Conclusions: Facilitating using ROTA improves peri-procedural success without increasing complications for severely calcified ULM stenosis. Especially in no HD patients, excellent results were obtained at 1-year. However, the development of TLR-MB had still occurred in 38% of the HD patients despite optimal stent expansion.

Comparison of Coronary Artery Bypass Surgery, Percutaneous Drug-eluting Stent Implantation, and Medical Therapy for Unprotected Left Main Coronary Artery Disease

Igor Zyrjanov1, Ivan Bessonov2, Kazetsvet Vadim1
1Tyumen cardiology center, Tyumen, Russian Federation

Background: Unprotected left main coronary artery (ULMCA) disease is considered an indication for revascularization. However, in “real-world” clinical practice some patients receive medical therapy only. The aim of this study was to evaluate long-term results in patients with ULMCA disease in a “real-world” practice.

Methods: Between January 2006 and June 2011, 218 stable patients were diagnosed with de novo ULMCA stenosis. 52 (23.9%) patients received medical therapy only, coronary artery bypass grafting (CABG) was performed in 106 (48.6%) patients, percutaneous coronary intervention (PCI) in 60 (27.9%) patients. The composite of death, myocardial infarction, and stroke defined as major adverse cardiac and cerebrovascular events (MACCE) and target vessel revascularization (TVR) were defined as primary endpoints. The median follow-up period was 4 years.

Results: Baseline clinical and descriptive morphology of coronary artery disease revealed more comorbidities and more complex anatomies in the medical therapy group compared with CABG and PCI groups. Revascularization might not have been used due to physician’s decision (operative risk considered excessive) in 24 (46.2%) cases or were patients refused revascularization in 28 (51.8%) cases. At 4 years, MACCE rate was higher in nonsurgical group (34.6%) compared with CABG (13.2%; p=0.002) and PCI (14.5%; p=0.016) groups, but there was no difference between CABG and PCI groups. Survival in CABG (47.7%; p<0.001) and PCI (55.5%; p=0.009) groups was higher in compare with nonsurgical group (23%; p<0.001). On the multivariable Cox regression analysis, coronary revascularization (CABG and PCI) was independent predictor of long-term survival (HR 3.49; 95% CI 1.39-8.75; P<0.001).

Conclusions: PCI, like CABG improves survival for patients with unprotected left main coronary artery disease compared with medical therapy only in “real-world” clinical practice.

DES with biodegradable polymer in the treatment of true bifurcation lesions – results of a large registry

Antonio Serra1, Bernard Chevalier2, Thomas Hovasse2, Andres Iñiguez3
1Hospital de Sant Pau y Santa Creu, Barcelona, Spain, 2ICPS, Massy, France, 3Academian E.N Mesолнk State Research Institute of circulation Pathology, Novosibirsk, Russian Federation, 4Jeroen Bosch Ziekenhuis, s'Hertogenbosch, Netherlands

Background: Clinical outcomes after treatment of true bifurcation lesions (Medina classification: 1.1.1, 1.0.1 and 0.1.1) are in general inferior when compared to non-true bifurcation lesions (1.1.0, 0.0.1, 0.1.0). Therefore, our aim was to compare clinical outcomes of the patients with true and non-true bifurcation lesions treated with Nobori DES. This stent with open cell design and biodegradable polymer is expected to perform well in lesions involving bifurcation.

Methods: Within the large, prospective, single-arm, multi-centre, eNOBORI registry, 898 patients (1541 lesions) had at least one bifurcation treated. Bifurcation lesions (BL) were divided into true (TBL, 512 patients; 927 lesions) and non-true bifurcation lesions (NTBL, 386 patients; 614 lesions). All adverse events are adjudicated by an independent clinical event committee. Primary endpoint of the study is target lesion failure (TLF) at 1 year.

Results: Patia was 95% for both groups. No patients were lost to follow-up and the median follow-up was 4 years. In the NTBL group, 1 patient died (0.5%; cardiac), 2 patients had TV-MI (0.9%) and 4 patients had TLR (1.7%) and 9 patients a TLR (3.0%) at 12 months, resulting in TLF of 6.0%. In the TBL group, 3 patients died (1.0%; cardiac), 5 patients had TV-MI (1.7%) and 9 patients a TLR (3.0%) at 12 months, resulting in TLF of 6.0%.

Conclusions: As expected, clinical outcomes after treatment of true bifurcation lesions were less favorable compared to the non-true bifurcation lesions however, the results of both cohorts are very good up to one year.

Background: Long term clinical outcomes after biodegradable polymer eluting stents implantation at bifurcation lesions are unclear.

Methods: We analyzed 203 consecutive patients (208 bifurcation lesions treated) who were treated with PCI with biodegradable polymer coating biolimus-eluting stent(BES) exclusively at our institution between February 2005 and April 2009. They were followed up prospectively after the PCI (median follow-up 1931 days).

Results: One hundred sixty one patients (79%) were male and mean ages were 67 ± 10.3. LMT lesions were 63(30%). Eighty lesions(38%) were treated by culotte stenting technique and other 128 lesions(61%) treated by stenting and kissing balloon technique(S-KBT). We evaluated the incidence for MACCE, which were defined as a combined end point of cardiac death, MI or TLR. During this period, the rate of MACCE, cardiac death, MI and TLR were 15.8%, 4.3%, 1.0%, 10.0% respectively. The rate of MACCE and TLR were not different between culotte stenting technique and S-KBT (p=0.35 and p=0.29 respectively).

Conclusions: Long term outcome after PCI of bifurcation lesions with biodegradable polymer coating BES might be promising.
