Constructing Recursion Operators in Intuitionistic Type Theory

LAWRENCE C. PAULSON

Computer Laboratory, Corn Exchange Street, Cambridge CB2 3QG, England

(Received 28 March 1986)

Martin-Löf's Intuitionistic Theory of Types is becoming popular for formal reasoning about computer programs. To handle recursion schemes other than primitive recursion, a theory of well-founded relations is presented. Using primitive recursion over higher types, induction and recursion are formally derived for a large class of well-founded relations. Included are < on natural numbers, and relations formed by inverse images, addition, multiplication, and exponentiation of other relations. The constructions are given in full detail to allow their use in theorem provers for Type Theory, such as PRL. The theory is compared with work in the field of ordinal recursion over higher types.

1. Introduction

Per Martin-Löf originally developed his Intuitionistic Type Theory (1984) as a formal notation for constructive mathematics, but it may also be regarded as a programming language (Martin-Löf, 1982). It supports the principle of *propositions as types*: there is a type forming operator for each logical connective and quantifier, with typing rules that correspond to the intuitionistic rules of natural deduction. This type structure is rich enough to completely specify computational problems: Nordström & Smith (1984) specify a program to produce a KWIC index. Its potential for the systematic development for correct programs is attracting the interest of computer scientists (Backhouse & Khamiss, 1985; Chisholm, 1985).

Many people have used the interactive theorem prover LCF to verify functional programs by computer. Most LCF work until now (Gordon *et al.*, 1979; Paulson, 1985) has been conducted in a logic for domain theory. Petersson (1982*a*) has already implemented a version of LCF for Intuitionistic Type Theory (henceforth Type Theory). Constable's group (1986) has implemented an elaborate theorem prover, called PRL, for a version of Type Theory. I am also experimenting with Type Theory in a new theorem prover, Isabelle (Paulson, 1986*a*).

Type Theory has no explicit principle of general recursion: it forces all functions to terminate by allowing only primitive recursion. Many functions that are not primitive recursive can be defined as primitive recursive *functionals*: the classic example is Ackermann's function (Nordström, 1981). The study of functionals leads to a simple theory of types, including at least the natural numbers Nat, and function types $A \rightarrow B$ if A and B are types (Terlouw, 1982). Each type A can be assigned a level L(A) such that L(Nat) = 0 and $L(A \rightarrow B)$ is the greater of L(A) + 1 and L(B). (This scheme of type levels is too simple for Intuitionistic Type Theory.) Primitive recursive functionals are also called primitive recursive functions of *higher type*.

Primitive recursive functionals do not constitute a natural programming language. To facilitate reasoning about programs in Type Theory, this paper formalises a more conventional programming style: writing arbitrary recursion equations annotated with a termination proof.

Every computer scientist knows of Quicksort, a total function not obviously definable by primitive recursion. Jan Smith (1983) defines Quicksort in Type Theory by first deriving appropriate rules of induction and recursion, using primitive recursion over higher types. The "while rule" of Backhouse & Khamiss (1985) is also a form of primitive recursion. This paper considers induction and recursion over a wide class of well-founded (w.f.) relations.

The rule of induction over a well-founded relation \prec is

$$\frac{\forall x. (\forall x' \prec x. P(x')) \rightarrow P(x)}{\forall x. P(x)}.$$

Classically, this rule is sound if \prec has no infinite descending chains $x_1 > x_2 > \ldots$. W.f. induction (or Noetherian induction) is often used in program verification, and is the fundamental method for proving termination (Manna, 1974). Total functions can be defined by the related principle of w.f. recursion.

Even if it is apparent that a relation is w.f., proving this may be difficult. W.f. relations are most easily constructed from simpler ones, using rules that preserve the w.f. property. Later sections present Type Theory derivations of induction and recursion over

- the ordering < on the *natural numbers*
- -a subrelation of a w.f. relation
- the inverse image of a w.f. relation
- --- the transitive closure of a w.f. relation
- the disjoint sum of two w.f. relations
- -the lexicographic product of two w.f. relations
- -the lexicographic power of a w.f. relation
- --- the *immediate subtree* relation on a wellordering type.

These ideas have been extensively studied by both computer scientists and logicians. Manna & Waldinger (1986) describe and verify similar rules for w.f. relations. The sole induction principle of the Boyer-Moore (1979) theorem prover is w.f. induction, over lexicographic products of inverse images of <. The theory of ordinal recursion concerns recursion over total wellorderings constructed by addition, multiplication, and exponentiation of simpler wellorderings (Tait, 1965). These operations suffice to reach wellorderings of order type ε_0 , which is the first ordinal α to satisfy $\omega^{\alpha} = \alpha$. The functions definable by ordinal recursion up to ε_0 include all functions provably recursive in Peano arithmetic. Terlouw's work (1982) on ordinal recursion over higher types is related to the role for powers in section 12.

It should not surprise anyone that various principles of w.f. recursion can be developed within Intuitionistic Type Theory. The point of this paper is to present the derivations in *full* detail. They can be used with a mechanical theorem prover like PRL. The present set of w.f. relations is complete in two senses. (1) It includes nearly all the w.f. relations I have encountered in the literature. (2) The set includes order types well beyond ε_0 , indeed, any ordinal that a proof of program termination could reasonably require. The paper assumes a basic knowledge with Type Theory. Good introductions include Martin-Löf (1982, 1984) and Nordström & Smith (1984). Jan Smith (1984) presents the inference rules and gives a formal interpretation of the semantics. Each section begins with an easy introduction, then becomes increasingly formal. At any point you may skip to the next section. The remaining sections

-describe a notation for Type Theory

- -describe the LCF style of backwards proof used in this paper
- -formalise w.f. relations, induction, and recursion operators in Type Theory
- -define the function Quicksort using a recursion operator, and show that it satisfies the usual recursion equations
- -derive w.f. induction and recursion for each rule for constructing w.f. relations
- -- show that w.f. relations are precisely the inverse images of wellordering types
- -use the rules to construct w.f. relations taken from the literature
- -comment on drawbacks and questions about the approach.

2. Notation

There is a lamentable diversity of notations for Type Theory. Constable and Backhouse have completely different notations; Martin-Löf's has evolved between his earlier and later papers. The notation of Chalmers University (Nordström & Smith, 1984) is Martin-Löf's except for the names of the selectors. The application of the function f to arguments a_1, \ldots, a_n is written $f(a_1, \ldots, a_n)$; the abstraction of an expression c over the variables x_1, \ldots, x_n is written $(x_1, \ldots, x_n)c$. A function of several arguments is regarded as a function-valued function, a device known as *currying*; so f(a, b) abbreviates f(a)(b), and (x, y)c abbreviates (x)(y)c.

My notation for Type Theory is similar. Types include

 \perp , the empty type

T, the type containing the one value 0

Bool, the type of truth values $\{T, F\}$.

a = Aa', the equality type Eq(A, a, a'), where A is a type (the subscript A may be omitted if obvious from context).

The selectors take their arguments in an unconventional order: the argument p being eliminated appears last rather than first. If the constructions c, c_0, c_1, \ldots , have type C, then so do the following selections. Each is listed together with Martin-Löf's (1984) version:

For $p \in \bot$, I use contr(p) instead of $R_0(p)$.

For $p \in \text{Bool}$, I use cond (c_1, c_2, p) instead of $R_2(p, c_1, c_2)$.

For $p \in A \times B$, I use split((x, y)c, p) instead of E(p, (x, y)c).

For $p \in A + B$, I use when $((x)c_1, (y)c_2, p)$ instead of $D(p, (x)c_1, (y)c_2)$.

For $p \in Nat$, I use natrec $(c_0, (x, y)c_1, p)$ instead of $R(p, c_0, (x, y)c_1)$, similarly for listrec, transrec, etc.

This argument order works well with curried functions. For instance, $cond(c_1, c_2)$ means the same as $(p)cond(c_1, c_2, p)$; it is a function on type **Bool**, mapping T to c_1 and F

to c_2 . If f, g, and h are appropriate functions, then split(f) is a function with domain $A \times B$ and when(g, h) is a function with domain A + B. The advantages of this argument order are apparent in complex expressions involving selectors, such as

 λ (when(natrec(p, q), split((x)split((y, z)r(x, y, z))))),

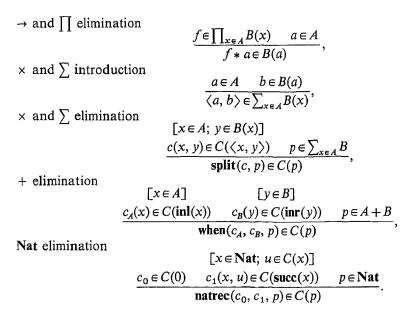

which could have type $(Nat + (A \times (B \times C))) \rightarrow D$. The standard argument order requires additional variables v_1, v_2, v_3, v_4 , denoting intermediate values that we have no wish to see:

 λv_1 . when $(v_1, (v_2)$ natrec $(v_2, p, q), (v_3)$ split $(v_3, (x, v_4)$ split $(v_4, (y, z)r(x, y, z))))$.

Actually, the details of selectors are not important; in my presentation of proof constructions, most selectors are banished in favour of new functions and equations defining them.

The pair of a and b is written $\langle a, b \rangle$. The functions fst and snd are special cases of split, with $fst(\langle a, b \rangle) = a$ and $snd(\langle a, b \rangle) = b$. The application of the function object f to the object a is written f * a rather than the usual apply(f, a). The canonical objects of a function type have the form $\lambda((x)b)$, which may equivalently be written in the traditional lambda style, $\lambda x \cdot b$. When d is a large expression, $\lambda(d)$ is simpler and clearer than $\lambda x \cdot d(x)$.

Here are a few inference rules in the notation:

Classically, a wellordering is a linear well-founded relation. Martin-Löf's wellordering type is a general kind of tree structure. Both uses of "wellordering" are firmly established. To prevent confusion, I always write "wellordering type" for Martin-Löf's usage, and "wellordering" for the classical usage.

The rule for wellordering elimination uses the latest innovation, hypothetical hypotheses. A hypothesis of the form $f(x) \in B[x \in A]$ asserts that f is a function from A to B. This is hardly different from the assumption $f \in A \rightarrow B$, but allows the wellordering types to be defined without mention of function types. The types in Type Theory are

defined independently of each other.

$$\begin{bmatrix}
x \in A \\
f(z) \in \mathbf{W}_{x \in A} B(x) \quad [z \in B(x)] \\
u(z) \in C(f(z)) \quad [z \in B(x)]
\end{bmatrix}$$

$$\frac{p \in \mathbf{W}_{x \in A} B(x) \quad c(x, f, u) \in C(\sup(x, f))}{\operatorname{transrec}(c, v) \in C(p)}.$$

I make occasional non-essential use of the subtype $\{x \in A | B(x)\}$. This is similar to the type $\sum_{x \in A} B(x)$, but its elements are those of A instead of pairs $\langle a, b \rangle$. Subtypes are convenient when B(x) represents a proposition such as equality, whose elements are uninteresting. Constable gives a fuller explanation (1983, p. 74), as does Petersson (1982b). Rules include

type formation

	A type	$[x \in A]$
	л сурс	B(x) type
	$\overline{\{x \in A B(x)\} \text{ type }},$	
introduction	$a \in A$	$b \in B(a)$
		$\frac{1}{A B(x)},$
elimination	```	F A D (X) A
		$[x \in A; B(x) \text{ true}]$
	$a \in \{x \in A B(x)\}$	$c(x) \in C(x)$

$$c(a) \in C(a)$$

The assumption B(x) true means that B(x) is a true proposition, namely that the type B(x) contains an element. Such reasoning can be formalised by introducing a set of rules about true propositions. An alternative is to regard this assumption as an abbreviation of $y \in B(x)$, with the restriction that y must not appear free elsewhere in the rule.

3. Backwards Proof

A traditional method of searching for a proof is to work backwards from goals to subgoals. For instance, to prove $A \wedge B$, it suffices to prove A and B separately. Backwards proof is more difficult in Type Theory: the goal would be written $p \in A \times B$, for an *unknown* construction p. As the proof proceeds, constraints upon p accumulate; when the proof is finished, they determine p completely. Recording the constraints requires tedious bookkeeping, whether the proof is conducted by hand or by computer. The LCF architecture does not allow unknown expressions in goals, so Petersson's Type Theory system does not support backwards proof. PRL (Constable, 1986) works explicitly with types only, handling constructions internally.

I have worked out the proofs in this paper by hand. If the type A represents a proposition to be proved, then the initial goal is $p \in A$, for some construction p. In proving $p \in A$, each backwards step decomposes the type A, incrementally discovering the structure of p. The letters p, q, r, \ldots , stand for unknown constructions.

Unification gives a flexible treatment of unknown expressions in goals (Paulson, 1986a). An inference rule

 $\frac{\Phi_1(\vec{p})\ldots\Phi_n(\vec{p})}{\Phi(\vec{p})},$

where \vec{p} stands for a vector of unknowns, specifies a way to reduce a goal Φ to subgoals Φ_1, \ldots, Φ_n . Suppose that the goal is $\Psi(\vec{q})$, and that the vector of expressions \vec{a} unifies the goal with the conclusion of the rule: $\Phi(\vec{a})$ is identical to $\Psi(\vec{a})$. Then instantiating the unknowns \vec{p} and \vec{q} reduces $\Psi(\vec{q})$ to $\Phi_1(\vec{a}), \ldots, \Phi_n(\vec{a})$. The unifier \vec{a} may contain new unknowns. Most hand proofs only require trivial unifications.

Backwards proof is natural for both discovering and presenting formal proofs. Consider this backwards proof of the Axiom of Choice. You might compare it with Martin-Löf's (1982, 1984) forwards proof.

If suffices to find some construction choice of type

$$\left(\prod_{x\in A}\sum_{y\in B(x)}C(x, y)\right)\to \sum_{f\in\Pi(A, B)}\prod_{x\in A}C(x, f(x)).$$

By product introduction, *choice* could be $\lambda z \cdot p$, where

$$p \in \sum_{f \in \Pi(A, B)} \prod_{x \in A} C(x, f(x)) [z \in \prod_{x \in A} \sum_{y \in B(x)} C(x, y)].$$

By sum introduction, p could be the pair $\langle f, q \rangle$, where $f \in \Pi(A, B)$ and $q \in \prod_{x \in A} C(x, f(x))$. First try to find f. By product introduction, f could be $\lambda x \cdot r$, where

$$r \in B(x) \begin{bmatrix} z \in \prod_{x \in A} \sum_{y \in B(x)} C(x, y) \\ x \in A \end{bmatrix}.$$

Product elimination gives $z * x \in \sum_{y \in B(x)} C(x, y)$. By sum elimination, r is fst(z * x), and $f = \lambda x$. fst(z * x); by similar reasoning, $q = \lambda x$. snd(z * x). Putting the pieces together gives

choice = $\lambda z . \langle \lambda x . \mathbf{fst}(z * x), \lambda x . \mathbf{snd}(z * x) \rangle$.

4. Well-founded Relations in Type Theory

In Type Theory, the rule of w.f. induction can be stated as

$$\frac{x \in A}{[ih(x', ls) \in P(x')[x' \in A; ls \in x' \prec x]]}$$

$$\frac{a \in A}{s(x, ih) \in P(x)}$$
wfrec(s, a) $\in P(a)$

(Note that the induction hypothesis *ih* is itself hypothetical.) The operator wfree can be used to define functions on A. From our understanding of w.f. recursion, it is natural to expect wfree to satisfy the *recursion rule*

$$\frac{(\text{premises as above})}{\text{wfrec}(s, a) = s(a, (x, ls) \text{wfrec}(s, x)) \in P(a)}.$$

DEFINITION. A binary relation \prec on a type A is well-founded (w.f.) precisely when the rules of w.f. induction and recursion hold.

A w.f. relation need not be transitive, hence need not be an ordering. It must be irreflexive and asymmetric. The recursion rule has a key advantage: its conclusion does not make use of the propositional variable ls. This variable justifies the recursion but plays no role in computation. When using a function f defined by w.f. recursion, the induction rule serves to prove facts about f, while the recursion rule allows computation

of f. By w.f. induction, it is trivial to prove that wfree gives the *unique* solution to this recursion equation.

The symbol wfree denotes a complex Type Theory construction dependent upon the relation \prec . A version of wfree is derived for each w.f. relation considered below. For a w.f. relation defined in terms of other w.f. relations, its wfree invokes the wfree of those relations.

How does wfree compare with the fixed-point operator of domain theory? For $x \in A$, let $[A]_{\prec x}$ denote the subtype of A below x, namely $\{x \in A | x \prec a\}$. Roughly speaking, w.f. recursion produces a total function of type $A \rightarrow B$ given something that maps $x \in A$ to $([A]_{\prec x} \rightarrow B) \rightarrow B$. Domain theory produces a function of type $A \rightarrow B$, given something of type $(A \rightarrow B) \rightarrow (A \rightarrow B)$. So the two recursion operators have similar functionality.

The universe rules of Type Theory allow us to form universes of w.f. relations, with induction and recursion restricted to small types. Abstract over the rules' premises, including implicit ones like P(x) type. For the type of a w.f. induction step, use the abbreviation

$$\text{STEP}(A, \prec, P) \equiv \prod_{x \in A} \left(\prod_{x' \in A} x' \prec x \to P * x' \right) \to P * x.$$

The universe WF_0 of small w.f. relations is

$$\sum_{A \in U_0} \sum_{\langle eA \times A \to U_0 \rangle} \prod_{\substack{P \in A \to U_0 \\ f \in \prod_{x \in A}}} \prod_{A \in V_0} \prod_{\substack{A \in V_0 \\ x \in A}} p_{*x} | \prod_{x \in A} wf * x = p_{*x} step * x * (\lambda x'ls . wf * x') \}.$$

Derivations of w.f. relations can be regarded as constructions within WF_0 . The ordering < is an element of WF_0 ; lexicographic product is a binary operation on WF_0 , etc. Members of WF_0 have the form $\langle A, \langle \prec, wf \rangle \rangle$. If $P(x) \in U_0$ for any $x \in A$, then w.f. induction and recursion hold under the definition

wfrec(s, a)
$$\equiv$$
 wf * $\lambda(P)$ * (λx ih. s(x, (x', ls)ih * x' * ls)) * a.

5. Defining Quicksort by Well-founded Recursion

Before plunging into the formal derivations of w.f. induction and recursion, let us see how to use these rules to reason about recursive functions in Type Theory. Consider an example due to Smith (1983). If A is a type with some total ordering of type $A \times A \rightarrow Bool$, then any list of elements of A can be sorted into ascending order. Quicksort sorts a nonempty list **cons**(a, l) by partitioning I into two sublists: one containing the elements that are less or equal to a, and one containing the elements that are greater. It recursively sorts these sublists, then concatenates them.

Smith introduces Quicksort within Type Theory by deriving a new principle of primitive recursion. Below, Quicksort is defined by w.f. recursion over a w.f. relation, \prec . Each recursive call includes an explicit termination argument involving \prec . An unfolding step shows that the resulting function satisfies the usual recursion equations for Quicksort.

Quicksort terminates because the length of the list is smaller in each recursive call. The function *length* is defined as

$$length \equiv listrec(0, (x, l, u)succ(u)).$$

Thus *length* satisfies the recursion equations

$$length(nil) = 0$$

$$length(cons(a, l)) = succ(length(l)).$$

Henceforth, functions will be defined by recursion equations whenever these can obviously be translated into a formal definition involving **natrec**, **listrec**, etc. The two equations for *length* give a precise and readable definition.

Define the w.f. relation \prec on lists such that $l' \prec l$ means length(l') < length(l). In other words, \prec is the inverse image of < under the function *length*. Quicksort is defined by recursion over \prec . Be careful not to confuse the total ordering on A with the w.f. relation on List(A).

Partitioning the input list requires a function *filter*. Given a predicate function $pf \in A \rightarrow Bool$, and a list, *filter* returns the list of elements for which pf returns T:

$$filter(pf, nil) = nil$$

$$filter(pf, cons(a, l)) = \begin{cases} cons(a, filter(pf, l)) & \text{if } pf * a = T \\ filter(pf, l) & \text{if } pf * a = F. \end{cases}$$

It is straightforward to prove that *filter* does not make the list longer:

 $length(filter(pf, l)) \leq length(l)$ true.

A corollary of this, needed to justify the recursion of Quicksort, is (for some construction *qless*)

$$[pf \in A \rightarrow \mathbf{Bool}; x \in A; l \in \mathbf{List}(A)]$$

 $qless(pf, x, l) \in length(filter(pf, l)) < length(cons(a, l))$

or equivalently

$$qless(pf, x, l) \in filter(pf, l) \prec cons(a, l).$$

Two predicate functions provide the ordering used for sorting:

$$before(a) * b$$
 whether b is less than or equal to a $after(a) * b$ whether b is greater than a.

Let \oplus denote the *append* operation on lists (concatenation). We would like to establish the usual recursion equations for Quicksort, namely

$$quick(nil) = nil$$

$$quick(cons(a, l)) = (quick(filter(before(a), l)))$$

$$\oplus cons(a, quick(filter(after(a), l))).$$

Defining Quicksort by w.f. recursion requires defining an induction step s(l, ih) in terms of a list l and induction hypothesis

$$ih(l', ls) \in \text{List}(\text{Nat})[l' \in \text{List}(\text{Nat}); ls \in l' \prec l].$$

The induction hypothesis allows a recursive call for any list l' smaller than l. A proof of $l' \prec l$ must be supplied as an argument. This proof will be a construction, involving *qless*, of type $l' \prec l$. Since the list may be empty or not, the definition of s considers two cases:

$$s(nil, ih) = nil$$

$$s(cons(a, l), ih) = ih(filter(before(a), l), qless(before(a), a, l))$$

$$\oplus cons(a, ih(filter(after(a), l), qless(after(a), a, l))).$$

Now Quicksort is just $quick \equiv wfrec(s)$. To produce the familiar recursion equations, unfold *quick* according to the recursion rule for wfrec:

$$quick(l) = s(l, (l', ls)quick(l')).$$

The termination arguments involving *qless* drop out:

$$quick(\mathbf{cons}(a, l)) = s(\mathbf{cons}(a, l), (l', ls)quick(l'))$$
$$= (quick(filter(before(a), l)))$$
$$\oplus \mathbf{cons}(a, quick(filter(after(a), l))).$$

Quicksort is correct if its result is always an ordered permutation of its argument. The proof involves w.f. induction, where the induction hypothesis states that *quick* is correct in its recursive calls. Manna & Waldinger (1986) verify Quicksort in detail.

How efficient is the execution of Quicksort in Type Theory? A detailed analysis of Quicksort's version of wfrec is required. Efficiency questions are particularly delicate because Type Theory programs are executed under lazy evaluation. Ideally, Quicksort's recursion equations should be executed directly as rewrite rules: we know that they represent a terminating computation.

6. The Less-than Ordering on the Natural Numbers

Well-founded induction over the ordering < on natural numbers is the familiar *course-of-values* induction. It is easy to derive from mathematical induction, just as course-of-values recursion is easy to derive from primitive recursion. The relation < is defined to satisfy (remember that + denotes disjoint union!)

$$m < 0 = \bot$$

$$m < \operatorname{succ}(n) = (m = \operatorname{Nat} n + m < n).$$

The substructure relation for lists and other tree-like types is analogous to <. Manna & Waldinger (1981) use w.f. induction on this relation for their *l*-expressions. I was surprised to discover that w.f. induction on *l*-expressions has essentially the same derivation as that for <. However, we shall see later on that the substructure relation for any tree-like type follows from the rules for wellordering types and transitive closure.

6.1. INDUCTION

Assume throughout that P(n) is a type for $n \in Nat$, and assume the induction step

$$step \in \prod_{n \in Nat} \left(\prod_{m \in Nat} m < n \to P(m) \right) \to P(n)$$

To justify w.f. induction, it suffices to find $wf * n \in P(n)$ for $n \in Nat$. Appealing to the induction step, wf could be λn . step * n * p(n), where

$$p(n) \in \prod_{m \in \operatorname{Nat}} m < n \to P(m)$$

By natural number induction, p(n) could be natrec(p_0, p_1, n), where

$$p_0 \in \prod_{m \in \operatorname{Nat}} m < 0 \to P(m)$$

and

$$p_1(n, u) \in \prod_{m \in \text{Nat}} m < \text{succ}(n) \to P(m) \begin{bmatrix} n \in \text{Nat} \\ u \in \prod_{m \in \text{Nat}} m < n \to P(m) \end{bmatrix}$$

Clearly p_0 is $\lambda m \, ls$. contr(ls). By product introduction and unfolding the less-than relation, $p_1(n, u)$ could be $\lambda m \, ls \cdot p_2$, where

$$p_2 \in P(m)[n; u; m \in Nat; ls \in m = n + m < n].$$

To save space, I have abbreviated the assumptions $n \in Nat$ and $u \in \prod_{m \in Nat} m < \rightarrow P(m)$ as n and u. By + elimination, p_2 could be when (q_1, q_2, ls) , where

and $q_1(e) \in P(m)[n; u; m; e \in m = n]$ $q_2(ls) \in P(m)[n; u; m; ls \in m < n].$

The induction hypothesis u solves both goals. Replacing m by n, the w.f. induction step gives $q_1(e) = step * n * u$; also $q_2(ls) = u * m * ls$. \Box

The definition of wf is too long to work with directly. Instead, we can derive a set of equations for it, retaining p as an auxiliary function. Even p is inconveniently complex. It involves the selectors **natree** and **when**. Therefore it is described by equations where the selectors can be eliminated:

$$p(0) * m * ls = \operatorname{contr}(ls) \in P(m) \quad [ls \in m < 0]$$

$$p(\operatorname{succ}(n)) * m * \operatorname{inl}(\operatorname{eq}) = step * m * p(n) \in P(m) \quad [\operatorname{eq} \in m = m]$$

$$p(\operatorname{succ}(n)) * m * \operatorname{inr}(ls) = p(n) * m * ls \in P(m) \quad [ls \in m < n]$$

$$wf * n = step * n * p(n) \in P(n).$$

Most of derivations of constructions in this paper end with such equations, which summarise the derivation. The following proof of the recursion rule illustrates that the equations provide the needed information in a convenient form.

6.2. RECURSION

The desired property is

$$wf * n = step * n * (\lambda m \, ls \, . \, wf * m) \in P(n) [n \in \mathbf{Nat}]$$

Unfolding wf, it remains to show

step
$$* n * p(n) = step * n * (\lambda m \, ls \, . \, wf * m) \in P(n) [n \in \mathbf{Nat}].$$

Cancelling (product elimination and introduction), it is enough to show

$$p(n) * m * ls = wf * m \in P(m)[n; m \in Nat; ls \in m < n]$$

By equality and product elimination, it is enough to show

$$\prod_{l \le m \le n} p(n) * m * ls =_{P(m)} wf * m \operatorname{true} [n; m \in \operatorname{Nat}].$$

By natural number induction on n, and product introduction, it remains to show

$$p(0) * m * ls = wf * m \in P(m) [m \in Nat; ls \in m < 0],$$

which holds by the contradiction m < 0, and also to show

$$\begin{array}{c} m \in \mathbf{Nat} \\ n \in \mathbf{Nat} \\ u \in \prod_{ls \in m < n} p(n) * m * ls = p(m) & wf * m \\ ls \in m = n + m < n \\ p(\mathbf{succ}(n)) * m * ls = wf * m \in P(m) \end{array}$$

By + elimination, it remains to consider two cases, using the appropriate equation for $p(\mathbf{succ}(n))$:

and

$$step * n * p(n) = wf * n \in P(n) [m; n; u; e \in m = n]$$

 $p(n) * m * ls = wf * m \in P(m) [m; n; u; ls \in m < n].$

. .

The first goal is the equation for wf; the second is an instance of the induction hypothesis.

7. Subrelations

This paper is less concerned with particular w.f. relations like < as it is with rules for constructing w.f. relations from others. The simplest rule concerns subrelations of w.f. relations. Suppose that \prec is a w.f. relation on the type A, and that \ll is a subrelation of \prec , namely there is a function f satisfying

$$f(x', x, lt) \in x' \prec x [x \in A; x' \in A; lt \in x' \ll x].$$

Then A is a w.f. by the relation \ll .

A typical use of this rule is to justify w.f. induction on the "properly divides" relation on natural numbers (Manna & Waldinger, 1986). If m properly divides n, then m < n. But the main application in Type Theory is when one relation is logically equivalent to another. A proposition may be expressed as many different types; this rule provides compatibility between them.

For instance, the proof that < is w.f. uses a particular definition of <. You may prefer to work with the logically equivalent definition

$$m \ll n \equiv \sum_{k \in \operatorname{Nat}} \operatorname{succ}(m \operatorname{plus} k) = n.$$

In order to justify w.f. induction on \ll , you need only show that $m \ll n$ implies m < n.

7.1. INDUCTION

Assume throughout that P(x) is a type for $x \in A$, and assume the induction step

$$step \in \prod_{x \in A} \left(\prod_{x' \in A} x' \ll x \to P(x') \right) \to P(x).$$

It suffices to find $wf * x \in P(x)$ for $x \in A$. Since the relation \prec is w.f., induction gives $wf = \lambda x$. wfrec(s, x), where

$$s(x, ih) \in P(x) \begin{bmatrix} x \in A \\ ih(x', ls) \in P(x') [x' \in A; ls \in x' \prec x] \end{bmatrix}.$$

Using the induction step, s(x, ih) could be step *x * t, where

$$t \in \prod_{x'} x' \ll x \to P(x').$$

By product introduction, t is $\lambda x' \cdot \lambda lt \cdot ih(x', f(x', x, lt))$, and we have

$$s(x, ih) = step * x * (\lambda x' lt . ih(x', f(x', x, lt))). \quad \Box$$

7.2. RECURSION

Since A is w.f. under \prec , it satisfies the recursion rule

$$wfrec(s, a) = s(a, (x, ls)wfrec(s, x)).$$

The recursion rule A under \ll is easy to prove, by unfolding wf:

$$wf * x = wfrec(s, x) = s(x, (x', ls)wf * x') = step * x * (\lambda x' lt . ((x', ls)wf * x')(x', f(x', x, lt))) = step * x * (\lambda x' lt . wf * x'). \Box$$

8. Inverse Image

Suppose that \prec_B is a w.f. relation on the type *B*, and that *f* is a function such that $f(x) \in B$ if $x \in A$. Define the relation \prec_A on *A* as the inverse image of \prec_B under *f*:

$$x' \prec_A x \equiv f(x') \prec_B f(x)$$

A function used for this purpose is often called a rank or measure function. Measure functions play the central role in the induction principle of Boyer & Moore (1979), and in my characterisation of w.f. types (section 14).

8.1. INDUCTION

Assume throughout that, if $x \in A$, then P(x) is a type and $f(x) \in B$. Also assume

$$step \in \prod_{x \in A} \left(\prod_{x' \in A} x' \prec_A x \to P(x') \right) \to P(x).$$

It suffices to find $wf * x \in P(x)$ for $x \in A$. By reflexivity, equality introduction, substitution, and product elimination, wf could be $\lambda x \cdot wf_2 * eq$, where

$$wf_2 \in (f(x) =_B f(x)) \rightarrow P(x) [x \in A].$$

Now rename certain occurrences of x as z: put

$$R(y) \equiv \prod_{z \in A} (f(z) =_B y) \to P(z).$$

By product elimination, wf_2 could be $wf_3 * x$, where

$$wf_3 \in R(f(x)) [x \in A].$$

W.f. induction on $\prec_{\mathcal{B}}$ gives $wf_3 = wfrec_{\mathcal{B}}(s, f(x))$, where

$$s(y, ih) \in R(y) \begin{bmatrix} x \in A \\ y \in B \\ ih(y', ls) \in R(y') [y' \in B; ls \in y' \prec_B y] \end{bmatrix}$$

By product introduction, s(y, ih) could be $\lambda ze \cdot s_2(z, e)$, where

$$s_2(z, e) \in P(z)[x; y; ih; z \in A; e \in f(z) =_B y].$$

The induction step gives $s_2(z, e) = step * z * t(y, ih)$, where

$$t(y, ih) \in \prod_{x' \in \mathcal{A}} (f(x') \prec_{\mathcal{B}} f(z)) \to P(x')[x; y; ih; z; e].$$

Using the assumption f(z) = y, product introduction gives $t(y, ih) = \lambda x' ls \cdot t_2$, where

$$t_2 \in P(x') [x; y; ih; z; x' \in A; ls \in f(x') \prec_B y].$$

By reflexivity and the induction hypothesis, t_2 is ih(f(x'), ls) * x' * eq.

Let $p(y) \equiv wfrec_B(s, y)$. Then we can summarise the derivation with equations:

$$\begin{aligned} t(y, ih) &= \lambda x' ls \cdot ih(f(x'), ls) * x' * \mathbf{eq} \in \prod_{x' \in A} (f(x') \prec_B y) \to P(x') \\ p(y) * x * e &= step * x * t(y, (y', ls)p(y)) \in P(x) \quad [e \in f(x) =_B y] \\ wf * x &= p(f(x)) * x * \mathbf{eq} \quad \in P(x)P(x). \end{aligned}$$

The equation for p uses the recursion rule for \prec_{B} , which is valid under the assumption that \prec_{β} is w.f. This is used in several summaries below, and will not be pointed out again.

8.2. RECURSION

The recursion rule for \prec_A follows from the equations above:

$$wf * x = p(f(x)) * x * eq \in P(x)$$

= step * x * t(f(x), (y', ls)p(y'))
= step * x * ($\lambda x'$ ls. p(f(x')) * x' * eq)
= step * x * ($\lambda x'$ ls. wf * x'). \Box

9. Transitive Closure

A relation \prec is stronger than its transitive closure \prec^+ . This means that \prec^+ gives a more powerful induction rule, while it is easier to prove that \prec is w.f. We get the best of both worlds by showing that the (irreflexive) transitive closure of any w.f. relation is a w.f. ordering. Suppose that \prec is a w.f. relation on the type A. The derivation of induction and recursion works for any definition of the transitive closure \prec^+ satisfying

$$x' \prec^+ x \leftrightarrow x' \prec x + \left(\sum_{y \in A} x' \prec^+ y \times y \prec x\right).$$

The \rightarrow direction is particularly important: it means there is a construction treases such that if $x' \in A$, $x \in A$, and $lt \in x' \prec^+ x$, then

$$trcases(x', x, lt) \in x' \prec x + \left(\sum_{y \in A} x' \prec^+ y \times y \prec x\right).$$

For example, recursion on the natural numbers defines finite powers \prec " of the relation \prec , satisfying

$$\begin{aligned} x \prec^0 y &= (x =_A y) \\ x \prec^{\operatorname{succ}(n)} z &= \sum_{y \in A} x \prec^n y \times y \prec z. \end{aligned}$$

We can now define the transitive closure \prec^+ , and the reflexive/transitive closure \prec^* (which is obviously not w.f.):

$$\begin{aligned} x \prec^+ y &\equiv \sum_{n \in \operatorname{Nat}} x \prec^{\operatorname{succ}(n)} y \\ x \prec^* y &\equiv \sum_{n \in \operatorname{Nat}} x \prec^n y. \end{aligned}$$

The proof for this definition of \prec^+ uses the Nat elimination rule instead of case analysis on treases.

9.1. INDUCTION

Assume that P(x) is a type for $x \in A$. Introduce the abbreviation

$$Q(x) \equiv \prod_{x' \in \mathcal{A}} x' \prec^+ x \to P(x').$$

Assume the induction step, which is simply

$$step \in \prod_{x \in A} Q(x) \to P(x).$$

It suffices to find $wf * x \in P(x)$ for $x \in A$. Using the induction step, wf * x could be step * x * q(x), where $q(x) \in Q(x)$. W.f. induction on x gives q(x) = wfrec(s, x), where

$$\begin{bmatrix} x \in A \\ ih(y, ls) \in Q(y) [y \in A; ls \in y \prec x] \end{bmatrix}$$

$$s(x, ih) \in Q(x)$$

By product introduction, unfolding Q, and sum elimination, s(x, ih) could be $\lambda x' lt \cdot s_1$, where

$$s_1 \in P(x') [x; ih; x' \in A; lt \in x' \prec^+ x].$$

Using treases and + elimination, s_1 could be when $(s_2, s_3, treases(x', x, lt))$, where

$$s_2(ls) \in P(x')[x; ih; x'; ls \in x' \prec x]$$

and also

$$s_3(y, lt, ls) \in P(x')[x; ih; x'; y \in A; lt \in x' \prec^+ y; ls \in y \prec x]$$

Clearly $s_2(ls) = step * x' * ih(x', ls)$ and $s_3(y, lt, ls) = ih(y, ls) * x' * lt$. Summarising,

$$q(x) * x' * lt_0 = \begin{cases} step * x' * q(x') & \text{if } trcases(x', x, lt_0) = \text{inl}(ls) \\ q(y) * x' * lt \in P(x') & \text{if } trcases(x', x, lt_0) = \text{inr}(\langle y, \langle lt, ls \rangle \rangle) \\ wf * x = step * x * q(x) \in P(x). \end{cases}$$

9.2. RECURSION

The desired rule is

$$wf * x = step * x * (\lambda x' lt . wf * x') \in P(x) [x \in A].$$

Unfolding wf in the left side, and cancelling, it suffices to prove

$$\prod_{lt \in x' \prec +x} q(x) * x' * lt =_{P(x')} wf * x' [x \in A; x' \in A].$$

W.f. induction over \prec on x, followed by product introduction, gives

$$\begin{bmatrix} x' \in A \\ x \in A \\ ih(y, ls) \in \prod_{lt \in x' \prec^+ y} q(y) * x' * lt =_{P(x')} wf * x' [y \in A; ls \in y \prec x] \\ lt \in x' \prec^+ x \\ q(x) * x' * lt = wf * x' \in P(x') \end{bmatrix}$$

Using trcases(x', x, lt), it is enough to show both

$$step * x' * q(x') = wf * x' \in P(x') [x'; x; ih; ls \in x' \prec x],$$

which follows from the definition of wf, and also

 $q(y) * x' * lt = wf * x' \in P(x')[x'; x; ih; y \in A; lt \in x' \prec^+ y; ls \in y \prec x],$ which follows from the induction hypothesis. \Box

10. Disjoint Sum

Suppose that \prec_A and \prec_B are w.f. on the types A and B respectively. The relation \prec on the type A + B puts the elements of A before the elements of B. With x', x in A and y', y in B, it satisfies

$$inl(x') < inl(x) = x' \prec_A x$$

$$inl(x) < inr(y) = \top$$

$$inr(y) < inl(x) = \bot$$

$$inr(y') < inr(y) = y' \prec_B y.$$

10.1. INDUCTION

Assume that P(z) is a type for all $z \in A + B$, and assume the induction step

$$step \in \prod_{z \in A+B} \left(\prod_{z' \in A+B} z' \prec z \rightarrow P(z') \right) \rightarrow P(z).$$

Before proving P(z) for all z in A + B, consider the special case of finding $p(x) \in P(inl(x))$, for $x \in A$. W.f. induction on \prec_A gives $p(x) = wfrec_A(p_1, x)$, where

$$p_1(x, ih) \in P(\operatorname{inl}(x)) \begin{bmatrix} x \in A \\ ih_A(x', ls) \in P(\operatorname{inl}(x')) [x' \in A; ls \in x' \prec_A x] \end{bmatrix}.$$

The induction step gives $p_1(x, ih_A) = step * inl(x) * q(x, ih_A)$, where

$$q(x, ih_A) \in \prod_{z' \in A + B} z' \prec \operatorname{inl}(x) \to P(z') [x; ih_A].$$

By product introduction and + elimination, $q(x, ih_A)$ could be $\lambda(\text{when}(p_3, p_4))$, where

$$p_{3}(x') \in \operatorname{inl}(x') \prec \operatorname{inl}(x) \to P(\operatorname{inl}(x')) [x; ih_{A}; x' \in A]$$
$$p_{4}(y') \in \operatorname{inr}(y') \prec \operatorname{inl}(x) \to P(\operatorname{inr}(y')) [x; ih_{A}; y' \in B].$$

and

The equations for
$$\prec$$
 give $p_3(x') = \lambda ls \cdot ih_A(x', ls)$ and $p_4(y') = \lambda ls \cdot contr(ls)$.

Now try to find $wf * z \in P(z)$ for $z \in A+B$. By + elimination, wf could be $\lambda(when(p, r))$, where p(x) is as above and $r(y) \in P(inr(y))$ for $y \in B$. Reasoning as for p, using w.f. induction on \prec_B and then the induction step, gives

where

$$r(y) = \mathbf{wfrec}_{B}((y, ih_{B})step * \mathbf{inr}(y) * s(y, ih_{B}), y),$$

$$\begin{bmatrix} y \in B \\ ih_{B}(y', ls) \in P(\mathbf{inr}(y')) [y' \in B; ls \in y' \prec_{B} y] \end{bmatrix}$$

$$s(y, ih_{B}) \in \prod_{z' \in A+B} z' \prec \mathbf{inr}(y) \rightarrow P(z')$$

Product introduction followed by case analysis on z', using p again, gives

 $s(y, ih_B) = \lambda(\text{when}((x')\lambda ls \cdot p(x'), (y')\lambda ls \cdot ih_B(y', ls))). \quad \Box$

Summarising,

$$\begin{split} s(y, ih_B) * \mathbf{inl}(x') * ls &= p(x') \in P(\mathbf{inl}(x')) \\ s(y, ih_B) * \mathbf{inr}(y') * ls &= ih_B(y', ls) \in P(\mathbf{inr}(y')) \\ r(y) &= step * \mathbf{inr}(y) * s(y, (y', ls)r(y')) \in P(\mathbf{inr}(y)) \\ q(x, ih_A) * \mathbf{inl}(x') * ls &= ih_A(x', ls) \in P(\mathbf{inl}(x')) \end{split}$$

$$q(x, ih_A) * \operatorname{inr}(y') * ls = \operatorname{contr}(ls) \in P(\operatorname{inr}(y'))$$

$$p(x) = step * \operatorname{inl}(x) * q(x, (x', ls)p(x')) \in P(\operatorname{inl}(x))$$

$$wf * \operatorname{inl}(x) = p(x) \in P(\operatorname{inl}(x))$$

$$wf * \operatorname{inr}(y) = r(y) \in P(\operatorname{inr}(y)).$$

10.2. RECURSION

It suffices to show

$$wf * z = step * z * (\lambda z' ls . wf * z') \in P(z).$$

By + elimination on z, it suffices to show

$$wf * \operatorname{inl}(x) = step * \operatorname{inl}(x) * (\lambda z' \, ls \, . \, wf * z') \in P(\operatorname{inl}(x)),$$

and a similar goal for inr(y). Unfolding wf and p and cancelling, it is enough to show

$$q(x, (x', ls)p(x')) = \lambda z' \, ls \, . \, wf \, \ast \, z' \in \prod_{z' \in A + B} z' \prec \operatorname{inl}(x) \to P(z').$$

Product introduction and + elimination on z', unfolding q, gives two goals. We already know the first, p(x') = wf * inl(x'); the second has the contradictory assumption $inr(y') \prec inl(x)$.

Proving the goal for inr(y) is similar; the final case analysis reduces it to the known equations

$$p(x') = wf * inl(x')$$
 and $r(y') = wf * inr(y')$.

11. Lexicographic Product

The lexicographic product of w.f. relations \prec_A and \prec_B is perhaps the most familiar method of combining w.f. relations. Induction over the product amounts to little more than induction over \prec_A followed by induction over \prec_B .

This section actually derives w.f. induction for the sum of a family of types $\sum_{x \in A} B(x)$, of which $A \times B$ is a special case. Suppose that A is a type with a w.f. relation \prec_A . Suppose also that B(x) is a family of types indexed by $x \in A$, with a family of w.f. relations $\prec_{B(x)}$. Define the lexicographic relation \prec on the type $\Sigma(A, B)$ as

$$\langle x' y' \rangle \prec \langle x, y \rangle \equiv x' \prec_A x + (x' =_A x \times y' \prec_{B(x)} y).$$

11.1. INDUCTION

Assume that P(z) is a type for all $z \in \Sigma(A, B)$, and assume the induction step

$$step \in \prod_{z \in \Sigma(A, B)} \left(\prod_{z' \in \Sigma(A, B)} z' \prec z \to P(z') \right) \to P(z).$$

It suffices to find $wf * z \in P(z)$ for $z \in \Sigma(A, B)$. By sum elimination, wf could be $\lambda(split(wf_1))$, where

$$wf_1(x, y) \in P(\langle x, y \rangle) [x \in A; y \in B(x)]$$

By product elimination, $wf_1(x, y)$ could be p(x) * y, where

$$p(x) \in \prod_{y \in B(x)} P(\langle x, y \rangle) [x \in A].$$

W.f. induction on \prec_A gives $p(x) = \mathbf{wfrec}_A(p_1, x)$, where

$$\begin{bmatrix} x \in A \\ ih_A(x', ls_A) \in \prod_{y \in B(x)} P(\langle x', y \rangle) [x' \in A; ls_A \in x' \prec x] \\ p_1(x, ih_A) \in \prod_{y \in B(x)} P(\langle x, y \rangle) \end{bmatrix}.$$

By product introduction, $p_1(x, ih_A)$ could be $\lambda y \cdot q(x, ih_A, y)$, where

$$q(x, ih_A, y) \in P(\langle x, y \rangle) [x; ih; y \in B(x)].$$

W.f. induction on $\prec_{B(x)}$ gives $q(x, ih_A, y) = \mathbf{w} \mathbf{frec}_{B(x)}(q_2, y)$, where

$$\begin{bmatrix} x \in A \\ ih_A(x', ls_A) \in \prod_{y \in B(x)} P(\langle x', y \rangle) [x' \in A; ls_A \in x' \prec x] \\ y \in B(x) \\ ih_B(y', ls_B) \in P(\langle x, y' \rangle) [y' \in B(x); ls_B \in y' \prec_{B(x)} y] \\ q_2(y, ih_B) \in P(\langle x, y \rangle)$$

By the induction step, $q_2(y, ih_B)$ could be step $*\langle x, y \rangle * r(x, ih_A, y, ih_B)$, where

$$r(x, ih_A, y, ih_B) \in \prod_{z' \in \Sigma(A, B)} z' \prec \langle x, y \rangle \to P(z') [x; ih_A; y; ih_B],$$

By product introduction and sum elimination on z', unfolding \prec , $r(x, ih_A, y, ih_B)$ could be λ (split($(x', y')\lambda(t)$)), where

$$t \in P(\langle x', y' \rangle) \begin{bmatrix} x; ih_A; y; ih_B \\ x' \in A \\ y' \in B(x') \\ ls \in x' \prec_A x + (x' =_A x \times y' \prec_{B(x)} y) \end{bmatrix}$$

By + elimination on *ls*, *t* could be when $(t_A, \operatorname{split}(t_B), ls)$, where (suppressing the assumptions x, ih_A, \ldots, y') $f(l_B) \in P(\langle x' | v' \rangle) \cap [l_{S_A} \in x' \prec_A x]$

and

$$t_A(ls_A) \in I(\langle x, y' \rangle) [ls_A \in x \prec_A x]$$
$$t_B(e, ls_B) \in P(\langle x', y' \rangle) [e \in x' =_A x; ls_B \in y' \prec_{B(x)} y].$$

Clearly $t_A(ls_A) = ih_A(x', ls_A) * y'$. For the second goal, replacing x' by x gives $t_B(e, ls_B) = ih_B(y', ls_B)$. \Box

Define $p' \equiv (x', ls)p(x')$. This simplifies the equation about p in the summary:

$$\begin{split} r(x, ih_A, y, ih_B) &* \langle x', y' \rangle * \operatorname{inl}(ls_A) = ih_A(x', ls_A) * y' \in P(\langle x', y' \rangle) \\ r(x, ih_A, y, ih_B) &* \langle x', y' \rangle * \operatorname{inr}(e, ls_B) = ih_B(y', ls_B) \in P(\langle x', y' \rangle) \\ q(x, ih_A, y) &= step * \langle x, y \rangle * r(x, ih_A, y, (y', ls)q(x, ih_A, y')) \in P(\langle x, y \rangle) \\ p(x) &* y = q(x, p', y) \in P(\langle x, y \rangle) \\ wf * \langle x, y \rangle &= p(x) * y \in P(\langle x, y \rangle). \end{split}$$

11.2. RECURSION

For the recursion rule of \prec on $\Sigma(A, B)$, it suffices to show

$$wf * z = step * z * (\lambda z' ls . wf * z') \in P(z) [z \in \Sigma(A, B)].$$

By sum elimination on z, it suffices to show

$$p(x) * y = step * \langle x, y \rangle * (\lambda z' \, ls \, . \, wf * z') \in P(\langle x, y \rangle) [x \in A; y \in B(x)].$$

Unfolding p, it is enough to show

$$q(x, p', y) = step * \langle x, y \rangle * (\lambda z' \, ls \, . \, wf * z') \in P(\langle x, y \rangle) [x \in A; y \in B(x)].$$

Unfolding q and cancelling on both sides, it is enough to show

$$[x \in A; y \in B(x)]$$

$$r(x, p', y, (y', ls)q(x, p', y')) = \lambda z' ls \cdot wf * z' \in \prod_{z' \in \Sigma(A, B)} z' \prec \langle x, y \rangle \to P(z').$$

By product introduction and sum elimination on z', it is enough to show

$$[x; y; x' \in A; y' \in B(x'); ls \in \langle x', y' \rangle \prec \langle x, y \rangle]$$

$$r(x, p', y, (y', ls)q(x, p', y')) * \langle x', y' \rangle * ls = wf * \langle x', y' \rangle \in P(\langle x', y' \rangle).$$

By case analysis on $\langle x', y' \rangle \prec \langle x, y \rangle$, unfolding r, it remains to show

$$p(x') * y' = wf * \langle x', y' \rangle,$$

which is the equation for wf, and

$$q(x, p', y') = wf * \langle x', y' \rangle,$$

which follows from the equations for wf and p. \Box

12. Lexicographic Exponentiation

Suppose that \prec_A is a w.f. relation on A. The alphabetic ordering of words in a dictionary can be formalised as the lexicographic relation on lists $[x_1, \ldots, x_n]$, where $x_1, \ldots, x_n \in A$. Define the relation \prec) to satisfy $[x_1, \ldots, x_m] \prec [a_1, \ldots, a_n]$ whenever there is some k such that $x_i = a_i$ for $i \leq k$, and either k = m < n or $x_{k+1} \prec_A a_{k+1}$. Note that \prec is not necessarily w.f.—there is a descending chain [1], [0, 1], [0, 0, 1], \ldots

To rule out such chains we must allow only lists whose elements appear in decreasing order. The w.f. relation \prec is simply \prec) restricted to the set

$$\{[x_1,\ldots,x_n]|x_1\succ_A\ldots\succ_A x_n\},\$$

formalised as a type of the form $\sum_{l \in \text{List}(A)} D(l)$. I call this the power type of A, or **Pow**(A). Its elements correspond to finite subsets of A whenever \prec_A is a total ordering; furthermore, if \prec_A has order type α , then \prec has order type 2^{α} .

12.1. DEFINITION OF POWER TYPES

The derivation of induction for Pow(A) is the most complex in this paper. We begin with basic concepts of lists:

$$[x_1, \ldots, x_n]$$
 abbreviates $cons(x_1, \cdots cons(x_n, nil) \cdots)$.

The operations of append (\oplus) and reverse (*rev*) satisfy by definition

$$\mathbf{nil} \oplus l = l$$

$$\mathbf{cons}(x, l_1) \oplus l = \mathbf{cons}(x, l_1 \oplus l)$$

$$rev * \mathbf{nil} = \mathbf{nil}$$

$$rev * \mathbf{cons}(x, l) = (rev * l) \oplus [x].$$

The relation \prec is defined such that

$$l' \prec \operatorname{nil} = \bot$$

$$\operatorname{nil} \prec \operatorname{cons}(x, l) = \top$$

$$\operatorname{cons}(x', l') \prec \operatorname{cons}(x, l) = x' \prec_A x + (x' =_A x \times l' \prec l).$$

We have the familiar facts

$$l \oplus \mathbf{nil} = l$$

$$(l_1 \oplus l_2) \oplus l_3 = l_1 \oplus (l_2 \oplus l_3)$$

$$rev * (rev * l) = l.$$

The constructions *apls* and *lsap* assert facts about \prec , proved by induction on the lists *l* and *l*':

$$apls(l', l'', l) \in l' \oplus l'' \prec l \to l' \prec l$$

$$lsap(l', l, l_2) \in l' \prec l \oplus l_2 \to l' \prec l + \sum_{l_1 \in \text{List}(A)} (l' = l \oplus l_1 \times l_1 \prec l_2)$$

Normally we build lists by adding elements to the front, using cons. Here we also must consider adding elements to the rear. Define

 $\mathbf{rlistrec}(c_0, c_1, l) \equiv \mathbf{listrec}(c_0, (x, l, u)c_1(rev * l, x, u), rev * l);$

it is easy to verify the rule of reverse list induction:

$$\frac{[l \in \operatorname{List}(A); x \in A; u \in C(l)]}{c_1(l, x, u) \in C(l \oplus [x])}$$

$$\frac{l \in \operatorname{List}(A) \quad c_0 \in C(\operatorname{nil}) \quad c_1(l, x, u) \in C(l \oplus [x])}{\operatorname{rlistrec}(c_0, c_1, l) \in C(l)}.$$

Functions defined by reverse list recursion obey the computation rules

rlistrec
$$(c_0, c_1, \operatorname{nil}) = c_0 \in C(\operatorname{nil})$$

rlistrec $(c_0, c_1, l \oplus [x]) = c_1(l, x, \operatorname{rlistrec}(c_0, c_1, l)) \in C(l \oplus [x]).$

The predicate D(l), defined using **rlistrec**, expresses that the elements of the list l appear in descending order:

$$D(\mathbf{nil}) = \top$$
$$D([x]) = \top$$
$$D(l \oplus [x] \oplus [x']) = x' \prec_A x \times D(l \oplus [x]).$$

Evidently $D(l \oplus [x])$ implies D(l); reverse list induction on l gives

$$descap(l_1, l) \in D(l_1 \oplus l) \to D(l_1) \times D(l)$$

endls(l, y, x) $\in D(l \oplus [y]) \times l \oplus [y] \prec [x] \to y \prec_A^+ x.$

Recall that \prec_A^+ denotes the transitive closure of \prec_A .

Define the power type of A as

$$\mathbf{Pow}(A) \equiv \sum_{l \in \mathrm{List}(A)} D(l)$$

The w.f. relation \prec compares the underlying lists using \triangleleft :

$$\langle l', d' \rangle \prec \langle l, d \rangle = l' \prec \rangle l.$$

12.2. INDUCTION

Assume that P(z) is a type for $z \in \mathbf{Pow}(A)$; define

$$Q(z) \equiv \prod_{z' \in \operatorname{Pow}(A)} z' \prec z \to P(z');$$

assume the induction step

$$step \in \prod_{z \in Pow(A)} Q(z) \to P(z).$$

It suffices to find $wf * z \in P(z)$ for $z \in Pow(A)$. By the induction step, wf could be λz . step $* z * wf_1$, where $wf_1 \in Q(z)$. By sum elimination on z, wf_1 could be split(wf_2, z), where

$$wf_2(l, d) \in Q(\langle l, d \rangle) [l \in \text{List}(A); d \in D(l)].$$

By product elimination, $wf_2(l, d)$ could be p(l) * d, where

$$p(l) \in \prod_{d \in D(l)} Q(\langle l, d \rangle).$$

By reverse list induction, p(l) could be $rlistrec(p_0, p_1, l)$, where

$$p_0 \in \prod_{d \in D(\mathsf{nil})} Q(\langle \mathsf{nil}, d \rangle),$$

and

$$p_{1}(l, x, u) \in \prod_{d \in D(l \oplus [x])} Q(\langle l \oplus [x], d \rangle) \begin{bmatrix} l \in \text{List}(A) \\ x \in A \\ u \in \prod_{d \in D(l)} Q(\langle l, d \rangle) \end{bmatrix}$$

In the nil goal, unfolding Q gives the contradictory assumption $z' \prec \langle nil, d \rangle$; thus p_0 is $\lambda dz' ls$. contr(ls). By product elimination, $p_1(l, x, u)$ could be q(x) * l * u, where

$$q(x) \in \prod_{l \in Lisl(A)} \left(\prod_{d \in D(l)} Q(\langle l, d \rangle) \to \prod_{d \in D(l \oplus [x])} Q(\langle l \oplus [x], d \rangle) \right) [x \in A].$$

Now use w.f. induction over the *transitive closure* of \prec_A . Iterating the induction hypothesis proves Q for a descending list of any length, provided its elements are all smaller than x. This key step is discussed at length below. Write the recursion operator as wfrec⁴_A. Then q(x) could be wfrec⁴_A (q_1, x) , where

$$\begin{bmatrix} x \in A \\ ih(x', ls) \in \prod_{l \in \text{List}(A)} \left(\prod_{d \in D(l)} Q(\langle l, d \rangle) \to \prod_{d \in D(l \oplus [x'])} Q(\langle l \oplus [x'], d \rangle) \right) \\ [x' \in A; \ ls \in x' \prec_A^+ x] \\ q_1(x, ih) \in \prod_{l \in \text{List}(A)} \left(\prod_{d \in D(l)} Q(\langle l, d \rangle) \to \prod_{d \in D(l \oplus [x])} Q(\langle l \oplus [x], d \rangle) \right) \end{bmatrix}$$

By product introduction and sum elimination on z', unfolding Q and \prec , gives

$$q_1(x, ih) = \lambda lud \cdot \lambda(\operatorname{split}((l', d')\lambda lx \cdot r(ih, l, u, d, x, l', d', lx))),$$

where

$$r(ih, l, u, d, x, l', d', lx) \in P(\langle l', d' \rangle)$$

$$x; lh; l \in List(A)$$

$$u \in \prod_{d \in D(l)} Q(\langle l, d \rangle)$$

$$d \in D(l \oplus [x])$$

$$l' \in List(A)$$

$$d' \in D(l')$$

$$lx \in l' \prec l \oplus [x]$$

Using *lsap*, case analysis on $l' \prec l \oplus [x]$ gives

 $r(ih, l, u, d, x, l', d', lx) = when(r_1, split((l_1)split((e, lx)r_2)), lsap(l', l, [x], lx)),$ where $r_1(lx) \in P(\langle l', d' \rangle) [x; ih; l; u; d; l'; d'; lx \in l' \prec) [$

and, substituting with $l' = l \oplus l_1$,

and

$$r_2 \in P(\langle l \oplus l_1, d' \rangle) [x; ih; l; u; d; l_1 \in \text{List}(A); d' \in D(l \oplus l_1); lx \in l_1 \triangleleft [x]].$$

Since u gives $Q(\langle l, d \rangle)$ for any $d \in D(l)$, the first goal holds with

 $r_1(lx) = u * \operatorname{fst}(\operatorname{descap}(l, [x], d)) * \langle l', d' \rangle * lx.$

(To be absolutely formal, I should write descap(l, [x]) * d, but descap(l, [x], d) is simpler and clearer. Likewise for *lsap*, *apls*, *endls*.)

In the second goal, the induction step gives r_2 as step $* \langle l \oplus l_1, d' \rangle * r_3$, where

$$r_3 \in Q(\langle l \oplus l_1, d' \rangle) [x; ih; l; u; d; l_1; d'; lx]$$

Product elimination gives r_3 as $s(ih, l, u, d, x, l_1) * lx * d'$, where

$$s(ih, l, u, d, x, l_1) \in l_1 \triangleleft [x] \rightarrow \prod_{d' \in D(l \oplus l_1)} Q(\langle l \oplus l_1, d' \rangle) [x; ih; l; u; d; l_1].$$

Reverse list induction shows that the elements of l_1 are all smaller than x. Take $s(ih, l, u, d, x, l_1)$ as rlistrec (s_0, s_1, l_1) , where

$$s_{0} \in \operatorname{nil} \prec [x] \rightarrow \prod_{d' \in D(l \oplus nil)} Q(\langle l \oplus \operatorname{nil}, d' \rangle) [x; ih; l; u; d]$$

$$\begin{bmatrix} x; ih; l; u; d; l_{1} \in \operatorname{List}(A); y \in A \\ v \in l_{1} \prec [x] \rightarrow \prod_{d' \in D(l \oplus l_{1})} Q(\langle l \oplus l_{1}, d' \rangle) \end{bmatrix}$$

$$s_{1}(l, y, v) \in l_{1} \oplus [y] \prec [x] \rightarrow \prod_{d' \in D(l \oplus l_{1} \oplus [y])} Q(\langle l \oplus l_{1} \oplus [y], d' \rangle)$$

The first goal holds because $l \oplus nil = l$ and the assumption u gives $Q(\langle l, d \rangle)$; take $s_0 = \lambda lx \cdot u$.

The second goal holds because the w.f. induction hypothesis allows us to append y to the list $l \oplus l_1$, preserving the truth of Q. The construction is complex; let us consider it in pieces. Under the assumptions x, ih, ..., v, recalling that \oplus is associative, note the facts

$$descap(l, l_1 \oplus [y], d') \in D(l) \times D(l_1 \oplus [y])) [d' \in D(l \oplus (l_1 \oplus [y]))]$$

$$endls(l, y, x, d_1, lx) \in y \prec_A^+ x \begin{bmatrix} d_1 \in D(l_1 \oplus [y]) \\ lx \in l_1 \oplus [y] \rightsquigarrow [x] \end{bmatrix}$$

$$apls(l_1, [y], [x], lx) \in l_1 \rightsquigarrow [x] [lx \in l_1 \oplus [y] \rightsquigarrow [x]]$$

$$ih(y, ls) * (l \oplus l_1) * (v * lx_1) * d' \in Q(\langle l \oplus l_1 \oplus [y], d' \rangle) \begin{bmatrix} ls \in y \prec_A^+ x \\ lx_1 \in l_1 \rightsquigarrow [x] \\ d' \in D((l \oplus l_1) \oplus [y]) \end{bmatrix}.$$

The construction using *endls* to assert $y \prec_A^+ x$ from $l_1 \oplus [y] \triangleleft [x]$ and $D(l_1 \oplus [y])$ is the sole essential appeal to the descending property D. These constructions combine to solve the second goal:

Define $q' \equiv (x', ls)q(x')$. Summarising,

$$s(ih, l, u, d, x, nil) * lx = u \in \prod_{d \in D(l)} Q(\langle l, d \rangle)$$

$$s(ih, l, u, d, x, l_1 \oplus [y]) * lx * d' = ih(y, endls(l, y, x, snd(descap(l, l_1 \oplus [y], d')), lx)) * (l \oplus l_1) * (s(ih, l, u, d, x, l_1) * apls(l_1, [y], [x], lx)) * d' \in Q(\langle l \oplus l_1 \oplus [y], d' \rangle)$$

$$q(x) * l * u * d * \langle l', d' \rangle * lx_0 = \begin{cases} u * fst(descap(l, [x], d)) * \langle l', d' \rangle * lx \in P(\langle l', d' \rangle) \\ if lsap(l', l, [x], lx_0) = inl(lx) [lx \in l' \prec l] \\ step * \langle l \oplus l_1, d' \rangle * (s(q', l, u, d, x, l_1) * lx * d') \\ if lsap(l', l, [x], lx_0) = inr(\langle l_1, \langle e, lx \rangle \rangle) \\ [l' = l \oplus l_1; lx \in l_1 \prec [x]] \end{cases}$$

$$p(nil) * d * z' * ls = contr(ls) \in P(z')$$

$$p(l \oplus [x]) = q(x) * l * p(l) \in \prod_{d \in D(l \oplus [x])} Q(\langle l \oplus [x], d \rangle) \\ wf * \langle l, d \rangle = step * \langle l, d \rangle * (p(l) * d) \in P(\langle l, d \rangle).$$

The equation for q(x) uses the recursion rule of wfrec⁺_A.

12.3. INTERMEZZO

This derivation is related to work in the theory of ordinal recursion. Let α be any ordinal less than ε_0 . Terlouw (1982) derives recursion on 2^{α} , using recursion on α to define a functional of a higher type level. To examine the connection with the present derivation of induction over \prec on **Pow**(A) from induction over \prec_A , our first problem is reconciling the notations. Let \prec (also) denote a wellordering of order type 2^{α} , and \prec_A a wellordering of order type α , and $[F]_{\prec z}$ the restriction of the function F to arguments below z. Let the function $F_0(z)$ defined by the transfinite recursion $F_0(z) = G([F_0]_{\prec z}, z)$. Terlouw expresses F_0 using a functional H defined in terms of G by transfinite recursion on \prec_A .

Below x, y, z range over ordinals, while + denotes ordinal addition, and < ordinal comparison. Transfinite induction on the proposition P(x) requires that P be progressive. The property Prog(P) is essentially a w.f. induction step:

$$\operatorname{Prog}(P) \equiv \forall x . ((\forall y < x . P(y)) \to P(x)).$$

Terlouw remarks: To prove P(x) for all x up to ε_0 , let α be arbitrary and prove $\forall x < 2^{\alpha}. P(x)$ using only transfinite induction up to α . This follows by proving $\forall x < \alpha. B(x)$, where

$$B(x) \equiv \forall z . ((\forall y < z . P(y)) \rightarrow \forall y < z + 2^{x}. P(y)).$$

Induction is sound because Prog(P) implies Prog(B).

Up to ε_0 there is a one-to-one correspondence between ordinals and descending lists of ordinals $2^{\alpha_0} + \cdots + 2^{\alpha_n}$, where $\alpha_0 > \cdots > \alpha_n$. So we can regard any ordinal z uniquely as a list $[\alpha_0, \ldots, \alpha_n]$, and if $x < \alpha_n$, adding 2^x to z corresponds to putting x on the end of the list. Thus B(x) is essentially the type of the construction q(x) above. Induction up to the ordinal α proves B(x); w.f. recursion over \prec_A^+ establishes q(x).

Terlouw does not incant "propositions as types", but remarks (page 398) that the relationship between the functionals H and G "is nothing other than the functionalanalogy" of the relationship between B and P. In H, the variables x and z are those of B, while F denotes a function defined below z, of "type" $\forall y < z . P(y)$. The construction q(x) * l * u corresponds to H(x, z, F), for u is a function asserting P everywhere below l. To clarify the correspondence between H and q, define the Type Theory function h(x, z, F) such that $h(x, \langle l, d \rangle, F) = q * l * F * d$. Take the type A to be the natural numbers, and take x = 0. Suppressing constructions of type $z' \prec z$, unfold the equations for q and s in the previous subsection. The second equation for q has $l_1 \prec [0]$, which is only possible if $l_1 = nil$ and l' = l. This gives

$$h(0, z, F) * z' = \begin{cases} F * (\cdots) * z' & \text{if } z' \prec z \\ \lambda \, lx \, . \, step * z' * (F * \cdots) & \text{if } z' = z. \end{cases}$$

Terlouw defines H to satisfy

$$H(0, z, F)(z') = \begin{cases} F(z') & \text{if } z' \prec z \\ G([F]_{\prec z'}, z) & \text{if } z' = z. \end{cases}$$

Noting that $[F]_{\prec z}$ corresponds to some construction F' of type Q(z), and that $G([F]_{\prec z}, z)$ corresponds to step *z * F', the two sets of equations are nearly identical. Unfortunately, I cannot carry the correspondence between H and q any further. The rest of the definition of H is more complicated, involving functions for computing ordinal operations in terms of an embedding in the natural numbers. Apparently, H builds up its result in a different manner from q.

12.4. RECURSION

The desired property is

$$wf * z = step * z * (\lambda z' ls . wf * z') \in P(z) [z \in A]$$

Unfolding wf and cancelling, it suffices to prove

$$p(l) * d = \lambda z' \, ls \, . \, wf * z' \in Q(\langle l, d \rangle) \, [l \in \operatorname{List}(A); \, d \in D(l)].$$

By product elimination, it suffices to show

$$\prod_{d \in D(l)} \prod_{z' \in \mathsf{Pow}(A)} \prod_{ls \in z' \prec \langle l, d \rangle} p(l) * d * z' * ls =_{P(z')} wf * z' true [l \in \mathsf{List}(A)].$$

By reverse list induction on l, followed by product introduction, it is enough to show

 $\mathbf{contr}(ls) = wf * z' \in P(z')[d; z'; ls \in z' \prec \langle \mathbf{nil}, d \rangle]$

(which holds by contradiction), and also

$$\begin{bmatrix} l \in \mathbf{List}(A); x \in A \\ u \in \prod_{d \in D(l)} \prod_{z' \in \mathbf{Pow}(A)} \prod_{ls \in z' \prec \langle l, d \rangle} p(l) * d * z' * ls =_{P(z')} wf * z' \\ d \in D(l \oplus [x]); z' \in \mathbf{Pow}(A); ls \in z' \prec \langle l \oplus [x], d \rangle \\ q(x) * l * p(l) * d * z' * ls = wf * z' \in P(z') \end{bmatrix}$$

By sum elimination on z', unfolding \prec , it suffices to show

$$[l; x; u; d; l' \in \operatorname{List}(A); d' \in D(l'); lx \in l' \prec l \oplus [x]]$$
$$q(x) * l * p(l) * d * \langle l', d' \rangle * lx = wf * \langle l', d' \rangle \in P(\langle l', d' \rangle)$$

By case analysis with *lsap* on $l' \prec l \oplus [x]$, unfolding q, it suffices to show

$$[l; x; u; d; l'; d'; lx \in l' \prec l]$$

$$p(l) * \mathbf{fst}(descap(l, [x], d)) * \langle l', d' \rangle * lx = wf * \langle l', d' \rangle \in P(\langle l', d' \rangle)$$

(which holds by the induction hypothesis), and also

$$[l; x; u; d; l_1 \in \mathbf{List}(A); d' \in D(l \oplus l_1); lx \in l_1 \prec [x]]$$

step * $\langle l \oplus l_1, d' \rangle * (s(q', l, p(l), d, x, l_1) * lx * d') = wf * \langle l \oplus l_1, d' \rangle \in P(\langle l \oplus l_1, d' \rangle)$

By cancelling and product elimination, it suffices to show

$$[l; x; u; d; l_1]$$

$$\prod_{lx \in l_1 \prec [x]} \prod_{d' \in D(l \oplus l_1)} s(q', l, p(l), d, x, l_1) * lx * d' =_{Q(\langle l \oplus l_1, d' \rangle)} p(l \oplus l_1) * d' \text{ true.}$$

Use reverse list induction on l_1 , then product introduction, and then unfold s. It suffices to show $p(l) = p(l \oplus nil)$, which is trivial, and also

$$\begin{bmatrix} l; x; u; d; l_1 \in \mathbf{List}(A); y \in A \\ v \in \prod_{lx \in l_1 \Rightarrow [x]} \prod_{d' \in D(l \oplus l_1)} s(q', l, p(l), d, x, l_1) * lx * d' =_{Q(\langle l \oplus l_1, d' \rangle)} p(l \oplus l_1) * d' \\ \lfloor lx \in l_1 \oplus [y] \prec [x]; d' \in D(l \oplus l_1 \oplus [y]) \\ q(y) * (l \oplus l_1) * (s(q', l, p(l), d, x, l_1) * apls(l_1, [y], [x], lx)) * d' \\ = p(l \oplus l_1 \oplus [y]) * d' \in O(\langle l \oplus l_1 \oplus [y], d' \rangle).$$

Unfolding p and cancelling, it remains to show

$$s(q', l, p(l), d, x, l_1) * apls(l_1, [y], [x], lx) = p(l \oplus l_1) \in \prod_{d' \in D(l \oplus l_1)} Q(\langle l \oplus l_1, d' \rangle),$$

which follows by product introduction and the induction hypothesis. \Box

13. Wellordering Types

If A is a type, and B(x) is a type for each $x \in A$, then there is a type $\mathbf{W}_{x \in A} B(x)$, equivalently $\mathbf{W}(A, B)$. Each value of this *wellordering* type is a tree such that each node is labelled with some element a of A, and has a branch for each element b in B(a). A tree has the form $\sup(a, f)$, where $f(y) \in \mathbf{W}_{x \in A} B(x)$ for $y \in B(a)$. In this notation, a labels the node, while f(b) follows the branch for b to a subtree having the same wellordering type.

The natural numbers belong to a simple wellordering type. There are two kinds of node:

-those with no branches represent 0;

- those with one branch represent successor numbers.

A possible definition is

Nat = W(Bool, cond(
$$\bot$$
, \top)).

Lists are a similar wellordering type: the second kind of node contains a member of the list, while the branch points to the rest of the list. Wellordering types can also have infinite branching, as in the second number class of ordinals (Martin-Löf, 1984, p. 82). (Note: the w.f. relation defined below is not < on the second number class.)

There is a close connection between wellordering types and well-founded relations, as the terminology suggests. Every wellordering type W is w.f. under the relation \prec_W , where $w' \prec_W w$ whenever w' is an immediate subtree of w. Formally (by transfinite induction), it is easy to define \prec_W such that

$$w' \prec_{W} \sup(a, f) = \{ y \in B(a) | w' =_{W} f(y) \}.$$

Since the natural numbers can be defined as the wellordering type N, with < as the transitive closure of \prec_N , w.f. induction for < follows from that of wellordering types. I include the separate proof for < because it is a simple introduction to w.f. relations. There is an apparent circularity: the proof for transitive closure involves **Nat** elimination, the rule for induction over the natural numbers. But this is merely to argue by cases, a number is either 0 or is **succ**(n). It does not require w.f. induction for <.

13.1. INDUCTION

Assume that P(w) is a type for $w \in W(A, B)$, and assume the induction step

$$step \in \prod_{w \in W(A, B)} \left(\prod_{w' \in W(A, B)} w' \prec w \to P(w') \right) \to P(w)$$

To justify w.f. induction, it suffices to find $wf * w \in P(w)$ for $w \in W(A, B)$. By transfinite induction, wf could be λw . transrec(p, w), where

$$p(a, f, u) \in P(\sup(a, f)) \begin{bmatrix} a \in A \\ f(y) \in \mathbf{W}(A, B)[y \in B(a)] \\ u(y) \in P(f(y))[y \in B(a)] \end{bmatrix}$$

Using the induction step, p(a, f, u) could be $step * sup(a, f) * p_1$, where

$$p_1 \in \prod_{w' \in W(A, B)} w' \prec \sup(a, f) \to P(w') [a; f; u].$$

Unfolding \prec , product introduction gives $p_1 = \lambda w' ls \cdot p_2(ls)$, where

$$p_2(ls) \in P(w')[a; f; u; w' \in \mathbf{W}(A, B); ls \in \{y \in B(a) | w' = f(y)\}]$$

Using subset elimination and replacing w' by f(y), the goal becomes

$$p_2(y) \in P(f(y))[a; f; u; w' \in \mathbf{W}(A, B); y \in B(a)].$$

Appealing to the induction hypothesis, $p_2(y)$ is u(y).

Summarising,

$$wf * \sup(a, f) = step * \sup(a, f) * (\lambda w' ls . wf * f(ls)) \in P(\sup(a, f)).$$

13.2. RECURSION

The desired property is

$$wf * w = step * w * (\lambda w' ls \cdot wf * w') \in P(w).$$

By W-elimination, w must have the form $\sup(a, f)$, in

$$\begin{bmatrix} a \in A \\ f(y) \in \mathbf{W}(A, B) [y \in B(a)] \end{bmatrix}$$

wf * sup(a, f) = step * sup(a, f) * $(\lambda w' ls \cdot wf * w') \in P(\sup(a, f))$

Unfolding the left side, cancelling, and unfolding \prec , it remains to show

$$wf * f(ls) = wf * w' \in P(w') \begin{bmatrix} a; f \\ w' \in \mathbf{W}(A, B) \\ ls \in \{y \in B(a) | w' = f(y)\} \end{bmatrix}$$

By subset elimination, it remains to show

$$wf * f(y) = wf * w' \in P(w')[a; f; w'; y \in B(a); w' = f(y)$$
true].

This holds because w' equals f(y). \Box

14. A Characterisation of Well-founded Relations

Classically, a relation \prec on a set A is w.f. whenever there are no infinite descending chains $a_0 \succ a_1 \succ a_2 \cdots$. Another classical characterisation is that every non-empty subset of A contains a minimal element (Manna & Waldinger, 1986). I know of no constructive derivation of w.f. induction from either of these characterisations. However, there is a constructive characterisation:

THEOREM. A relation \prec_A on a type A is w.f. if and only if there is some wellordering type W, and rank function $wof \in A \rightarrow W$, such that \prec_A is logically equivalent to the inverse image of \prec_W .

PROOF. The *if* part is immediate, because every wellordering type is w.f., and taking an inverse image preserves this property. To show the converse requires constructing a wellordering type and rank function whose inverse image is \prec_A . Each node of the wellordering type is labelled by an element of A and has one branch for every predecessor a' of a: define

$$W \equiv \mathbf{W}_{a \in A} \left(\sum_{x \in A} x \prec_A a \right).$$

The rank function wof is defined by w.f. recursion, such that wof *a is a tree rooted in a and with branches to subtrees wof *a' for every predecessor a'. There is a branch for each pair $\langle a', ls \rangle$ where $a' \in A$ and $ls \in a' \prec_A a$, so the definition involves split:

$$s(a, ih) \equiv \sup(a, \operatorname{split}(ih))$$

 $wof \equiv \lambda(\operatorname{wfrec}(s)).$

Unfolding wof using the recursion rule gives

$$wof * a = wfrec(s, a)$$

= $s(a, (x, ls)wfrec(s, x))$
= $s(a, (x, ls)wof * x)$
= $sup(a, split((x, ls)wof * x)).$

By a trivial transfinite recursion, the function $aof \in W \to A$ maps any element $\sup(a, f)$ to a: put $aof \equiv \lambda(\operatorname{transrec}((a, f, e)a))$. Then wof is one-to-one, since aof * (wof * a) = a for all a. Also

$$wof * a' \prec_{W} wof * a = wof * a' \prec_{W} \sup(a, \operatorname{split}((x, ls)wof * x))$$
$$= \{ y \in \sum_{x \in A} x \prec_{A} a | wof * a' =_{W} \operatorname{split}((x, ls)wof * x, y) \}.$$

To show that \prec_A is logically equivalent to the inverse image under wof of \prec_W , it suffices to show

$$a' \prec_A a \leftrightarrow wof * a' \prec_W wof * a true [a \in A; a' \in A].$$

For the \rightarrow direction, it is enough to show

$$\{y \in \sum_{x \in A} x \prec_A a | wof * a' =_W \operatorname{split}((x, ls) wof * x, y)\} \operatorname{true} [ls \in a' \prec_A a]$$

which is immediate, putting $\langle a', ls \rangle$ for y.

For the \leftarrow direction, by product introduction, subset elimination, and sum elimination, it is enough to show

$$a' \prec_{A} a \text{ true} \begin{bmatrix} x \in A \\ ls \in x \prec_{A} a \\ e \in wof * a' =_{W} wof * x \end{bmatrix}.$$

Since wof is one-to-one, a' = x. \Box

The wellordering types generalise the notion of ordinal. The theorem generalises the notion of order type: each w.f. relation has a normal form, the inverse image of a wellordering type. This characterisation of w.f. relations seems less natural than the classical ones.

15. Well-founded Relations in the Literature

People have proved program termination using a variety of w.f. relations, most of which are easily constructed in this Type Theory framework. The lexicographic product of w.f. relations appears often, but sometimes in disguise. In deriving a unification algorithm, Manna & Waldinger (1981) define the "unification ordering" \prec_{un} on pairs of expressions. Let vars(x) denote the (finite) set of variables in an expression, and \prec the (w.f.) substructure relation on expressions. Manna & Waldinger define $\langle x', y' \rangle \prec_{un} \langle x, y \rangle$ to hold whenever

or
$$vars(x') \cup vars(y') \subset vars(x) \cup vars(y)$$
$$vars(x') \cup vars(y') = vars(x) \cup vars(y) \text{ and } x' \prec x$$

The proper subset relation is w.f. on finite sets: if |a| denotes the cardinality of a, then $a \subset b$ implies |a| < |b|. So \prec_{un} is also w.f.: it is a subrelation of the inverse image of a lexicographic product, mapping each $\langle x, y \rangle$ to the lexicographically ordered pair $\langle |vars(x) \cup vars(y)|, x \rangle$.

Generalising the lexicographic product from $A \times B$ to the sum $\sum_{x \in A} B(x)$ produces many more w.f. relations. The second number class is the set of all countable ordinals, and is the smallest class of ordinals containing 0 and closed under successor and countable limits (Church, 1938). These three principles underlie standard systems of ordinal notations such as Kleene's O (Rogers, 1967). In Type Theory, take \perp for 0, and $A + \top$ for successor, and $\sum_{n \in Nat} A(n)$ for limit. Then any notation for a constructive ordinal can be translated into a w.f. relation of the same order type.

A concrete application of lexicographic product for both Σ and \times is the stepped lexicographic ordering (Dershowitz & Manna, 1979, p. 474) on n-tuples of A:

$$A^{\omega} \equiv \sum_{n \in \text{Nat}} A^n \text{ where } A^0 = \top$$
$$A^{\text{succ}(n)} = A \times A^n.$$

The empty relation on the type T is trivially w.f., so the relation \prec_{A^n} on the finite power A^n is w.f. by induction on *n*. Each element of A^{ω} is an *n*-tuple, represented in the form $\langle n, \langle x_1, \ldots, \langle x_n, 0 \rangle \rangle$. Under the w.f. relation on A^{ω} , shorter tuples precede longer ones and tuples of equal length are compared lexicographically.

Now consider lexicographic exponentiation of the relation \prec_A . Recall that elements of the power type **Pow**(A) are lists $[x_1, \ldots, x_n]$ with elements in descending order $x_1 \succ_A \cdots \succ_A x_n$. The w.f. relation on power types differs from that on A^{ω} , for $[1, 0] \prec [2]$ even though [1, 0] is the longer list.

A two-argument form of exponentiation is sometimes seen (Tait, 1965). Suppose B is a type with w.f. relation \prec_B . An element of the type B^A is a list of pairs from $A \times B$, descending under \prec_A :

$$\{[\langle x_1, y_1 \rangle, \ldots, \langle x_n, y_n \rangle] | x_1 \succ_A \cdots \succ_A x_n\} \quad \begin{cases} x_1, \ldots, x_n \in A \\ y_1, \ldots, y_n \in B. \end{cases}$$

This list represents a finite function from A to B. The w.f. relation on lists is that for **Pow** $(A \times B)$, comparing each pair $\langle x_i, y_i \rangle$ under the relation for $A \times B$. Clearly, $x_1 \succ_A \cdots \succ_A x_n$ implies $\langle x_1, y_1 \rangle \succ_{A \times B} \cdots \succ_{A \times B} \langle x_n, y_n \rangle$; formalising this implication as a Type Theory function defines the w.f. relation for B^A as an inverse image of that for **Pow** $(A \times B)$. In fact, we could generalise exponentiation to the "finitary product" of the family of types B(x) for $x \in A$, as an inverse image of **Pow** $(\Sigma(A, B))$. If \prec_A has order type α and \prec_B has order type β , then the relation on B^A has order type β^{α} .

If \prec_A is a total ordering, then taking *B* as the natural numbers gives Dershowitz & Manna's (1979) ordering on finite multisets of *A*; define $\mathbf{M}(A) \equiv \mathbf{Nat}^A$. Informally, a *multiset* is like a set except that multiple occurrences of an element are significant. Suppose that $a_1 \prec_A \cdots \prec_A a_n$, where $a_i \in A$ for $1 \leq i \leq n$. Then the finite multiset containing m_i occurrences of a_i is represented in $\mathbf{M}(A)$ as $[\langle a_1, m_1 \rangle \ldots, \langle a_n, m_n \rangle]$.

The type $\mathbf{M}^*(A)$ of nested multisets over A contains finite multisets with members drawn from both A and $\mathbf{M}^*(A)$. Nesting is finite: $\mathbf{M}^*(A)$ is built up in stages using the family $\mathbf{M}^n(A)$ of multisets nested to depth n. The w.f. derivations for + and Σ give the appropriate w.f. relation for $\mathbf{M}^*(A)$. Define

$$\mathbf{M}^*(A) \equiv \sum_{n \in \operatorname{Nat}} \mathbf{M}^n(A) \quad \text{where} \quad \begin{array}{l} \mathbf{M}^0(A) = A \\ \mathbf{M}^{\operatorname{succ}(n)} = \mathbf{M}^n(A) + \mathbf{M}(\mathbf{M}^n(A)) \end{array}$$

The definition of $\mathbf{M}^*(A)$ will be complete once we have defined operations like \cup and $\{x\}$ for nested multisets, expressing each multiset as $\langle n, \mathbf{M}^n(A) \rangle$ for the smallest *n* possible.

The type $\mathbf{M}^*(\mathsf{T})$ is essentially Gentzen's (1938) notation for the ordinals up to ε_0 . While order type ε_0 is larger than necessary for most termination questions in computer science, Dershowitz & Manna give several examples where multisets allow simpler proofs. Often the only alternative ordering is the inverse image of < under a complex and subtle arithmetic function (Boyer & Moore, 1979).

As defined here, the type $\mathbf{M}(A)$ contains only those multisets whose elements are pairwise related under \prec_A . If \prec_A is not a total ordering, then some multisets are excluded. I doubt that this restriction will seriously complicate program proofs. The typical partial ordering is an inverse image of <. For example, multisets are often used with the subtree ordering on trees; a termination proof using multisets of trees is easily changed to one using multisets of heights of trees. No problems arise in the examples by Dershowitz & Manna (1979). Still, I would like to eliminate the restriction by proving, in Type Theory, that the multiset ordering is w.f. Their proof is far from constructive—it appeals to König's Infinity Lemma—but perhaps can be formalised using wellordering types.

Boyer & Moore (1979, pp. 67–71) present a particularly interesting termination question. Calling the recursive function norm(x) puts the expression x into a certain normal form. Its termination is not obvious because it sometimes calls itself with a larger expression than it was called with. Boyer & Moore justify the definition of *norm* using a

complicated measure function. The LCF system, based on domain theory, can deal with partial functions; it allows a different termination proof, using a lemma that norm(x) terminates for certain x. I have proved the termination of norm in Type Theory by defining a relation corresponding to norm's recursive calls, and deriving w.f. induction and recursion for this relation (Paulson, 1986b). The Type Theory proof bears a striking resemblance, in its outer structure, to the LCF proof; furthermore, it suggests an obviously total alternative definition of norm.

16. Questions

Type Theory seems ideal for working with w.f. recursion and induction. The rules and constructions make computational sense, having as natural a feel as can be expected from a formal notation. I am generally satisfied with this theory of w.f. relations, and look forward to using it in computer proofs. However, some questions present themselves.

16.1. COMPUTATION ON PROOF OBJECTS

The ability to represent propositions as types allows for a compact logical system, since type operators serve also as logical connectives. Its drawback is that uninteresting propositional constructions can complicate computational ones. Treating the proposition $x' \prec x$ as a type causes complications, even though the recursion rule allows **wfrec**(s, a) to be computed without computation on elements of $x' \prec x$. Recall the rule of w.f. induction:

$$\frac{x \in A}{\lfloor ih(x', ls) \in P(x') [x' \in A; ls \in x' \prec x] \rfloor}$$

$$\frac{a \in A}{s(x, ih) \in P(x)}$$
wfrec(s, a) $\in P(a)$

Completely eliminating the dependence of *ih* on *ls* would give the rule

$$\frac{\begin{bmatrix} x \in A \\ ih(x') \in P(x') [x' \in A; x' \prec x \text{ true}] \end{bmatrix}}{\frac{a \in A}{\text{ wfree}(s, a) \in P(x)}}$$

The conclusion of the recursion rule, which is now

wfrec
$$(s, a) = s(a, (x, ls)wfrec(s, x)) \in P(a),$$

would simplify to

wfrec
$$(s, a) = s(a, wfrec(s)) \in P(a)$$
.

For the characterisation of w.f. relations, the type W would become

$$W \equiv \mathbf{W}_{a \in A} \{ x \in A | x \prec_A a \},\$$

and the rank function wof would be just $\lambda(wfrec(sup))$.

To achieve all this requires deriving w.f. induction from an induction step that has the slightly stronger induction hypothesis

$$ih(x') \in P(x')[x' \in A; x' \prec x \text{ true}].$$

The proof of ih(x') may no longer use a particular element ls of $x' \prec x$, though assuming

its truth. I doubt that this can be done in general. Though the derivations for subrelations and inverse images use *ls* only for appealing to w.f. induction on another relation, most other derivations depend crucially on *ls*.

Consider decidable relations defined as $x' \prec x \equiv (f(x', x) = T)$, where f is a computable function. The rule of equality elimination prevents any dependence on an element of $x' \prec x$. Many w.f. relations are decidable: for every constructive ordinal α , there is a recursive relation corresponding to < for the ordinals below α (Rogers, 1967). But it is unpleasant to impose decidability when none of the derivations appeal to it; furthermore, the subtree relation on infinitely branching wellordering types is clearly undecidable.

Dybjer (1985) suggests a radical alternative: reason about programs in an untyped Logical Theory of propositions. Type Theory interprets propositions as types; the Logical Theory takes propositions as primitive and adopts the more conventional interpretation of types as predicates (Smith, 1984). Because there are no type constraints, the fixed-point combinator Y exists and can define recursive functions. Proving that a function has a type amounts to proving its termination. Well-founded induction is still required, but Y takes the place of well-founded recursion.

16.2. DOES INDUCTION ENTAIL RECURSION?

Each derivation of a w.f. relation consists of a derivation of w.f. induction, followed by a proof of the recrusion rule for the resulting construction. In every case I have encountered, the proof of the recursion rule closely follows the derivation of induction. It is natural to imagine that the recursion rule always follows from induction, yet this seems impossible to prove. Nor is there an obvious counter example.

Due to the new ideas involved in Type Theory, and the scarcity of published material, I have relied more than usual on discussions with other people. Particular thanks are due to Peter Aczel and Robert Constable, who visited Cambridge, answered many questions, and provided literature. Martin Hyland gave important advice about ordinals. Thanks also to Michael Fourman, Per Martin-Löf, Bengt Nordström, Kent Petersson, Dana Scott, Jan Smith, Richard Waldinger, and Glynn Winskel.
