and cement glands, and a slight dorsal-flexure of the axis; however, there was only a delay in blastopore and neural fold closure.

**XTRPM7 is required for gastrulation**

To further delineate the role of XTRPM7 in early development, we designed two anti-sense Morpholino oligonucleotides (XTRPM7 MO1 and MO2) to deplete the endogenous XTRPM7 protein (Supplementary Fig. 2B). Both Morpholinos effectively inhibited translation of a Myc-tagged XTRPM7 construct when injected into *Xenopus* embryos (Supplementary Fig. 2C). Injection of the control MO at the highest dose of 75 ng into the ventral marginal zones of the four-cell embryo had little effect on *Xenopus* development (data not shown). Injection of the control MO into the dorsal cells also had little effect on development (Figs. 1B, C) or on Myc-XTRPM7 cDNA expression (Supplementary Fig. 2C). However,
injection of either XTRPM7 MO1 or XTRPM7 MO2 into the dorsal marginal zones of the four-cell embryo dose-dependently produced severe gastrulation defects (Figs. 1B, C). The phenotype induced by injection of the XTRPM7 MO1 and MO2 combined (hereafter referred to as XTRPM7 MOs) was rescued by co-injection of murine TRPM7 RNA (Figs. 1B, C). Injection of this dose of TRPM7 RNA by itself produced no severe gastrulation defects (Supplementary Fig. 3).

**TRPM7's kinase domain is not required for gastrulation**

To determine whether TRPM7's channel or kinase was required for gastrulation, we injected a kinase-inactive mutant TRPM7–G1618D (Su et al., 2006) (TRPM7-KD) RNA into the dorsal blastomeres of the four-cell embryo and observed gastrulation defects similar to those obtained with the full-length TRPM7. Interestingly, co-injection of TRPM7–G1618D RNA with the XTRPM7 MOs rescued the XTRPM7 MO-induced defects, indicating that TRPM7's kinase activity is not required for the protein's role during gastrulation (Figs. 1B, C). To confirm that TRPM7's channel was required for the ability of TRPM7 to induce gastrulation defects, we injected a channel-inactive mutant TRPM7–E1047K (Li et al., 2007) (TRPM7-CD) RNA into the dorsal blastomeres of the four-cell embryo and observed lesser defects in gastrulation as compared to injection to the TRPM7 RNA or the kinase-inactive mutant TRPM7–G1618D (Figs. 1B, C). Likewise, co-injection of TRPM7–E1047K RNA with the XTRPM7 MOs failed to rescue the XTRPM7 MO-induced defects, indicating that TRPM7's channel activity was required for its effect on gastrulation (Figs. 1B, C). To determine whether TRPM7's channel was unique in its ability to regulate gastrulation via the cations it conducts, we tested whether TRPM6 (Schlingmann et al., 2002), a channel closely related to TRPM7, regulates gastrulation via the cations it conducts, we tested whether TRPM7's channel domain was required for the ability of TRPM7 to induce gastrulation defects, we injected a channel-inactive mutant TRPM7. Interestingly, co-injection of TRPM7–G1618D RNA with the XTRPM7 MOs rescued the XTRPM7 MO-induced phenotype, indicating that TRPM7’s kinase activity is not required for the protein's role during gastrulation (Figs. 1B, C). To determine whether TRPM7's kinase activity was required for its effect on gastrulation (Figs. 1B, C). To determine whether TRPM7's kinase activity was required for the protein's role during gastrulation (Figs. 1B, C). To determine whether TRPM7's kinase activity was required for the protein's role during gastrulation (Figs. 1B, C).

**Mg2+ suppresses the XTRPM7 morpholino-induced phenotype**

TRPM6 RNA's ability to suppress the XTRPM7 MO-induced phenotype suggested that TRPM7's ability to permeate Mg2+ and Ca2+ was central for the regulation of gastrulation. Elimination of TRPM7 expression from DT40 cells has been shown to arrest cell growth and proliferation, which can be overcome by growth of the cells in 10 mM extracellular Mg2+ or by expression of the Mg2+ transporter SLC41A2 (Sahni et al., 2007; Schmitz et al., 2003). The Mg2+ transporter SLC41A2 has been shown to specifically allow the passage of Mg2+ but not Ca2+ ions (Goytain and Quamme, 2005; Sahni et al., 2007). We therefore employed a similar approach and found that raising the concentration of Mg2+, but not Ca2+, in the buffer in which the embryos were cultured restored development of the embryos injected with the XTRPM7 MOs in a dose-dependent manner (Figs. 2A, B). Similarly, co-injection of SLC41A2 RNA with the XTRPM7 MOs also rescued the XTRPM7 morpholino-induced phenotypes (Figs. 1B, C). Additionally, injection of SLC41A2 RNA at higher doses than those used to rescue the XTRPM7 MO-induced phenotypes also increased gastrulation (Figs. 1B, C and Supplementary Fig. 3). These results suggest that XTRPM7's permeation of Mg2+ is required for gastrulation and that this critical developmental process is exquisitely sensitive to Mg2+ influx.

**XTRPM7 is required for convergent extension movements**

During embryogenesis, a failure of mesodermal specification can produce gastrulation defects, and therefore we examined whether XTRPM7 was required for mesodermal specification. We assayed the dorsal mesodermal markers Chordin and Goosecoid, the pan-mesodermal marker Brachyury (Xbra), and the ventral mesodermal marker Wnt8 (Xwnt8) by RT-PCR. Injection of XTRPM7 MO1 and MO2, either singly or combined, had no effect on the expression levels of these molecular markers (Fig. 2C). Together, these studies indicate that XTRPM7 regulates gastrulation independently of mesodermal cell fate specification.
A major feature of gastrulation is convergent extension in which a series of highly orchestrated polarized cell movements allows the establishment of the physical body axis of the embryo. To further delineate how TRPM7 regulates gastrulation, we examined its effects on convergent extension movements using Keller explant assays. In control, uninjected embryos, we observed normal elongation of the explanted dorsal tissues, while embryos injected with TRPM7 RNA produced dramatically suppressed elongation of the explants, similar to injection of dominant negative Dishevelled (Xdd1) RNA (Figs. 3A, B). Injection of XTRPM7 MOs also strongly suppressed elongation of the explants, which could be rescued by co-injection of TRPM7 RNA (Figs. 3A, B). Similar to the results obtained using whole embryos, injection of the Mg\(^{2+}\) transporter SLC41A2 RNA as well as Mg\(^{2+}\) supplementation of the explant culture buffer restored the elongation of the explants while supplementation of the buffer with additional Ca\(^{2+}\) did not restore extension of the explants derived from the XTRPM7 MO-injected embryos (Figs. 3A, B).

Fig. 3. XTRPM7 is required for convergent extension movements. (A) Dorsal marginal zone (Keller) explant assay revealed that overexpression of TRPM7 (2 ng) and injection of XTRPM7 MOs inhibit convergent extension movements. Dominant negative Dishevelled (Xdd1, 2 ng) was used as a positive control. Inhibition of convergent extension produced by depletion of XTRPM7 was rescued by co-injection of XTRPM7 MOs with TRPM7 RNA (400 pg) and the Mg\(^{2+}\) transporter SLC41A2 (400 pg), as well as supplementation of the buffer with 5 mM Mg\(^{2+}\) but not 5 mM Ca\(^{2+}\). (B) Quantification of Keller explant assay; bars indicate the average length to width ratio of Keller explants and the number of explants analyzed is shown above each bar.
To better understand XTRPM7’s regulation of convergent extension movements during gastrulation, we examined the polarization and cell shape changes of dorsal mesodermal cells. During convergent extension, these cells adopt an elongated and polarized shape with a long axis oriented towards the midline (Shih and Keller, 1992). For these studies, we examined the parameters of length-to-width ratio and of medial axial alignment of explanted dorsal mesodermal cells; both of which are dramatically affected by components regulating convergent extension (Liu et al., 2008; Wallingford et al., 2000). We observed that injection of TRPM7 RNA dramatically altered the length-to-width and medial axial alignment to levels similar to dominant negative Dishevelled (Xdd1) RNA (Figs. 4A–D). Injection of XTRPM7 MOs also significantly affected the length-to-width ratio and medial axial alignment of the explanted cells, and these effects

**Fig. 4.** XTRPM7 is required for dorsal mesodermal cell polarization, elongation and alignment. (A) Confocal imaging analysis revealed that injection of TRPM7 RNA and XTRPM7 MOs inhibits dorsal mesodermal cell polarization and elongation. Control cells were labelled with EGFP-CAAX (green, 500 pg) and membrane-tethered Cherry (red, 500 pg) was co-injected with either TRPM7 RNA (2 ng), dominant negative Dishevelled (Xdd1) RNA (2 ng), XTRPM7 MOs (75 ng), or XTRPM7 MOs (75 ng) and TRPM7 RNA (400 pg). (B) Illustration of calculations of average length to width ratio and average angular deviation. Length to width ratio was measured by taking the length of the cell (red arrow) divided by the width of the cell (blue line). Angular orientation of the cell was measured by taking the absolute value of the angle of the red arrow in reference to the lateral axis (L) and was used for calculations of average angular deviation. (C) Injection of Xdd1 RNA and TRPM7 RNA or injection of the XTRPM7 MOs disrupted dorsal mesodermal cell elongation as quantified by the length/width ratio of cells. The error bars represent the standard deviation (s.d.) from at least three independent experiments and the number of cells examined is shown at the top of each bar. (D) Injection of Xdd1 RNA and TRPM7 RNA or injection of the XTRPM7 MOs disrupted alignment of dorsal mesodermal cells undergoing convergent extension. The error bars represent the s.d. from at least three independent experiments and the number of cells examined is shown at the top of each bar.
were rescued by co-injection of the XTRPM7 MOs with TRPM7 RNA (Figs. 4A–D). These data reveal that XTRPM7 regulates polarization during convergent extension movements.

**XTRPM7 synergizes with Dishevelled to regulate gastrulation through the Rac GTPase**

As the non-canonical Wnt pathway regulates convergent extension movements through the cytoplasmic phosphoprotein Dishevelled (Dvl), we tested whether TRPM7's effect on convergent extension movements could be modulated by non-canonical Wnt signaling. We injected ΔDX-Dvl, an activated form of Dvl that can activate Rho and Rac (Habas et al., 2003; Wallingford and Habas, 2005) together with the XTRPM7 MOs and observed that ΔDX-Dvl strongly suppressed the XTRPM7 MO-induced phenotype (Figs. 5A, B). However, injection of ΔDEP-Dvl, which cannot activate the Rac arm of the planar cell polarity (PCP) pathway, did not have any effect (Habas et al., 2003). To further examine a possible connection between TRPM7 and non-canonical Wnt signaling, embryos were injected with sub-threshold levels of dominant negative Dishevelled (Xdd1) RNA (250 pg) or XTRPM7 MOs (25 ng), which individually produced little or no effects. We found that co-injection of both Xdd1 RNA and XTRPM7 MOs resulted in no synergistic effects on gastrulation, highlighting the importance of XTRPM7 in modulating gastrulation pathways. These findings indicate that XTRPM7 may regulate gastrulation by modulating Rac activity during development.

To further investigate the potential role of TRPM7 in modulating the activation levels of Rho and Rac, we tested whether XTRPM7 affected the endogenous activity levels of Rho and Rac during gastrulation. By employing pulldown assays (Habas and He, 2006), we detected higher levels of activated Rac in embryos injected with XTRPM7 MOs (Figs. 6A–D). These data reveal that XTRPM7 regulates polarization during gastrulation. By employing pulldown assays (Habas and He, 2006), we detected higher levels of activated Rac in embryos injected with XTRPM7 MOs (Figs. 6A–D), but observed no effects of the TRPM7 MOs on Rho activation levels. (A) Western blot analysis and quantification of levels of activated Rac at stage 10.5 during gastrulation. Injection of 75 ng of XTRPM7 MOs increased levels of activated Rac, which could be prevented by co-injection of 500 pg of TRPM7 RNA. (B) Quantification of the results in (A), the error bars represent the s.d. from at least five independent experiments. (C) Western blot analysis and quantification of levels of activated Rho at stage 10.5 during gastrulation. Levels of activated Rho were unaffected by injection of XTRPM7 MOs or TRPM7 RNA. (D) Quantification of the results in (C); error bars represent the s.d. from at least four independent experiments.
MORs on Rho activation levels (Figs. 6C–D). Taken together, these studies reveal a critical role for TRPM7 and its ability to modulate Rac activity for vertebrate gastrulation.

Discussion

In this study, we have investigated the role of TRPM7 during Xenopus development and uncovered a central role for this bifunctional ion channel in regulating gastrulation. Using both gain-of-function and loss-of-function analyses, we show that TRPM7 perturbs cell polarization and alignment during convergent extension movements (Figs. 3 and 4) and that this effect is independent of mesodermal cell fate specification (Fig. 2). The phenotypes induced by overexpression or depletion of TRPM7 resemble those uncovered by other studies examining components of non-canonical Wnt signaling (Yin et al., 2009), revealing an important role for TRPM7 in modulating levels of activated Rac, but not Rho, in the developing embryo. Our results suggest a model in which the intracellular signaling cascade initiated by TRPM7 regulates levels of the Rac GTPase for balanced coordination of cell polarization and migration during convergent extension movements, underscoring a critical role for the bifunctional ion channel in regulating gastrulation.

What is the mechanism by which TRPM7 regulates gastrulation? The TRPM7 protein has a channel domain physically linked to a COOH-terminal cytoplasmic kinase domain. Between the two activities, the role of the kinase domain is less understood, as the identified substrates for the TRPM7 kinase thus far include annexin 1, myosin IIA, IIB, and IIC (Clark et al., 2006, 2008a, 2008b; Dorovkov and Ryazanov, 2004). Surprisingly, our results indicate that the kinase domain of TRPM7 is not required for the protein’s ability to regulate gastrulation, as an inactivating mutation within the kinase domain did not alter the ability of the overexpressed protein to interfere with gastrulation. Importantly, injection of kinase-inactive mutant RNA was able to rescue the gastrulation defects produced by injection of the XTRPM7 MOs to a similar level obtained when using wild type TRPM7 RNA, whereas injection of the channel-inactive mutant did not reverse the XTRPM7 MOs phenotype (Figs. 1B–C). These results strongly indicate that the ability of TRPM7 to regulate gastrulation is dependent on its channel domain. As TRPM7 has been shown to allow the passage of both Ca2+ and Mg2+ ions (Li et al., 2006; Monteilh-Zoller et al., 2003; Voets et al., 2004), it was possible that Ca2+ may be the cation responsible for its regulation of gastrulation, since Ca2+ was shown to play a central role in non-canonical Wnt signaling and gastrulation (Kohn and Moon, 2005; Slusarski and Pelegri, 2007). However, we show that elevating external Ca2+ failed to rescue the XTRPM7 MO-induced phenotype, suggesting that disruption of Ca2+ signaling was likely not responsible for producing the XTRPM7 MO-induced gastrulation defects (Figs. 2A–B and 3A–B). Surprisingly, we found that Mg2+ supplementation ameliorated the disruption of convergent extension movements caused by depletion of XTRPM7 (Figs. 2A–B and 3A–B). Additionally, co-expression of the Mg2+ transporter SLC41A2, a transporter that specifically allows the passage of Mg2+ ions (Goytain and Quamme, 2005; Sahni et al., 2007), in XTRPM7 MO-injected embryos also suppressed the gastrulation defects induced by the XTRPM7 MOs (Figs. 2A–B and 3A–B). These studies suggest that the ability of the TRPM7 channel to passage Mg2+ is important for the ability of mesodermal cells to execute polarized cell movements during gastrulation. Therefore, these studies point to an important role for Mg2+ in regulating convergent extension movements, which to our knowledge was a previously undefined role for this divalent cation.

How does Mg2+ regulate cell behaviours including polarization and migration that are central for gastrulation? During gastrulation, the non-canonical Wnt pathway regulates convergent extension movements through activation of RhoA and Rac via the cytoplasmic phosphoprotein Dishevelled (Wallingford and Habas, 2005). Whereas RhoA is activated by Frizzled (Fz)/Dvl signaling through the Formin-homology protein Daam1 (Habas et al., 2001), Rac activation is independent of Wnt/Fz-triggered Rho activation, and mediates Wnt/Fz/Dvl activation of JNK (Habas et al., 2003). Indeed we show a strong synergy with a simultaneous depletion of XTRPM7 and expression of dominant-negative Dishevelled (Xdd1), suggesting a possible interplay between these two factors (Figs. 5C–D). Additionally, we observe that expression of a construct of Dishevelled, ΔDIX-Dvl that can rescue defects in convergent extension induced by a dominant negative form of Wnt11 (Tada and Smith, 2000; Wallingford and Habas, 2005), suppressed the gastrulation defects induced by the XTRPM7 morpholinos (Figs. 5A–B). ΔDIX-Dvl harbours the PDZ domain that functions in the Wnt/Dvl/Rho pathway and also the DEP domain that functions in the Wnt/Dvl/Rac pathway suggesting that Rho and/or Rac may be affected downstream of TRPM7 (Habas et al., 2003, 2001).

To tease out a potential interplay among TRPM7, Rho and Rac, we find that TRPM7 functions synergistically with Dvl independent of Rho and Daam1 to regulate convergent extension movements (Figs. 5E–F). To further uncover the possible mechanism by which TRPM7 regulates Rho and Rac, we show that the gastrulation defects induced by a loss of XTRPM7 are suppressed by expression of a Rac dominant negative construct, but not by that of a Rho dominant negative construct (Figs. 5E–F). This ability of TRPM7 to modulate Rac, but not Rho, activation level was further verified using Rac and Rho pulldown activation assays from Xenopus embryo lysates (Figs. 6A–D). We find that a loss of XTRPM7 leads to an elevation in the levels of activated Rac levels, and this effect is rescued by co-expression of TRPM7 RNA (Figs. 6A–B). However, it is important to note that while we observe that TRPM7 MO injections cause an elevation in the levels of activated Rac, expression of ΔDIX-Dvl, which can activate both Rho and Rac in mammalian culture cells (Habas et al., 2003), suppressed the TRPM7 MO-induced gastrulation in the embryo (Figs. 5A–B). As a complex inhibitory interplay exists between these two small GTPases (Pertz, 2010; Sander et al., 1999), it is possible that this may explain the ability of the ΔDIX-Dvl to rescue the TRPM7 MO-induced gastrulation defects. Additional studies to address the precise spatiotemporal activation of the Rho family of small GTPases during gastrulation are needed to resolve this important question.

In our study, we go further to show that expression of the closely related TRPM6, the only other vertebrate ion channel to contain a kinase domain, can also rescue the XTRPM7 morpholino-induced gastrulation defects (Figs. 1B–C). Interestingly, mice made deficient in TRPM6 were shown to result in embryonic lethality and neural tube closure defects, highlighting the role of these unique proteins in early development (Walder et al., 2009). It is worth noting that studies in humans as well as in animals have shown that Mg2+ deficiency adversely affects gestational outcomes, however, explanations for this have remained obscure (Almonte et al., 1999; Durlach, 2004). Our in vivo studies indicate that interfering with TRPM7’s regulation of Mg2+ during embryogenesis adversely affects processes in early development in which Mg2+-dependent directional cell motility plays an essential role. Our studies may offer an explanation for the embryonic lethality caused by deletion of TRPM7 in mice by revealing a crucial role for TRPM7 in regulating gastrulation (Dorovkov et al., 2005; Jin et al., 2008; Ryazanova et al., 2010).

In summary, our studies reveal a central role for TRPM7 and for Mg2+ cations in regulating gastrulation. Additional studies to further elucidate how Mg2+ ions regulate gastrulation are therefore warranted as such studies will shed light on previously undefined roles for the Mg2+ cation during early vertebrate development.
