SUMMARY

Recently, loss of beta-cell-specific traits has been proposed as an early cause of beta cell failure in diabetes. However, the molecular mechanisms that underlie the loss of beta cell features remain unclear. Here, we identify an Nkx6.1-controlled gene regulatory network as essential for maintaining the functional and molecular traits of mature beta cells. Conditional *Nkx6.1* inactivation in adult mice caused rapid-onset diabetes and hypoinsulinemia. Genome-wide analysis of Nkx6.1-regulated genes and functional assays further revealed a critical role for Nkx6.1 in the control of insulin biosynthesis, insulin secretion, and beta cell proliferation. Over time, Nkx6.1-deficient beta cells acquired molecular characteristics of delta cells, revealing a molecular link between impaired beta cell functional properties and loss of cell identity. Given that Nkx6.1 levels are reduced in human type 2 diabetic beta cells, our study lends support to the concept that loss of beta cell features could contribute to the pathogenesis of diabetes.

INTRODUCTION

Type 2 diabetes mellitus (T2D) is characterized by reduced insulin sensitivity of insulin target tissues and impaired insulin secretion by pancreatic beta cells. Although both of these factors play a role, genetic studies suggest that the ability of beta cells to respond to metabolic stressors is the predominant factor in determining the predisposition to T2D (Muoio and Newgard, 2008).

In T2D, beta cells exhibit an impaired capacity to compensate for increased insulin demand (Cerasi and Luft, 1967), a defect that has been ascribed to both inadequate cellular capacity to secrete insulin (Hosker et al., 1989) and beta cell death (Butler et al., 2003). Among the earliest defects observed in T2D patients is a reduced ability of beta cells to secrete insulin in response to elevated blood glucose levels (Hosker et al., 1989). This impairment in glucose-stimulated insulin secretion has been attributed to defects in glucose sensing (Froguel et al., 1992), mitochondrial

dysfunction (Supale et al., 2012), and oxidative stress (Robertson, 2004). Thus, mounting evidence suggests that defects in multiple cellular processes can compromise beta cell function and could be a factor in T2D development. Furthermore, hyperglycemia has been shown to impair the expression of genes that are important for beta cell identity (Jonas et al., 1999). More recently, Talchai et al. (2012) described a loss of beta cell features, characterized by a decline in insulin production, acquisition of progenitor-like characteristics, and fate conversion into other endocrine cell types in mouse models of T2D, suggesting that loss of the differentiated beta cell state also contributes to beta cell failure in T2D. However, it is currently unknown whether the loss of beta cell functional properties (namely, regulated insulin secretion) and loss of beta cell identity are linked during T2D progression. A simultaneous loss of beta cell function and identity could be explained by reduced expression of a central transcriptional regulator controlling genes involved in both processes.

Several lines of evidence suggest that the beta-cell-enriched transcription factor Nkx6.1 could have a role in T2D. First, genome-wide association studies suggest that variants of *Nkx6.1* associate with T2D (Yokoi et al., 2006). Second, decreased Nkx6.1 expression has been shown to accompany the development of T2D in rodents and humans (Guo et al., 2013; Talchai et al., 2012). Third, in vitro studies in beta cell lines and isolated islets suggest a possible role for Nkx6.1 in the regulation of glucose-stimulated insulin secretion as well as beta cell proliferation (Schisler et al., 2005, 2008). Additionally, we recently showed that Nkx6.1 is necessary and sufficient to confer beta cell identity to differentiating endocrine precursors in the embryo (Schaffer et al., 2013), raising the possibility that Nkx6.1 could also help maintain the differentiated state of adult beta cells. Together, these findings suggest that Nkx6.1 may be a regulator of beta cell function and identity in adult animals.

To explore the role of Nkx6.1 in mature beta cells, we ablated *Nkx6.1* specifically in beta cells of adult mice and identified Nkx6.1 target genes in beta cells by combining gene-expression profiling and chromatin immunoprecipitation with massively parallel sequencing (ChIP-seq). We found that loss of Nkx6.1 caused rapid-onset diabetes due to defects in insulin biosynthesis and secretion. The observed loss in insulin production and beta cell functional properties was later accompanied by ectopic activation of delta cell genes in beta cells. Thus, by impairing beta cell function and destabilizing beta cell identity,

reduced Nkx6.1 levels, as seen in T2D, could contribute to the pathogenesis of T2D.

RESULTS

Loss of Nkx6.1 in Mature Beta Cells Causes Diabetes and Reduced Insulin Production

To examine Nkx6.1 function in mature beta cells in vivo, we conditionally inactivated *Nkx6.1* in islet cells of adult mice by triggering recombination of an *Nkx6.1^{fllox}* (*Nkx6.1^{fl}*) allele with the tamoxifen-inducible *Pdx1-CreERTM* transgene. *Pdx1-CreERTM;Nkx6.1^{fl/-}* and *Pdx1-CreERTM;Nkx6.1^{fl/+}* mice were injected with tamoxifen between 4 and 6 weeks of age to produce *Nkx6.1^{Δadultβ}* and control mice, respectively (Figures 1A and 1B). Quantitative RT-PCR (qRT-PCR) and immunofluorescence staining for Nkx6.1 demonstrated efficient recombination of the *Nkx6.1^{fl}* allele in beta cells (Figures 1C, 1I, and 1J).

To determine whether *Nkx6.1* deletion affects beta cell function, we conducted glucose tolerance tests and measured blood glucose levels. Glucose tolerance tests performed 1 week after the last tamoxifen injection revealed elevated fasting blood glucose levels and glucose intolerance in male *Nkx6.1^{Δadultβ}* mice when compared with tamoxifen-treated and non-tamoxifen-treated control mice (Figure 1D). Likewise, blood glucose levels were significantly elevated in *Nkx6.1^{Δadultβ}* mice fed ad libitum, with levels reaching near 500 mg/dl within 8 weeks after the last tamoxifen injection (Figure 1E). Female *Nkx6.1^{Δadultβ}* mice also became diabetic, but the phenotype developed slightly later and was less severe than in males (Figures S1A–S1C). Thus, loss of Nkx6.1 in adult beta cells causes rapid development of diabetes.

To investigate whether diabetes in *Nkx6.1^{Δadultβ}* mice is caused by insulin insufficiency, we measured plasma insulin levels after glucose administration. As expected, control mice responded to a glucose bolus with a rapid increase in plasma insulin levels within 5 min of glucose administration (Figure 1F). By contrast, insulin levels did not increase in *Nkx6.1^{Δadultβ}* mice and blood glucose levels were significantly higher than in control mice (Figures 1F and 1G). A striking reduction in pancreatic insulin content in *Nkx6.1^{Δadultβ}* mice (Figure 1H) further demonstrated decreased overall pancreatic insulin production. To determine whether the reduction in pancreatic insulin levels in *Nkx6.1^{Δadultβ}* mice is a result of beta cell loss, we next examined beta cell survival and quantified beta cell mass. *Nkx6.1^{Δadultβ}* mice did not show increased beta cell apoptosis (Figures S2A–S2D) or reduced mass of endocrine or beta cells (Figures S2E–S2H), suggesting that diabetes in *Nkx6.1^{Δadultβ}* mice is caused by decreased insulin biosynthesis rather than beta cell loss. Consistent with a possible defect in the cellular production of insulin, the insulin fluorescence signal was dramatically reduced in Nkx6.1-deficient beta cells (Figures 1I and 1J). Notably, reduced insulin production did not appear to be accompanied by a change in endocrine cell type identity, as insulin⁺ cells in *Nkx6.1^{Δadultβ}* mice did not coexpress other pancreatic hormones (Figures S2I–S2N). These data suggest that diabetes following *Nkx6.1* inactivation is initially caused at least in part by loss of insulin production, but not by cell death or conversion into other endocrine cell types.

Nkx6.1 Directly Regulates Islet Transcription Factors and Genes Involved in Glucose Metabolism and Insulin Biosynthesis

To more globally understand how loss of Nkx6.1 impacts beta cell gene expression, and to identify molecular pathways that are immediately affected following *Nkx6.1* inactivation, we next conducted transcriptional profiling of *Nkx6.1^{Δadultβ}* and control islets 3 days after completion of tamoxifen-induced *Nkx6.1* ablation (Figure 2A). At this time point, *Nkx6.1^{Δadultβ}* mice were only mildly glucose intolerant and blood glucose levels of mice fed ad libitum were still below 250 mg/dl (Figures S3A and S3B). A comparison of gene-expression profiles between *Nkx6.1^{Δadultβ}* and control islets revealed significant differences in the expression of 1,455 genes (false discovery rate [FDR] < 0.01 and fold change [FC] > 1.5; Table S1), of which 887 were upregulated and 568 were downregulated. To define the cellular processes affected by *Nkx6.1* inactivation, we performed Gene Ontology (GO) analysis of the differentially expressed genes. Consistent with the diabetic phenotype, Nkx6.1-regulated genes showed association with biological processes that are critical for beta cell function, such as ion transport, regulation of secretion, oxidation reduction, insulin secretion, and hexose biosynthesis (Figure 2B). These data suggest that reduced insulin production may not be the only cause of hyperglycemia following *Nkx6.1* deletion, and that simultaneous impairment of multiple processes required for proper beta cell function could contribute to the development of diabetes in *Nkx6.1^{Δadultβ}* mice.

To distinguish between direct transcriptional target genes of Nkx6.1 and genes indirectly affected by *Nkx6.1* inactivation, we performed ChIP-seq for Nkx6.1 on primary mouse islets to identify Nkx6.1-occupied genes. We detected a total of 6,771 Nkx6.1 binding regions throughout the murine genome (FDR < 0.001; Table S2), 4,066 of which were near genes or intronic (Figure 2C). De novo motif analysis revealed a TAAT core motif and two flanking nucleotides on each side as the sequence motif preferentially occupied by Nkx6.1 (Figure 2D). Notably, the TAAT core of the Nkx6.1 de novo binding motif was previously identified by an in vitro electrophoretic mobility shift assay (Jørgensen et al., 1999). The TAAT motif is shared among many homeodomain transcription factors (Wilson et al., 1996), demonstrating binding of Nkx6.1 to the core homeodomain-binding motif.

Next, to determine the overlap between the genes occupied by Nkx6.1 in beta cells and genes whose expression is affected by Nkx6.1 loss, we analyzed which of the 1,988 Nkx6.1 binding sites within 10 kb of a transcriptional start site were associated with genes significantly regulated in Nkx6.1-deficient islets. Surprisingly, only 8% of Nkx6.1-occupied genes (135/1,818) were also regulated by Nkx6.1 (Figure 2E; Table S3). Similarly, of the 1,455 genes with statistically significant changes in expression, only 9% were bound by Nkx6.1 (Figure 2E), indicating that only a fraction of the genes affected by *Nkx6.1* inactivation depend directly on transcriptional input by Nkx6.1. Statistical analysis using hypergeometric distribution (Bhinge et al., 2007) revealed that this overlap between Nkx6.1-bound and -regulated genes was still significantly greater than randomly expected ($p < 0.05$). Interestingly, an equal percentage of Nkx6.1-bound and -regulated genes were upregulated as were downregulated

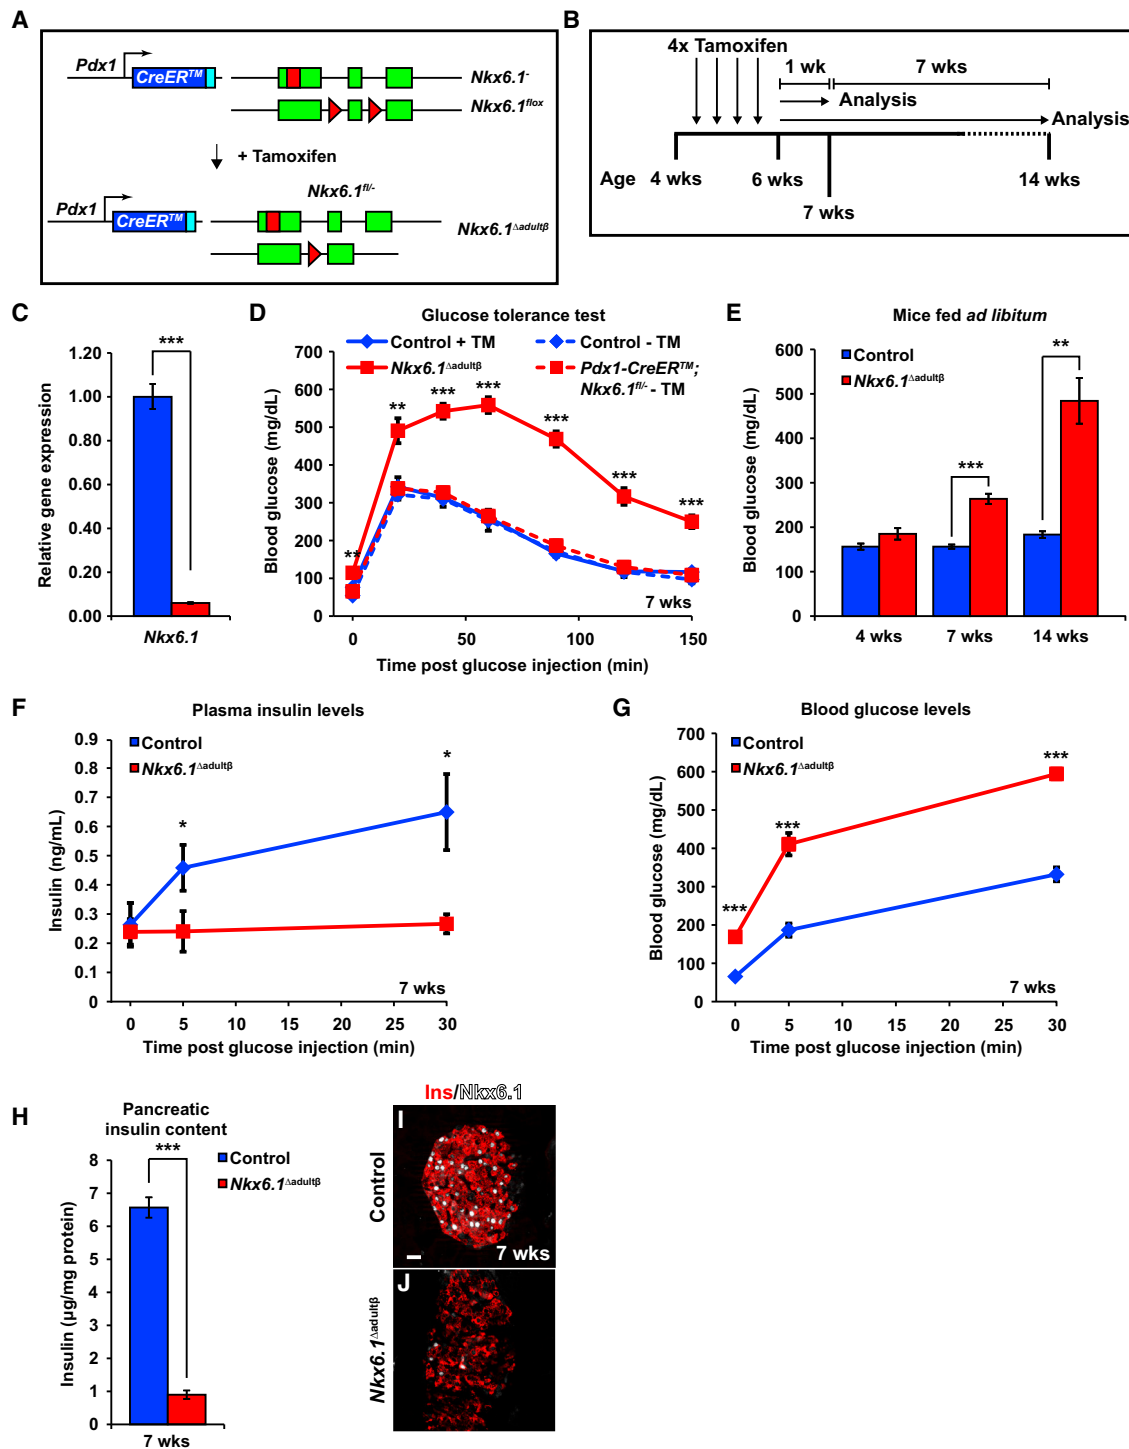

Figure 1. Deletion of *Nkx6.1* in Adult Beta Cells Results in Diabetes and Loss of Pancreatic Insulin

(C) qRT-PCR analysis of isolated islets shows a significant reduction of *Nkx6.1* in *Nkx6.1^{Δadultβ}* mice (n = 3).

(D) Intraperitoneal glucose tolerance test reveals glucose intolerance in male *Nkx6.1^{Δadultβ}* mice compared with noninjected and tamoxifen (TM)-treated control mice at 7 weeks (n = 6). Solid lines: post-TM treatment; dashed lines: without TM treatment.

(E) Blood glucose measurements of mice fed ad libitum show diabetes in male *Nkx6.1^{Δadultβ}* mice (n = 6).

(F and G) *Nkx6.1^{Δadultβ}* mice have lower plasma insulin levels and elevated blood glucose after a glucose stimulus compared with control mice (n = 6).

(legend continued on next page)

(Figures 2F and 2G), suggesting that *Nkx6.1* can act as both a transcriptional repressor and activator.

Nkx6.1 was found to directly regulate various critical beta cell genes, including genes involved in glucose uptake and metabolism (*Slc2a2* [*Glut2*], *Pcx*, and *G6pc2*) and insulin processing (*Ero1b* and *Slc30a8*), as well as transcriptional regulators with known roles in islet development and/or beta cell function (*MafA*, *Rfx6*, *Mnx1*, and *Tle3*; Figure 2E). These results suggest that *Nkx6.1* exerts its function by transcriptionally regulating mediators of multiple beta cell processes.

The Insulin Secretory Response Is Impaired after *Nkx6.1* Inactivation

The insulin secretory response of beta cells is regulated by the coupling of glucose metabolism to insulin secretion (Muoio and Newgard, 2008). Glycolysis results in an increase in the ATP:ADP ratio, which serves as the key trigger for closure of ATP-sensitive potassium channels (K_{ATP} channels), ultimately stimulating calcium influx and insulin secretion. Because *Nkx6.1* directly regulates the glucose metabolic genes *Glut2*, *Pcx*, and *G6pc2* (Table S1; Figures 3A–3C), we hypothesized that glucose uptake, glycolytic flux, and energy production could be impaired in *Nkx6.1*-deficient beta cells. Supporting the conclusion that the downregulation of *Glut2* is physiologically significant, we found that *Nkx6.1^{Δadultβ}* mice were resistant to streptozotocin-induced beta cell death (data not shown), which depends on *Glut2*-mediated uptake of streptozotocin (Schneid et al., 1994).

To investigate whether the changes in expression of glucose metabolic genes are associated with defects in energy production, we stained pancreata for phospho-AMP kinase (p-AMPK), a sensitive indicator of cellular energy depletion (low ATP:AMP ratio; Porat et al., 2011). *Nkx6.1^{Δadultβ}* islets displayed strikingly more intense p-AMPK staining than control islets (Figures 3D–3E'), indicating that loss of *Nkx6.1* causes reduced glycolytic flux and energy stress. Further supporting this conclusion, intracellular ATP content was also significantly decreased in *Nkx6.1^{Δadultβ}* islets (Figure 3F). We conclude that despite increased blood glucose levels, *Nkx6.1* deficiency results in energy-depleted beta cells. Since energy depletion has been shown to impair insulin secretion and cause diabetes in mice (Piston et al., 1999; Porat et al., 2011; Terauchi et al., 1995), the defect in energy production in *Nkx6.1^{Δadultβ}* mice could lead to a severely impaired insulin secretory response.

In addition to affecting ATP production, *Nkx6.1* deletion also led to reduced expression of *Syt14*, a vesicle-associated protein that has been implicated in the modulation of insulin secretion (Gomi et al., 2005), as well as *Ucn3* and *Glp1r* (Figures 3G–3I), which are involved in peptide-mediated potentiation of insulin secretion (Li et al., 2007; Preitner et al., 2004). These changes in gene expression suggest that *Nkx6.1* also has glucose-metabolism-independent roles in insulin secretion. Notably, core components of the stimulus-secretion-coupling mechanism (e.g., *Abcc8*, *Kcnj11*, and *Cacna1c*) and genes encoding pro-

teins important for vesicle docking (e.g., *Pclo* and *Noc2*) were normally expressed in *Nkx6.1*-deficient islets (Figure 3G).

To directly test whether the observed changes in gene expression affect insulin secretion at a functional level, we performed in vitro glucose-stimulated insulin secretion (GSIS) assays on isolated islets from *Nkx6.1^{Δadultβ}* and control mice. To account for the decreased insulin content of *Nkx6.1*-deficient beta cells, we calculated insulin secretion as a percentage of total islet insulin content. Islets from *Nkx6.1^{Δadultβ}* mice secreted less of their total insulin than the control islets under conditions of basal (2.7 mM) and high (16.7 mM) glucose concentrations (Figure 3J), showing that insulin secretion is impaired after *Nkx6.1* deletion. However, stimulation of secretion by glucose appeared to be unaffected by *Nkx6.1* deletion, as there was a similar increase in insulin secretion in *Nkx6.1^{Δadultβ}* and control islets under both low- and high-glucose conditions (3.75-fold increase between 2.7 mM and 16.7 mM glucose in *Nkx6.1^{Δadultβ}* islets versus a 3.06-fold increase in control islets). The insulin secretory pattern of *Nkx6.1^{Δadultβ}* islets is highly similar to the pattern observed in *Glut2*-deficient islets (Guillam et al., 2000), suggesting that loss of *Glut2* in *Nkx6.1^{Δadultβ}* beta cells makes a major contribution to the insulin secretory defect. Notably, additional defects downstream of K_{ATP} channel-mediated membrane depolarization also appear to exist, as insulin secretion in *Nkx6.1*-deficient islets was also reduced in response to membrane depolarization and calcium influx (30 mM KCl and 2 μ M Bay K8644, respectively; Figure 3J). Together, these results imply that impaired insulin secretion is a major contributor to the diabetic phenotype of *Nkx6.1^{Δadultβ}* mice.

Decreased Beta Cell Proliferation in *Nkx6.1^{Δadultβ}* Mice

It has been suggested that glycolytic flux and ATP production serve as a trigger for beta cell replication (Porat et al., 2011). Specifically, glucose metabolism is thought to control beta cell proliferation by regulating expression of *Cyclin D2* (*Ccnd2*) (Salpeter et al., 2010, 2011), which is a critical regulator of beta cell mass in mice (Georgia and Bhushan, 2004; Kushner et al., 2005). Since *Nkx6.1*-deficient beta cells have defects in energy production, we examined whether *Nkx6.1* deletion affects *Ccnd2* messenger RNA (mRNA) levels. We found that *Ccnd2* mRNA levels were indeed decreased in *Nkx6.1^{Δadultβ}* islets (Table S1; Figure 4A). Strikingly, *Nkx6.1* inactivation specifically affected *Ccnd2*, whereas the mRNA levels of other *cyclins* were unaffected (Table S1; Figure 4A). Immunofluorescence staining (Figures 4B–4C') and western blot analysis (Figure 4D) further demonstrated significantly reduced Cyclin D2 protein levels in beta cells of *Nkx6.1^{Δadultβ}* mice. Similar to the phenotype of *Ccnd2* null mutant mice (Georgia and Bhushan, 2004; Kushner et al., 2005), *Nkx6.1*-deficient beta cells exhibited a reduction in the number of beta cells expressing the proliferation marker Ki67 (Figure 4E), showing that beta cell proliferation is impaired after *Nkx6.1* inactivation. Notably, *Nkx6.1*

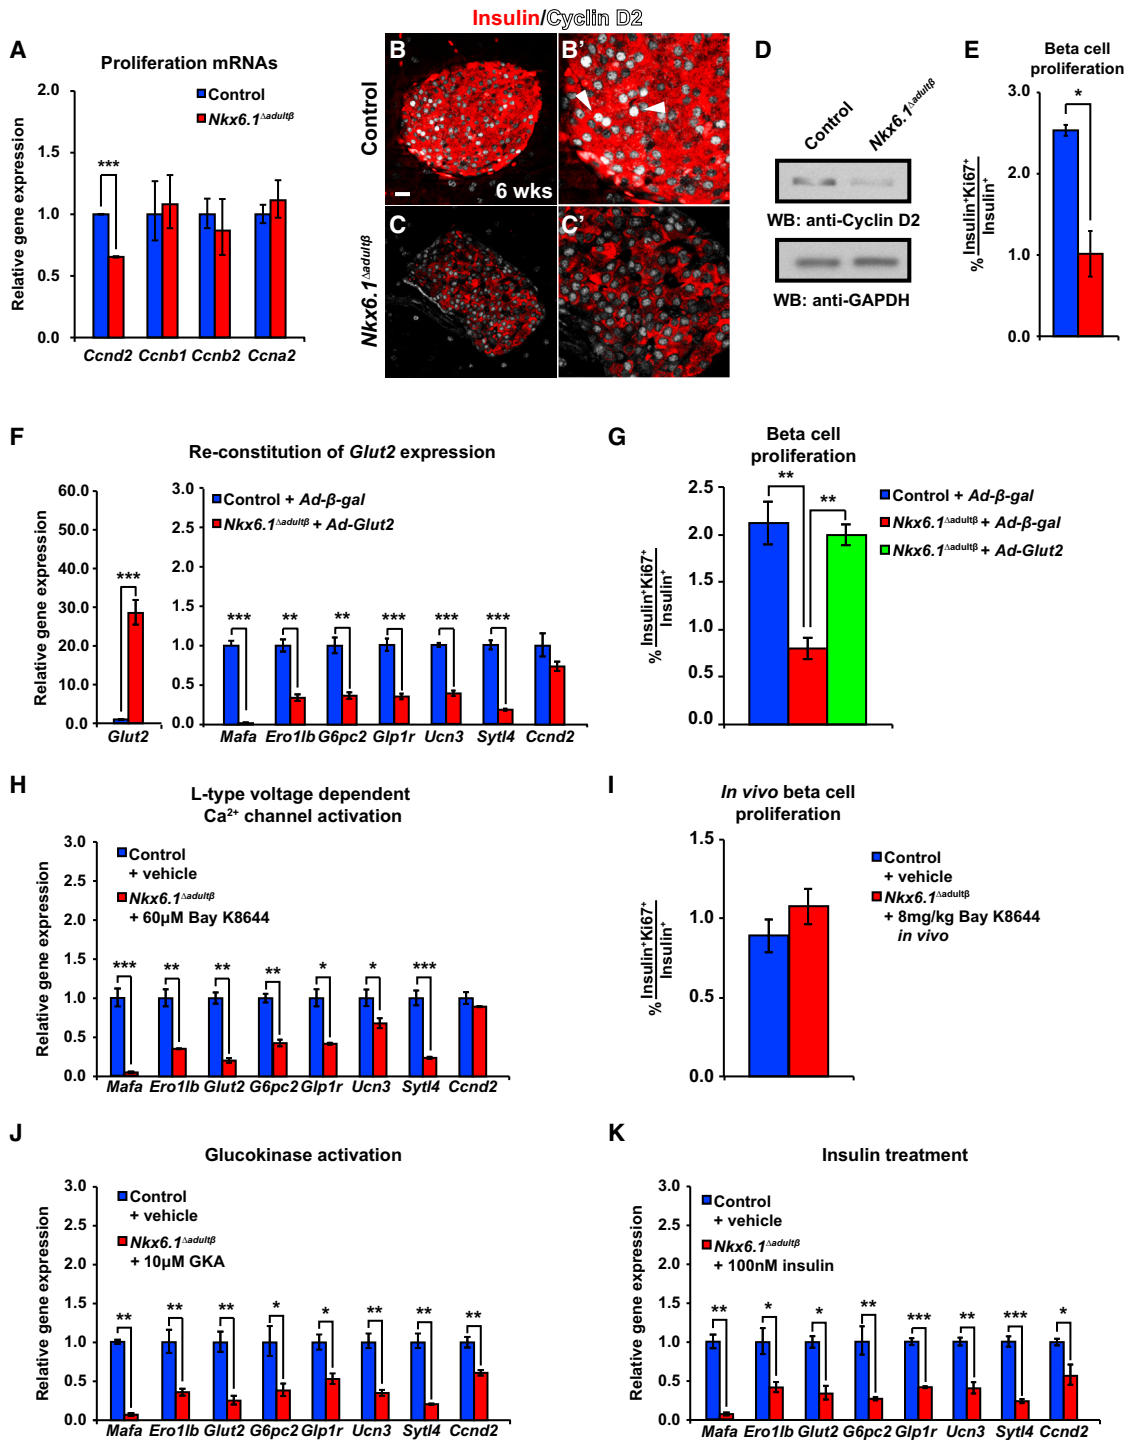

Figure 4. Nkx6.1 Maintains Cyclin D2 Expression and Beta Cell Proliferative Capacity through the Regulation of Glucose Uptake

(A) qRT-PCR analysis of islets shows a decrease in *Ccnd2* expression in *Nkx6.1^{Δadultβ}* compared with control mice at 6 weeks (n = 3). (B–C') Immunofluorescence staining for insulin and Cyclin D2 shows a decrease in Cyclin D2 expression in beta cells of *Nkx6.1^{Δadultβ}* mice at 6 weeks. (B') and (C') are higher-magnification images of (B) and (C), respectively. White arrowheads point to Cyclin D2^{high} cells. (D) Immunoblot analysis of whole-cell islet lysates confirms reduced Cyclin D2 expression in *Nkx6.1^{Δadultβ}* mice. (E) Quantification of the percentage of insulin⁺ cells expressing Ki67 shows decreased beta cell proliferation in *Nkx6.1^{Δadultβ}* mice at 6 weeks (n = 3). (F) qRT-PCR analysis of genes with decreased expression in islets from *Nkx6.1^{Δadultβ}* mice after adenoviral infection of *Nkx6.1^{Δadultβ}* islets with Ad-CMV-*Glut2* (*Ad-Glut2*) and control islets with Ad-CMV-β-gal (*Ad-β-gal*) (n = 3). *Ad-Glut2* restores *Ccnd2* expression to levels observed in control islets infected with *Ad-β-gal*. (legend continued on next page)

did not occupy *Ccnd2* regulatory sequences (Table S2), suggesting that the regulation of *Ccnd2* by Nkx6.1 could be indirect.

Restoring Glucose Import Reinstates *Ccnd2* Expression in *Nkx6.1^{Δadultβ}* Islets

To explore whether limited glucose uptake capacity due to loss of Glut2 could be the main cause of reduced *Ccnd2* expression in Nkx6.1-deficient islets, we investigated whether restoring Glut2-mediated glucose import could increase *Ccnd2* levels after *Nkx6.1* inactivation. To examine this, we reconstituted *Glut2* expression in *Nkx6.1^{Δadultβ}* islets using an adenovirus containing *Glut2* complementary DNA (cDNA; *Ad-Glut2*), which resulted in a 25-fold increase in *Glut2* mRNA levels compared with *Ad-β-gal*-treated control islets, and restored Glut2 protein expression (Figures 4F and S4). Glut2 reconstitution increased *Ccnd2* expression to the levels of the control islets, whereas expression of other Nkx6.1-regulated genes remained significantly reduced (Figure 4F). Glut2 reconstitution in *Nkx6.1^{Δadultβ}* islets also restored the number of insulin⁺ cells expressing Ki67 to control values (Figure 4G), indicating that Glut2 reexpression rescues the proliferation defect. These findings demonstrate that *Ccnd2* expression does not depend on direct transcriptional input from Nkx6.1, and that Nkx6.1 controls *Ccnd2* and beta cell proliferation indirectly by regulating glucose import.

Consistent with the notion that glycolytic flux regulates *Ccnd2* expression via the stimulus-secretion-coupling pathway (Salpeter et al., 2010, 2011), increasing calcium influx by treating islets with the L-type-dependent calcium channel opener Bay K8644 similarly restored *Ccnd2* expression in *Nkx6.1^{Δadultβ}* islets (Figure 4H). Significantly, Bay K8644 administration to mice increased the number of insulin⁺ cells expressing Ki67 to control values (Figure 4I), providing in vivo evidence that beta cell proliferation can be rescued by stimulating calcium influx. In contrast, culture of Nkx6.1-deficient islets in the presence of an activator for the rate-limiting enzyme of glycolysis, glucokinase, or the beta cell mitogen, insulin (Paris et al., 2003), failed to restore *Ccnd2* expression (Figures 4J and 4K; also compare with Figure 4A). These findings illustrate that the proliferative capacity of beta cells is coupled to glucose metabolism and that Nkx6.1 controls this process by regulating *Glut2* expression. Because beta cells have a low turnover rate in adult mice (Teta et al., 2005), the observed reduction in beta cell proliferation did not result in decreased beta cell mass in our acute *Nkx6.1* deletion model (Figures S2G and S2H). However, the decreased proliferative capacity could become metabolically relevant when beta cells need to undergo adaptive expansion under conditions of increased insulin demand.

Nkx6.1^{Δadultβ} Mice Have Posttranscriptional Defects in Insulin Biosynthesis

Our gene expression and ChIP-seq analysis revealed that Nkx6.1 also controlled genes required for insulin biosynthesis, which could explain the reduction in pancreatic insulin levels in *Nkx6.1^{Δadultβ}* mice. Most notably, expression of the T2D-associated zinc transporter *Slc30a8*, the oxidoreductase *Ero1b*, and the proinsulin-to-insulin convertase *Pcsk1* (PC1) was severely reduced in Nkx6.1-deficient beta cells (Table S1; Figures 5A–5E). These proteins have established roles in insulin processing and/or maturation of insulin secretory vesicles (Bellomo et al., 2011; Zhu et al., 2002; Zito et al., 2010), implying a role for Nkx6.1 in multiple aspects of the insulin biosynthesis pathway. Notably, the finding that *Ins1* and *Ins2* mRNA levels were not significantly changed (Table S1; Figure 5F) suggests that reduced insulin production in *Nkx6.1^{Δadultβ}* mice is mainly caused by posttranscriptional defects in insulin biosynthesis. To further define which steps in insulin biosynthesis are affected by *Nkx6.1* inactivation, we measured pancreatic proinsulin content and calculated the insulin-to-proinsulin ratio in *Nkx6.1^{Δadultβ}* islets. Compared with control mice, pancreatic proinsulin levels and the ratio of insulin to proinsulin were significantly reduced in *Nkx6.1^{Δadultβ}* mice (Figures 5G and 5H). Although the defect in proinsulin-to-insulin processing was expected based on the observed decrease in *Slc30a8*, *Ero1b*, and *Pcsk1* expression, it is less clear why loss of Nkx6.1 impairs proinsulin biosynthesis.

Because glucose is a direct stimulator of proinsulin translation (Wicksteed et al., 2003), we examined whether decreased Glut2 expression in *Nkx6.1^{Δadultβ}* mice limits the intracellular availability of glucose and in turn reduces proinsulin production. However, restoring *Glut2* expression in *Nkx6.1^{Δadultβ}*-dispersed islets had no effect on proinsulin or insulin levels (Figures S5A and S5B), suggesting that reduced expression of insulin biosynthetic enzymes, rather than glucose import, limits proinsulin synthesis in *Nkx6.1^{Δadultβ}* mice.

To determine whether the defect in insulin biosynthesis affects the formation of insulin secretory vesicles, we examined secretory vesicle numbers and morphology in beta cells from *Nkx6.1^{Δadultβ}* and control mice. According to the guidelines established by Pictet et al. (1972), secretory vesicles were considered immature if they had a homogeneous light gray appearance similar to the electron density of the cytoplasm, or mature if the vesicles contained an electron-dense granule darker than the density of the cytoplasm. Transmission electron microscopy (TEM) showed that the overall number of secretory granules was unchanged (Figures 5I–5K), suggesting that loss of Nkx6.1 does not affect vesicle formation or stability. In accordance with the observed defect in insulin biosynthesis, our examination of vesicle morphology revealed a smaller overall

(G) Quantification of the percentage of insulin⁺ cells expressing Ki67 after infection of *Nkx6.1^{Δadultβ}* and control islets with *Ad-Glut2* or *Ad-β-gal* shows that *Ad-Glut2* restores the number of Ki67⁺ beta cells in *Nkx6.1^{Δadultβ}* islets to control values (n = 3).

(A) qRT-PCR analysis of islets reveals reduced expression of genes involved in insulin biosynthesis in *Nkx6.1^{Δadultβ}* compared with control mice at 6 weeks (n = 3). (B–E) Immunofluorescence staining of pancreata from *Nkx6.1^{Δadultβ}* and control mice at 6 weeks. Dashed lines represent islet area. (F) qRT-PCR analysis of *Nkx6.1^{Δadultβ}* and control islets from mice at 6 weeks shows no significant difference in *Ins1* or *Ins2* expression (n = 3). (G) Proinsulin content normalized to the protein concentration of whole pancreatic lysates (n = 6). (H) The pancreatic insulin-to-proinsulin ratio is reduced in *Nkx6.1^{Δadultβ}* mice (n = 6). (I and J) TEM of pancreatic sections reveals smaller vesicle size and an increase in immature vesicles (red arrowheads) in *Nkx6.1^{Δadultβ}* compared with control mice. Dashed boxes indicate area of magnification (I') and (J'). Blue arrowheads point to vesicles containing mature insulin-dense core granules. Insets framed in red show a representation of a typical immature vesicle, and insets framed in blue show a typical mature vesicle. (K–M) Quantification of vesicle numbers (K), vesicle diameter (L), and the percentage of mature and immature vesicles (M) in *Nkx6.1^{Δadultβ}* and control mice (n = 10). In (G)–(M), mice were analyzed at 7 weeks. PC1, prohormone convertase 1/3. Data are shown as mean ± SEM for (A) and (F)–(H), and ±SD for (K)–(M). *p < 0.05, **p < 0.01, ***p < 0.001. See also Figure S5.

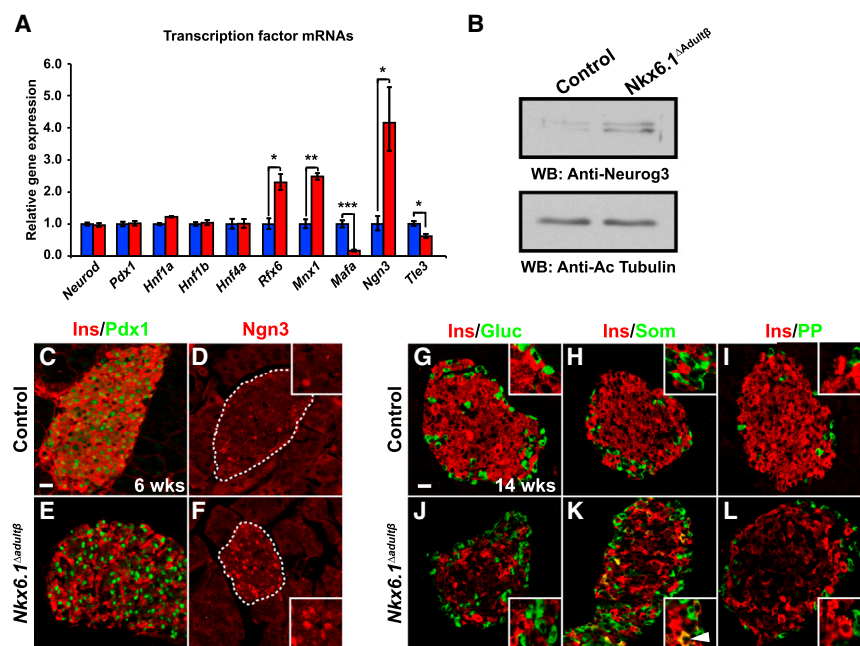

Figure 6. Increased Expression of the Progenitor Marker Ngn3 in Nkx6.1-Deficient Beta Cells

(A and B) qRT-PCR (A) and western blot analysis (B) of islets from *Nkx6.1^{Δadultβ}* and control mice at 6 weeks for multiple transcription factor genes (A) or Ngn3 (B); n = 3.

(C–L) Immunofluorescence staining of pancreata from *Nkx6.1^{Δadultβ}* and control mice at 6 weeks (C–F) and 14 weeks (G–L). Dashed lines represent islet area. Insets are magnifications of selected areas. Arrowhead in (K) points to a cell coexpressing insulin (Ins) and somatostatin (Som). The scale bar represents 20 μm. Gluc, glucagon; PP, pancreatic polypeptide. Data are shown as mean ± SEM. *p < 0.05, **p < 0.01, ***p < 0.001.

of metabolic stress (Table S1; Figures 6A, 6B, 6D, and 6F). To investigate whether the upregulation of Ngn3 is associated with destabilization of beta cell identity, we examined pancreata from *Nkx6.1^{Δadultβ}* mice at 14 weeks of age (8 weeks after *Nkx6.1* deletion) for coex-

pression of insulin with other pancreatic hormones. We did not observe coexpression of insulin with glucagon or pancreatic polypeptide in *Nkx6.1^{Δadultβ}* or control islets, but found a significant number of insulin⁺ cells coexpressing somatostatin in *Nkx6.1^{Δadultβ}* mice (Figures 6G–6L). This finding is consistent with our previous observation of a beta-to-delta cell fate switch after *Nkx6.1* ablation in embryonic beta cells (Schaffer et al., 2013) and suggests that, although it does not happen immediately, *Nkx6.1* inactivation in adult beta cells causes beta cells to adopt a delta cell identity over time. In conjunction with our previous findings, these data strongly suggest that loss of *Nkx6.1* in adult mice destabilizes beta cell identity, eventually leading to fate conversion of beta into delta cells.

Together, our analysis demonstrates that *Nkx6.1* is a critical regulator of insulin biosynthesis and secretion, as well as proliferative capacity and cell identity in adult beta cells. The severe beta cell defects observed after *Nkx6.1* inactivation suggest that restoring *Nkx6.1* levels could be a therapeutic strategy in T2D.

Nkx6.1 Inactivation Destabilizes Beta Cell Identity

In T2D mouse models of metabolic stress, reduced beta cell insulin production is associated with a decrease in *Nkx6.1*, *Pdx1*, and *NeuroD* expression, as well as increased expression of the pancreatic progenitor cell marker *Ngn3* and the pluripotency markers *Oct4*, *Nanog*, and *L-Myc* (Talchai et al., 2012). Because a subset of metabolically stressed beta cells eventually adopt other endocrine fates, it has been proposed that beta cell dedifferentiation followed by conversion into other endocrine cell types could cause beta cell failure in T2D (Talchai et al., 2012). Although *Nkx6.1* deletion did not affect the expression of *Pdx1*, *NeuroD*, or pluripotency markers (Table S1; Figures 6A, 6C, and 6E), we observed robust induction of *Ngn3* expression in beta cells similar to what has been observed in models

of metabolic stress (Table S1; Figures 6A, 6B, 6D, and 6F). To investigate whether the upregulation of Ngn3 is associated with destabilization of beta cell identity, we examined pancreata from *Nkx6.1^{Δadultβ}* mice at 14 weeks of age (8 weeks after *Nkx6.1* deletion) for coex-

pression of insulin with other pancreatic hormones. We did not observe coexpression of insulin with glucagon or pancreatic polypeptide in *Nkx6.1^{Δadultβ}* or control islets, but found a significant number of insulin⁺ cells coexpressing somatostatin in *Nkx6.1^{Δadultβ}* mice (Figures 6G–6L). This finding is consistent with our previous observation of a beta-to-delta cell fate switch after *Nkx6.1* ablation in embryonic beta cells (Schaffer et al., 2013) and suggests that, although it does not happen immediately, *Nkx6.1* inactivation in adult beta cells causes beta cells to adopt a delta cell identity over time. In conjunction with our previous findings, these data strongly suggest that loss of *Nkx6.1* in adult mice destabilizes beta cell identity, eventually leading to fate conversion of beta into delta cells.

DISCUSSION

It is widely recognized that beta cell dysfunction, specifically the inability of beta cells to properly secrete insulin in response to high blood glucose levels, is among the earliest clinical features during progression to T2D (Ferrannini, 2010). The ability to sense glucose levels and to couple this information to an insulin secretory response is bestowed upon beta cells by specialized transporters and enzymes. Although the mechanisms that underlie glucose-mediated insulin secretion are fairly well understood, it has remained unclear which transcriptional regulators initiate and maintain the expression of genes that enable beta cells to perform their highly specialized function. In this study, we show that the transcription factor *Nkx6.1* is a master regulator

Figure 7. Nkx6.1 Function in Adult Beta Cells

Nkx6.1 directly regulates transcription of genes encoding proteins involved in glucose uptake and metabolism (Glut2 and Pcx) and insulin biosynthesis (Ero1lb and Slc30a8). Reduced expression of these Nkx6.1 target genes affects beta cell function in three ways: First, decreased glucose uptake and metabolism diminishes ATP production, leading to impaired insulin secretion via the stimulus-secretion coupling pathway. Second, by enabling glucose uptake through Glut2 regulation, Nkx6.1 indirectly controls beta cell proliferative capacity. In the absence of Nkx6.1, expression of *Ccnd2*, which encodes the critical beta cell mitogen Cyclin D2, is reduced and beta cell proliferation is decreased. Reconstituting Glut2 expression in Nkx6.1-deficient beta cells restores *Ccnd2* levels and beta cell proliferation. Third, insulin biosynthesis is severely impaired, leading to reduced production of mature insulin and an overabundance of immature secretory vesicles. Gck, glucokinase; Glut2, glucose transporter 2; K_{ATP} , ATP-sensitive potassium channel; Pcx, pyruvate carboxylase.

of genes that define the functional beta cell state, a role that is consistent with its exclusive expression in beta cells of the adult pancreas.

We show that conditional inactivation of *Nkx6.1* in beta cells of adult mice results in overt diabetes within days of *Nkx6.1* ablation. Loss of Nkx6.1 activity had an immediate and dramatic impact on the expression of genes that give beta cells their unique ability to synthesize and release insulin in a regulated fashion. We found that genes involved in insulin biosynthesis (*Slc30a8* and *Ero1lb*), glucose import (*Glut2*), and glucose metabolism (*Pcx*) are direct transcriptional target genes of Nkx6.1. In addition, *Nkx6.1* ablation indirectly affected the expression of numerous genes that are important for beta cell function and, interestingly, also beta cell proliferation (Figure 7). The finding that islet *Ccnd2* levels and beta cell proliferation were decreased in *Nkx6.1* conditional mutant mice was somewhat surprising, as several studies have shown that hyperglycemia has a stimulatory effect on beta cell *Ccnd2* expression and self-renewal (Alonso et al., 2007; Bonner-Weir et al., 1989; Salpeter et al., 2011). We found that reduced availability of the beta cell mitogen insulin (Paris et al., 2003) made no apparent contribution to the reduced proliferative capacity of beta cells after *Nkx6.1* ablation. Instead, our results suggest that the proliferative capacity of Nkx6.1-deficient beta cells is limited by the reduced intracellular availability of glucose due to loss of *Glut2* expression (Figure 7). These find-

ings demonstrate an intricate link between the beta cell's ability to import glucose and its proliferative capacity, which lends further support to the emerging concept that glucose metabolism plays a critical role in the regulation of beta cell proliferation (Porat et al., 2011; Salpeter et al., 2010, 2011). Combined with the finding that Nkx6.1 levels are reduced in T2D models of metabolic stress (Talchai et al., 2012), our work suggests that Nkx6.1 acts as a metabolic sensor that modulates both insulin secretion and proliferative capacity in response to metabolic stress. By preventing the proliferation of beta cells that have lost glucose responsiveness, the cell-autonomous coupling of glucose import to beta cell proliferation might provide an inherent selection mechanism for healthy beta cells.

Our study also reconciles previously reported, seemingly contradictory findings about the role of Nkx6.1 in beta cell proliferation. We recently reported that transgenic overexpression of Nkx6.1 in beta cells of adult mice in vivo had no positive effect on beta cell proliferation or beta cell mass (Schaffer et al., 2011). By contrast, virus-mediated expression of Nkx6.1 in cultured islets had proproliferative activity (Schisler et al., 2008). A possible explanation for this apparent contradiction is that in vitro culture of islets compromises Nkx6.1 expression levels. It is known that once they are removed from their niche and put into culture, beta cells quickly lose Glut2 expression and cease to proliferate (Weinberg et al., 2007), indicating that expression of upstream Glut2 regulators, including Nkx6.1, could also be compromised. Thus, the observed proproliferative effect of Nkx6.1 in vitro may be explained by virally expressed *Nkx6.1* restoring reduced Nkx6.1 levels and, in turn, also Glut2 and *Ccnd2* levels in cultured islets. By contrast, increasing Nkx6.1 levels above normal in healthy beta cells in vivo appears to have no further stimulatory effect on glucose import and beta cell proliferation.

After *Nkx6.1* deletion, we observed an extremely rapid decline in beta cell insulin content. The loss of insulin was not associated with beta cell death, revealing a striking similarity between Nkx6.1-deficient beta cells and "empty" beta cells observed in mouse models of T2D (Talchai et al., 2012). Furthermore, as reported under conditions of metabolic stress (Talchai et al., 2012), we found that reduced *Nkx6.1* expression was also accompanied by derepression of the endocrine progenitor cell marker Ngn3. Based on the observation that beta cells undergo fate conversion into non-beta endocrine cell types in T2D models (Talchai et al., 2012), the loss of beta cell features and gain of Ngn3 expression has been proposed to render beta cells plastic and more prone to changing their identity.

Consistent with this notion, we observed that a subset of Nkx6.1-deficient beta cells ectopically expressed somatostatin 8 weeks after *Nkx6.1* deletion. Previously, we showed with lineage tracing studies that *Nkx6.1* deletion in embryonic beta cells leads to a rapid beta-to-delta cell fate switch (Schaffer et al., 2013). However, conversion of beta cells into other non-beta endocrine cell types was not observed after *Nkx6.1* inactivation in embryonic beta cells. Similarly, after *Nkx6.1* deletion in adult beta cells, we observed coexpression of insulin exclusively with somatostatin and no other pancreatic hormones. Thus, loss of Nkx6.1 leads to selective derepression of delta cell genes in both embryonic and adult beta cells. However, fate conversion

is more complete and occurs more rapidly when *Nkx6.1* is inactivated in immature beta cells. Therefore, a sequential loss of beta cell traits preceding the adoption of alternative endocrine cell fates seen after adult *Nkx6.1* inactivation closely mirrors the gradual loss of functional beta cell mass observed in T2D models (Talchai et al., 2012).

Our study provides support for an evolving concept that transcription factors, such as *Nkx6.1* and *FoxO1* (Talchai et al., 2012), are critical for maintaining beta cells in their differentiated state. A key question that requires further exploration is whether a destabilized beta cell state is observed in humans and possibly contributes to the pathogenesis of T2D. The observation that *NKX6.1* expression is decreased in beta cells from humans with T2D (Guo et al., 2013) suggests that findings in rodent models might indeed be relevant to human disease. Future studies will need to explore which aspects of the rodent phenotype are also found in humans and how loss of beta cell features relates to disease progression. Such knowledge could identify a window for therapeutic intervention during which the functional beta cell state could be restored before beta cells convert into other endocrine cell types.

EXPERIMENTAL PROCEDURES

Mouse Strains

The following mouse strains were utilized in this study: *Pdx1CreERTM* (Gu et al., 2002), *Nkx6.1^{+/-}* (Sander et al., 2000), and *Nkx6.1^{fllox}* (Schaffer et al., 2013). All animals carrying the *Nkx6.1^{fllox}* allele were maintained on a mixed 129Sv/C57Bl6/J genetic background. Unless otherwise stated in the text, male mice were used for the experiments. Tamoxifen (Sigma) was dissolved in corn oil at 20 mg/ml, and 2 mg was injected subcutaneously four times over a 2-week period. All animal experiments were approved by the Institutional Animal Care and Use Committees of the University of California, San Diego.

Tissue Preparation and Immunohistochemistry

Tissue preparation, immunofluorescence staining, TUNEL assays, and morphometry were performed as previously described (Schaffer et al., 2010, 2013). A description of the antibodies used (Tables S4 and S5) and detailed methods are provided in the Extended Experimental Procedures.

Microscopy and Image Analysis

All immunofluorescent images were acquired using a Zeiss AxioObserver.Z1 microscope (Carl Zeiss) with the Zeiss ApoTome module and processed in Zeiss AxioVision Release 4.8 and Adobe Photoshop CS5.1. Only brightness and contrast was adjusted in images in accordance with the *Journal of Cell Biology* figure manipulation guidelines.

Glucose Tolerance Tests, GSIS Assays, and Insulin and Proinsulin Measurements

Glucose tolerance tests, GSIS assays, and insulin measurements were performed as previously described (Schaffer et al., 2011). Proinsulin measurements were performed on whole pancreatic lysates using a mouse proinsulin ELISA (ALPCO). Details are described in the Extended Experimental Procedures.

Islet Isolation and Culture

Islet isolations were performed as previously described (Schaffer et al., 2011) with Liberase TL (Roche). For incubation of islets with chemical compounds, RPMI supplemented with 2.7 mM glucose and 1% BSA was used. *Nkx6.1^{Δadultβ}* islets were incubated with 100 nM recombinant insulin (Sigma), 60 μM ± Bay K8644 (Sigma), or 10 μM glucokinase activator (GKA; EMD Calbiochem), and control islets were incubated with DMSO (ATCC) for 3 hr. For infection of islets with *Ad-Glut2* and *Ad-β-gal*, the islets were dispersed and

plated before infection as described previously (Fiaschi-Taesch et al., 2009). Further details are provided in the Extended Experimental Procedures.

Microarray and qRT-PCR

RNA was isolated from islets obtained from six littermate control and six *Nkx6.1^{Δadultβ}* mice. Islets from two mice of identical genotypes were pooled to generate three independent cDNA probes per genotype for array hybridization. Labeled cDNA was hybridized to whole-mouse gene-expression G2519F microarrays (Agilent Technologies). A detailed description of the microarray and qRT-PCR analyses and a list of the primer sequences (Table S6) can be found in the Extended Experimental Procedures.

ChIP-Seq

ChIP was performed as previously described (Schaffer et al., 2013) with rabbit anti-*Nkx6.1* antiserum (1:250) on sheared chromatin obtained from ~10,000 islet equivalents (1,000 cells per islet) isolated from C57BL/6J mice. ChIP-seq libraries were prepared according to Illumina's instructions (<http://www.illumina.com>). Sequencing was performed on an Illumina/Solexa Genome Analyzer II in accordance with the manufacturer's protocols. Data analysis was performed using Hypergeometric Optimization of Motif Enrichment (HOMER) (Heinz et al., 2010). Peak annotation and de novo motif analysis were performed using HOMER, and venn diagrams were generated using BioVenn (Hulsen et al., 2008). See the Extended Experimental Procedures for details.

Statistics

Unless otherwise stated, all values are shown as mean ± SEM; p values were calculated using an unpaired Student's t test in Microsoft Excel, and hypergeometric distribution was determined using R; p < 0.05 was considered significant.

ACCESSION NUMBERS

The NCBI GEO (<http://www.ncbi.nlm.nih.gov/geo/>) accession number for the microarray data set reported in this paper is GSE40470. The GEO accession number for the ChIP-seq data set reported in this paper is GSE40975.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Extended Experimental Procedures, five figures, and six tables and can be found with this article online at <http://dx.doi.org/10.1016/j.celrep.2013.08.010>.

ACKNOWLEDGMENTS

We are grateful to D. Melton (Harvard University) for *Pdx1-CreERTM* mice, C. Newgard (Duke University) for *Ad-Glut2* and *Ad-β-gal* adenoviruses, and the following colleagues for anti-sera: P. Serup (DanStem) for anti-*Nkx6.1*, C. Wright (Vanderbilt University) for anti-*Pdx1*, M. Huisig (Salk Institute) for anti-*Ucn3*, D. Ron (University of Cambridge) for anti-*Ero1b*, D. Steiner (University of Chicago) for anti-*PC1/3*, and C. Kioussi (Oregon State University) for anti-GFP. We thank N. Rosenblatt for mouse husbandry, R. Xie for assistance with ChIP-seq library preparation, the University of California, San Diego, BioGEM Core for microarray experiments, the University of Pennsylvania Functional Genomics Core for ChIP-seq analysis, the University of California, San Diego, Electron Microscopy Core for assistance with sample preparation for electron microscopy, and members of the Sander laboratory for helpful discussions and critical readings of the manuscript. This work was supported by National Institutes of Health grants R01-DK068471 and U01-DK089567 to M.S.
