## ABSTRACT

The inositol 1,4,5-trisphosphate ( $\text{IP}_3$ ) receptor ( $\text{IP}_3\text{R}$ ) type 2 ( $\text{IP}_3\text{R}2$ ) is an intracellular  $\text{Ca}^{2+}$ -release channel located on the endoplasmic reticulum (ER).  $\text{IP}_3\text{R}2$  is characterized by a high sensitivity to both  $\text{IP}_3$  and ATP and is biphasically regulated by  $\text{Ca}^{2+}$ . Furthermore,  $\text{IP}_3\text{R}2$  is modulated by various protein kinases. In addition to its regulation by protein kinase A,  $\text{IP}_3\text{R}2$  forms a complex with adenylate cyclase 6 and is directly regulated by cAMP. Finally, in the ER,  $\text{IP}_3\text{R}2$  is less mobile than the other  $\text{IP}_3\text{R}$  isoforms, while its functional properties appear dominant in heterotetramers. These properties make the  $\text{IP}_3\text{R}2$  a  $\text{Ca}^{2+}$  channel with exquisite properties for setting up intracellular  $\text{Ca}^{2+}$  signals with unique characteristics.  $\text{IP}_3\text{R}2$  plays a crucial role in the function of secretory cell types (e.g. pancreatic acinar cells, hepatocytes, salivary gland, eccrine sweat gland). In cardiac myocytes, the role of  $\text{IP}_3\text{R}2$  appears more complex, because, together with  $\text{IP}_3\text{R}1$ , it is needed for normal cardiogenesis, while its aberrant activity is implicated in cardiac hypertrophy and arrhythmias. Most importantly, its high sensitivity to  $\text{IP}_3$  makes  $\text{IP}_3\text{R}2$  a target for anti-apoptotic proteins (e.g. Bcl-2) in B-cell cancers. Disrupting  $\text{IP}_3\text{R}/\text{Bcl-2}$  interaction therefore leads in those cells to increased  $\text{Ca}^{2+}$  release and apoptosis. Intriguingly,  $\text{IP}_3\text{R}2$  is not only implicated in apoptosis but also in the induction of senescence, another tumour-suppressive mechanism. These results were the first to unravel the physiological and pathophysiological role of  $\text{IP}_3\text{R}2$  and we anticipate that further progress will soon be made in understanding the function of  $\text{IP}_3\text{R}2$  in various tissues and organs.

## 1. Introduction

The inositol 1,4,5-trisphosphate ( $\text{IP}_3$ ) receptors ( $\text{IP}_3\text{Rs}$ ) are ubiquitously expressed intracellular  $\text{Ca}^{2+}$ -release channels. These channels are tetrameric in structure and predominantly localized in the endoplasmic reticulum (ER).  $\text{IP}_3$ , produced by phospholipase C after cell activation by hormones, growth factors or neurotransmitters, diffuses into the cytosol, binds to and activates the  $\text{IP}_3\text{R}$ , leading to  $\text{Ca}^{2+}$  release from the ER. This  $\text{Ca}^{2+}$  release is instrumental in the formation of the

spatio-temporal  $\text{Ca}^{2+}$  signals, fundamental for the regulation of multiple cellular processes, including proliferation, differentiation, metabolism, secretion, cell fate and memory [1–3].

In all vertebrate organisms, three different genes encode  $\text{IP}_3\text{Rs}$ , leading to three main types of  $\text{IP}_3\text{Rs}$ ,  $\text{IP}_3\text{R}1$  (first fully cloned in 1989 [4]),  $\text{IP}_3\text{R}2$  (first fully cloned in 1991 [5]) and  $\text{IP}_3\text{R}3$  (first fully cloned in 1993 [6]). Each monomer is about 2700 amino acids in length and consequently has a predicted molecular mass of approximately 300 kDa. The  $\text{IP}_3\text{R}$  proteins are structurally and functionally divided into 5 distinct domains: the N-terminal coupling domain (a.k.a. suppressor domain), the  $\text{IP}_3$ -binding core, the internal coupling domain (a.k.a. the modulatory and transducing domain), the channel domain and the C-terminal coupling domain (a.k.a. the gatekeeper domain) [7]. The three  $\text{IP}_3\text{R}$  isoforms share only 60–80% overall similarity at the amino acid level, but the similarity is much higher in certain defined regions (e.g. the  $\text{IP}_3$ -binding site, the 5th and 6th transmembrane regions, putative ER-retention signals) while much lower in others, allowing for the existence of very distinct properties between the isoforms (see Section 2). Finally, a further diversity can result from alternative splicing and the formation of heterotetramers [1,8,9].

The vast majority of cell types express more than one  $\text{IP}_3\text{R}$  isoform but their relative proportion can be highly variable [10–14]. Moreover, in various cases it was shown that the relative expression levels

depended on the differentiation or developmental state of the cells or could be modulated by specific treatments (e.g. [14–21]).

The participation of the IP<sub>3</sub>Rs in establishing distinct patterns of Ca<sup>2+</sup> signals resulting in different cellular outcomes depends therefore on the complement of the various IP<sub>3</sub>R (splice) isoforms expressed, their intracellular location, the presence of regulatory factors, including associated proteins, and their phosphorylation status [1,14,22–25].

On the basis of their almost exclusive expression of a single IP<sub>3</sub>R isoform, some cell types have been used as model system for the analysis of the role of the different IP<sub>3</sub>R isoforms [8]. However, only a rather limited set of cell types expresses predominantly IP<sub>3</sub>R2 (Table 1).

Interestingly, in many cells IP<sub>3</sub>R2 is expressed at a different subcellular location than the other IP<sub>3</sub>R isoforms. For example, in bovine aortic endothelial cells, bovine adrenal glomerulosa cells and COS-7 cells [26], the HepG2 liver cell line [27] and the hippocampal cell line HT22 [28] IP<sub>3</sub>R2 displayed a predominantly nuclear localization, while in hepatocytes IP<sub>3</sub>R2 is confined to the apical pole of the cell, near the canalicular membrane [29].

The nuclear localization of IP<sub>3</sub>R2 is particularly interesting with respect to the role of Ca<sup>2+</sup> signalling in the nucleus, e.g. for gene transcription. Although the presence of IP<sub>3</sub>Rs in the inner leaflet of the nuclear envelope remains the subject of debate [30–32], there is at least strong evidence that a subset of the IP<sub>3</sub>R2 is facing the nucleoplasm in HepG2 cells [27], in SKHep1 cells [33] and in atrial myocytes [34] where they can control Ca<sup>2+</sup> release directly into the nucleus.

Information concerning the regulation of IP<sub>3</sub>R2 expression is likewise still quite limited. The 5'-flanking region of murine IP<sub>3</sub>R2 has been sequenced and contained at least 7 transcription initiation sites with an upstream promoter containing no conventional TATA box but a GC box [35]. To the best of our knowledge, only two recent studies described pathways involved in the regulation of IP<sub>3</sub>R2 expression. First, in the heart, direct binding of nuclear factor of activated T cells (NFAT) c1 to the IP<sub>3</sub>R2 promoter drives IP<sub>3</sub>R2 expression [36]. Second, in dendritic cells, IP<sub>3</sub>R2 expression is controlled by the transcription factor ETS1, which itself depends on protein kinase B (AKT/PKB) 2 [37]. Finally, although not yet understood at the mechanistic level, in the HT22 cell line, oxidative stress leads to a specific upregulation of IP<sub>3</sub>R2 [38] (see Section 5).

Splicing of IP<sub>3</sub>R2 is much less documented than that of IP<sub>3</sub>R1, but two different splice variants have been described. One appears to be muscle-specific and is limited to the N-terminal 175 amino acids of IP<sub>3</sub>R2 supplemented with 6 additional amino acids; although a regulatory role has been proposed, its function has not yet been elucidated. [39]. The second splice variant uses the same splice acceptor site and is lacking amino acids 176–208. The deletion is localized fully within the suppressor domain, which plays an important role in both the regulation of IP<sub>3</sub> binding and in the coupling of the IP<sub>3</sub>R N-terminus to the channel region [40]. As a consequence, the resulting protein is defective in both IP<sub>3</sub> binding and Ca<sup>2+</sup> release. However, its expression in cells prevents the agonist-dependent clustering of the endogenous IP<sub>3</sub>Rs, probably via heterotetramerization, and can therefore impact intracellular Ca<sup>2+</sup> signalling [41].

Finally, also at the protein level, IP<sub>3</sub>R2 levels appear to be regulated in a different manner when compared to the other isoforms. While all IP<sub>3</sub>R isoforms are downregulated under conditions of chronic stimulation [12,42,43], IP<sub>3</sub>R2 appeared the least susceptible [12].

In spite of the unique molecular properties displayed by IP<sub>3</sub>R2 (see Sections 2.1–2.5), this protein is much less investigated than IP<sub>3</sub>R1 or indeed, even IP<sub>3</sub>R3. This apparent lack of progress was probably in retrospect multifaceted. The low general abundance of IP<sub>3</sub>R2 and the lack of good model systems for its investigation partially explain the fewer studies directed specifically towards the IP<sub>3</sub>R2. Additionally, but no less importantly, it appeared that it was historically difficult to make IP<sub>3</sub>R2 expression constructs. Moreover, the quality of the antibodies raised against IP<sub>3</sub>R2 was also generally poor. Finally, a recent analysis of classically used IP<sub>3</sub>R inhibitors demonstrated that IP<sub>3</sub>R2 expressed in DT40 triple knockout (DT40 TKO) chicken B lymphocytes was the least sensitive of all the IP<sub>3</sub>R isoforms to heparin, caffeine and 2-aminoethoxydiphenyl borate [44]. This latter observation may explain why pharmacological approaches to discern IP<sub>3</sub>R2 function have been largely unsuccessful.

Notwithstanding these issues, recent work has begun to unravel the significance of IP<sub>3</sub>R2 in a number of physiological settings. The aim of this review is therefore to highlight these important functions of IP<sub>3</sub>R2 and to so stimulate further research in the field.

## 2. Specific molecular and cellular properties of IP<sub>3</sub>R2

IP<sub>3</sub>R2 has a high sequence and structural homology with the other IP<sub>3</sub>R isoforms and consequently shares a large number of properties with IP<sub>3</sub>R1 and IP<sub>3</sub>R3. In this chapter, we will therefore focus on specific properties in which the IP<sub>3</sub>R2 clearly differs from the other isoforms (Fig. 1).

### 2.1. IP<sub>3</sub> affinity

Binding of IP<sub>3</sub> to the IP<sub>3</sub>-binding core is the key step needed for the induction of IP<sub>3</sub>-induced Ca<sup>2+</sup> release. As stated above (see Section 1), the three IP<sub>3</sub>R isoforms all have a very similar structure [45]. For example, all IP<sub>3</sub>R isoforms contain their IP<sub>3</sub>-binding core towards their N-terminus, preceded by the so-called suppressor domain [46].

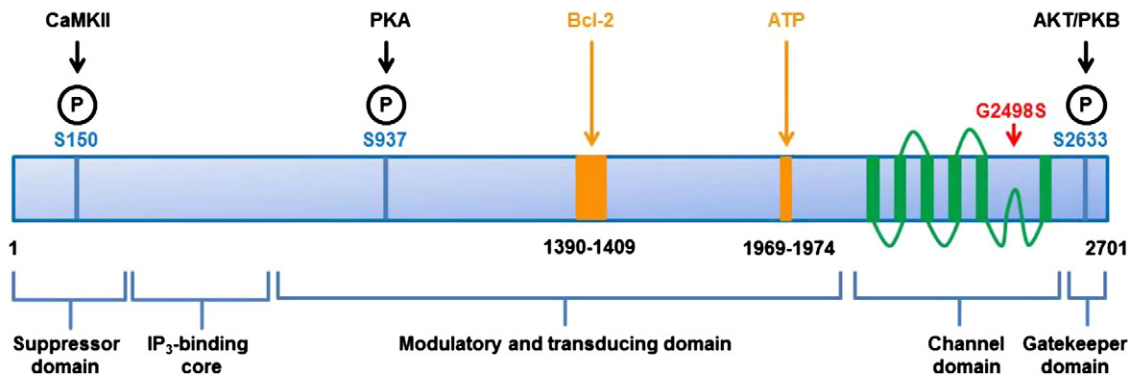

A striking property of the IP<sub>3</sub>R2 is its much higher affinity for IP<sub>3</sub> when compared with the two other IP<sub>3</sub>R isoforms. This was first observed in IP<sub>3</sub>-binding experiments, which under various conditions demonstrated a rank-order of IP<sub>3</sub> affinities IP<sub>3</sub>R2 > IP<sub>3</sub>R1 > IP<sub>3</sub>R3 [5,10,47]. Subsequent studies conclusively demonstrated that the IP<sub>3</sub>-binding cores of each of the IP<sub>3</sub>R isoforms display a similar affinity for IP<sub>3</sub> (about 2 nM), but as demonstrated by the analysis of normal and chimeric N-terminal domains of the different IP<sub>3</sub>R isoforms the presence of the suppressor domain determines the specific IP<sub>3</sub> affinity of the isoform (50, 14 and 163 nM for IP<sub>3</sub>R1, IP<sub>3</sub>R2 and IP<sub>3</sub>R3, respectively). These results underpin the importance of the suppressor domain for IP<sub>3</sub>R function [46].

The difference in IP<sub>3</sub> affinity is also reflected in functional experiments. Analysis of IP<sub>3</sub>-induced Ca<sup>2+</sup> release in DT40 TKO cells expressing a single IP<sub>3</sub>R isoform demonstrated that DT40 TKO cells heterologously expressing a single IP<sub>3</sub>R isoform could sustain Ca<sup>2+</sup> oscillations for an extended period after stimulation by an anti B-cell receptor antibody only if the expressed isoform was IP<sub>3</sub>R2 [48]. Very similar results were obtained in vascular myocytes, whereby only the cells expressing IP<sub>3</sub>R2 in addition to IP<sub>3</sub>R1 displayed a Ca<sup>2+</sup> oscillation pattern [49,50]. Comparison of native IP<sub>3</sub>R1 (from cerebellum) and IP<sub>3</sub>R2 (from heart) [51] or the comparative analysis of each of the three IP<sub>3</sub>R isoforms heterologously expressed in Sf9 insect cells [52] also confirmed the rank-order of the sensitivity of channel opening

**Fig. 1.** Linear representation of the IP<sub>3</sub>R2 based on the human sequence demonstrating the interaction sites for its major regulators. The IP<sub>3</sub>R2 is represented in blue; the 5 functional domains are indicated. In the channel domain, the 6 transmembrane helices as well as the connecting loops are depicted in green. The specific regulatory mechanisms discussed in the text are shown: identified phosphorylation sites are represented in dark blue, interaction sites for ATP and for Bcl-2 are in orange and the recently described Gly<sup>2498</sup>Ser mutation in the pore domain affecting IP<sub>3</sub>R2 function [126] is depicted in red.

towards IP<sub>3</sub> as IP<sub>3</sub>R2 > IP<sub>3</sub>R1 > IP<sub>3</sub>R3, when measured after incorporation in planar lipid bilayers.

It must however be pointed out that a number of studies found a rank-order of affinities that is different from that mentioned above [53,54]. Although this discrepancy has never been fully clarified, it can be assumed that variability in the experimental conditions (e.g. pH, [Ca<sup>2+</sup>]) as well as in the state of the IP<sub>3</sub>Rs (e.g. redox state, phosphorylation state, associated proteins, existence of heterotetramers) could explain this variability [1].

Taken together, most of the available evidence points to IP<sub>3</sub>R2 as being the most sensitive IP<sub>3</sub>R isoform. This observation raises the intriguing potential that IP<sub>3</sub>R2 can be active in the presence of basal, resting IP<sub>3</sub> levels.

## 2.2. Regulation by cytosolic Ca<sup>2+</sup>

It has long been recognized that IP<sub>3</sub>R activity can be biphasically regulated by cytosolic Ca<sup>2+</sup>, meaning that a relatively low [Ca<sup>2+</sup>] (usually less than 0.3 μM) potentiate IP<sub>3</sub>-induced Ca<sup>2+</sup> release, while higher [Ca<sup>2+</sup>] lead to an inhibition of the IP<sub>3</sub>R. Plotting IP<sub>3</sub>R activity against [Ca<sup>2+</sup>] therefore leads to a typical bell-shaped curve. The original observations were obtained in smooth muscle [55], neurons [56,57] and oocytes [58], all tissues later shown to be particularly rich in IP<sub>3</sub>R1. It was therefore a long-standing question whether this property was uniquely related to this isoform or whether IP<sub>3</sub>R2 and IP<sub>3</sub>R3 shared this property.

Although the stimulatory effect of Ca<sup>2+</sup> on IP<sub>3</sub>R2 (and IP<sub>3</sub>R3) activity has never been in doubt, the inhibitory action of a high [Ca<sup>2+</sup>] was not always clearly observed. The group of Mignery published single-channel data demonstrating that both IP<sub>3</sub>R2 endogenously expressed in heart [51] or recombinantly expressed IP<sub>3</sub>R2 [59] displayed a much broader bell-shaped dependence towards Ca<sup>2+</sup>, meaning that on the one hand the stimulatory phase starts at a much lower [Ca<sup>2+</sup>] than for IP<sub>3</sub>R1, and on the other hand that IP<sub>3</sub>R2 remains active at a [Ca<sup>2+</sup>] already fully inhibiting IP<sub>3</sub>R1. In contrast to these reports, the group of Bezprozvanny found quite similar (and narrow) [Ca<sup>2+</sup>] response curves for each of the three IP<sub>3</sub>R isoforms heterologously expressed in Sf9 insect cells and investigated in planar lipid bilayers [60].

As will be further explained below (see Section 2.3), the sensitivity of the IP<sub>3</sub>R2 towards Ca<sup>2+</sup> is not dependent on the presence of ATP, but the latter will increase the likelihood of IP<sub>3</sub>R2 being in an open state at all [Ca<sup>2+</sup>] (Fig. 2).

Taken together, these results indicate that IP<sub>3</sub>R2, similarly to the other IP<sub>3</sub>R isoforms, is regulated in a biphasic way by the cytosolic [Ca<sup>2+</sup>], though that depending on the exact state of the receptor, different sensitivities to Ca<sup>2+</sup> can be observed.

## 2.3. Regulation by ATP

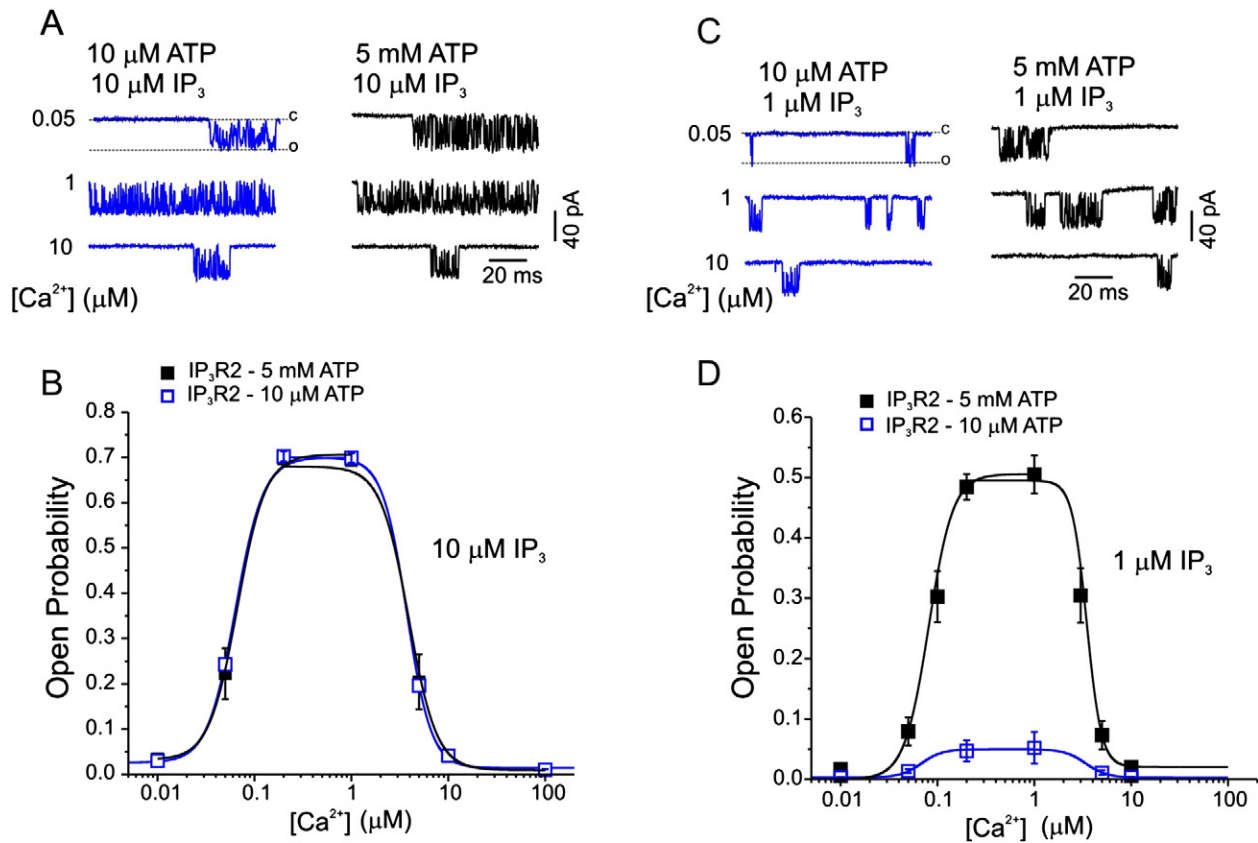

### 2.3.1. Regulation of IP<sub>3</sub>R2 is distinct from other IP<sub>3</sub>Rs

Adenine nucleotides were recognized by early studies [61–68] as important regulators of IP<sub>3</sub>-induced Ca<sup>2+</sup> release, raising the attractive possibility that channel activity could be fine-tuned to match the metabolic status of the cell. The diversity of cell types in which ATP modulates IP<sub>3</sub>-induced Ca<sup>2+</sup> release is consistent with a regulation affecting all IP<sub>3</sub>R family members. However, two initial studies reported that in contrast to IP<sub>3</sub>R1 and IP<sub>3</sub>R3, IP<sub>3</sub>R2 was not subject to modulation by adenine nucleotides [48,52]. Specifically, studying individual mammalian isoforms reconstituted in planar lipid bilayers, Bezprozvanny and colleagues reported that under conditions optimal for channel activity IP<sub>3</sub>R2 had no requirement for ATP [52]. This observation was independently confirmed studying Ca<sup>2+</sup> release from DT40 cells expressing a single IP<sub>3</sub>R isoform following genetic ablation of the other family members [48]. These reports are, in hindsight, important because they provide the first indication that ATP regulation of IP<sub>3</sub>R2 was distinct from the other family members. A subsequent detailed analysis of individual mammalian isoforms expressed in the DT40 TKO IP<sub>3</sub>R null background confirmed these earlier reports [69]. IP<sub>3</sub>R2 was indeed, in contrast to other IP<sub>3</sub>R family members, insensitive to ATP at maximal [IP<sub>3</sub>]. Nevertheless, it was demonstrated that IP<sub>3</sub>R2 activity, measured as Ca<sup>2+</sup> release, or at the single channel level in “on-nucleus” patch clamp recordings, was markedly enhanced at sub-saturating [IP<sub>3</sub>] [69]. Moreover, the sensitivity of ATP regulation of IP<sub>3</sub>-induced Ca<sup>2+</sup> release also differed between individual isoforms under identical conditions with IP<sub>3</sub>R2 being strikingly more sensitive than IP<sub>3</sub>R1 or IP<sub>3</sub>R3 (EC<sub>50</sub> 40 μM, 100 μM and 500 μM for IP<sub>3</sub>R2, IP<sub>3</sub>R1 and IP<sub>3</sub>R3 respectively) [69,70]. An issue posed by these data is the concentration range of ATP that might be expected to dynamically regulate IP<sub>3</sub>R activity. In turn, this raises the question whether modulation occurs at physiological levels of nucleotides or is only relevant under pathological conditions when ATP is depleted. Given the cellular levels of MgATP (~1 mM) and “free” ATP<sup>3-</sup> and ATP<sup>4-</sup> (10–100 μM) the answer is fundamentally dependent on the “species” of ATP that regulates IP<sub>3</sub>R channel activity. Several studies have addressed this issue and have reached disparate conclusions [67,71–73] and thus this important issue as well as the consequences of the high functional affinity of IP<sub>3</sub>R2 remains to be resolved.

### 2.3.2. Putative peptide motifs in IP<sub>3</sub>R2 responsible for ATP regulation

Modulation of IP<sub>3</sub>R activity is widely believed to occur by ATP binding to glycine-rich domains (Gly-Xaa-Gly-Xaa-Xaa-Gly), reminiscent of Walker type A repeats, present in a number of proteins that utilize ATP in a catalytic manner [74–77]. Consistent with this idea, a number of studies using either photo-affinity or fluorescent ATP probes have

**Fig. 2.** Modulation of IP<sub>3</sub>R2 single-channel activity by IP<sub>3</sub>, Ca<sup>2+</sup> and ATP. Representative single channel recordings of IP<sub>3</sub>R2 expressed in DT40 TKO cells using the “on-nucleus” configuration of the patch-clamp technique. In A, channel activity was stimulated with a maximal [IP<sub>3</sub>] (10 μM) at the indicated [Ca<sup>2+</sup>] and [ATP] (10 μM, in blue; 5 mM, in black). The pooled data in B reveal that channel activity stimulated by maximal [IP<sub>3</sub>] is modulated by [Ca<sup>2+</sup>] in a biphasic manner and that this relationship is unaffected by increasing the [ATP]. In C, channel activity was stimulated with a sub-maximal [IP<sub>3</sub>] (1 μM) at the indicated [Ca<sup>2+</sup>] and [ATP] (10 μM, in blue; 5 mM, in black). The pooled data in D demonstrate that while channel activity is also biphasically regulated by [Ca<sup>2+</sup>] at sub-maximal [IP<sub>3</sub>], the maximally achievable open probability, at each [Ca<sup>2+</sup>], is, in contrast to what happens at a maximal [IP<sub>3</sub>], markedly potentiated in the presence of a high [ATP]. Modified from [79], with permission.

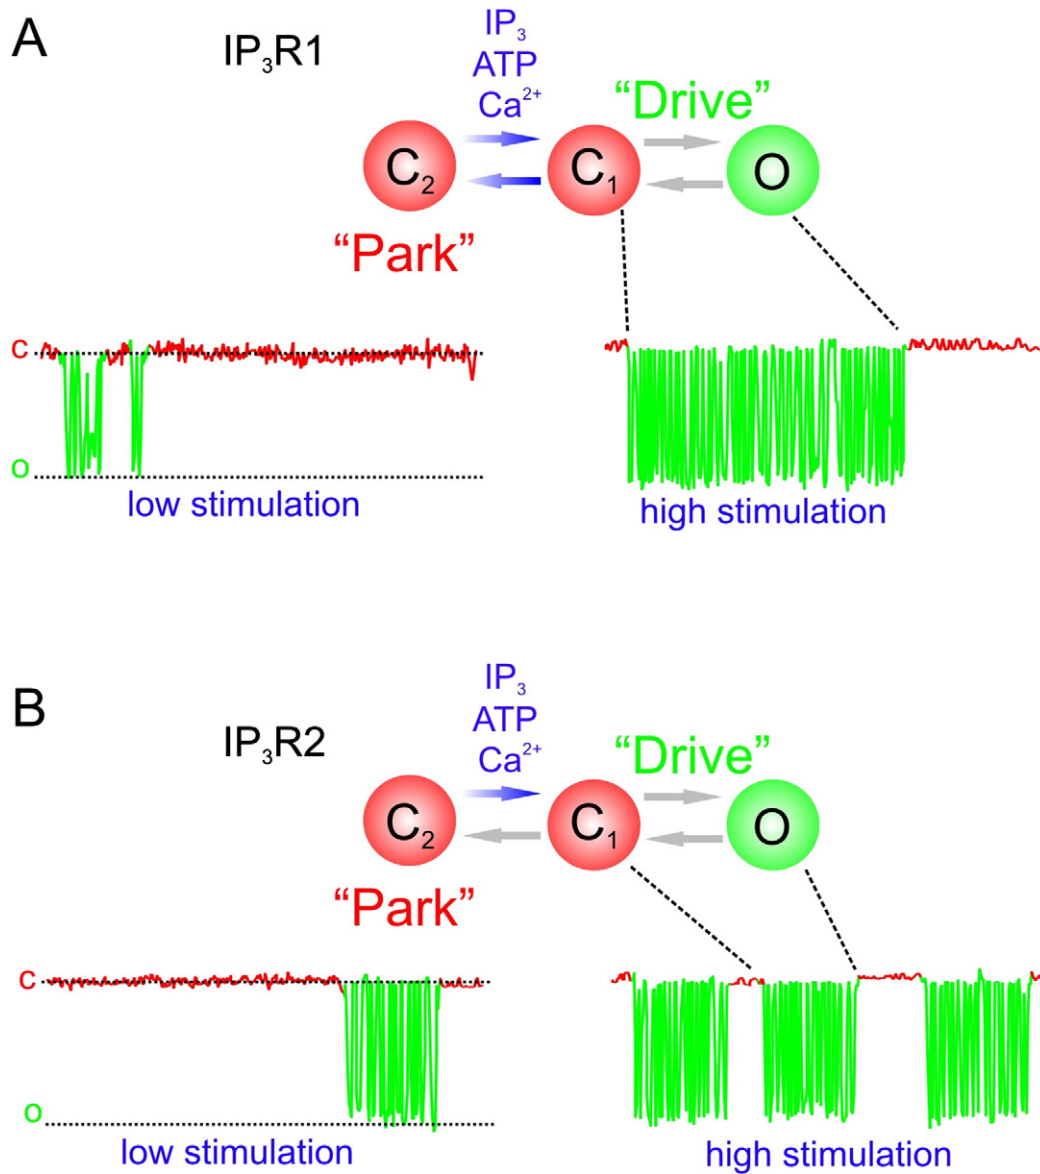

demonstrated binding to regions of IP<sub>3</sub>R or glutathione S-transferase-recombinant fragments harbouring these putative recognition sites [69,75–77]. The primary sequence of IP<sub>3</sub>R2 contains one such motif, Gly-Leu-Gly-Leu-Leu-Gly, spanning amino acids 1969–1974, which has been termed the “ATPB” site (Fig. 1). Mutagenesis of three Gly residues to Ala in the motif eliminated binding of ATP and nucleotide regulation of Ca<sup>2+</sup> release, confirming the functional importance of the ATPB site in IP<sub>3</sub>R2 [69]. Moreover, in cells expressing IP<sub>3</sub>R2 with an ATP binding-deficient ATPB motif, the frequency and amplitude of B cell receptor-activated Ca<sup>2+</sup> oscillations were markedly reduced compared with wild-type IP<sub>3</sub>R2, suggesting strongly that nucleotide regulation of Ca<sup>2+</sup> release is at least, constitutively required to shape cytosolic Ca<sup>2+</sup> signals at physiologically relevant ATP levels [69]. Unexpectedly, mutations of all known Walker A motifs in IP<sub>3</sub>R1 and IP<sub>3</sub>R3 failed to abrogate nucleotide modulation [70]. The somewhat surprising conclusion is therefore, that ATP regulation of IP<sub>3</sub>R1 and IP<sub>3</sub>R3 is independent of known ATP-binding motifs, and thus the identity of molecular sites of nucleotide regulation in these IP<sub>3</sub>R remains to be elucidated. Consequently, the ATPB site in IP<sub>3</sub>R2 is unique as the only molecular locus for regulation of IP<sub>3</sub>R family members by adenine nucleotides that is defined unequivocally.

### 2.3.3. Mechanism of ATP regulation of IP<sub>3</sub>R2

Several studies have investigated the biophysical basis for ATP regulation of IP<sub>3</sub>R channel activity. In accordance with the singular features of IP<sub>3</sub>R2 when compared with other family members, it also appears that ATP regulates IP<sub>3</sub>R2 in a similarly distinctive manner. Using “on-nucleus” patch clamp single channel recordings of both endogenous *Xenopus* IP<sub>3</sub>R1 or rat IP<sub>3</sub>R1 expressed in DT40 TKO cells, elevating ATP

levels increased the channel open probability (P<sub>o</sub>) by modulating the sensitivity of the channel to both activating and inhibitory [Ca<sup>2+</sup>], essentially left-shifting the bell-shaped [Ca<sup>2+</sup>] versus P<sub>o</sub> relationship at a given [IP<sub>3</sub>] [78,79].

In contrast, while IP<sub>3</sub>R2 displays an identical biphasic Ca<sup>2+</sup> sensitivity when exposed to saturating [IP<sub>3</sub>] (conditions in which IP<sub>3</sub>R2 is insensitive to ATP), at low [IP<sub>3</sub>], the Ca<sup>2+</sup> sensitivity of mouse IP<sub>3</sub>R2 was not altered by increasing ATP [79]. Elevating ATP simply dramatically enhanced P<sub>o</sub>, resulting in a marked increase in activity. A detailed kinetic analysis of the channel gating also indicated that IP<sub>3</sub>R2 displayed “bursting” activity with properties distinct from IP<sub>3</sub>R1 (Fig. 2). Specifically, with elevated ATP, the number of bursting episodes of relatively constant duration was increased, while IP<sub>3</sub>R1 bursts simply lengthened in time. By analogy to a gear change in a car, we have termed this the transition from ‘park’ into a ‘drive’ mode. A minimal scheme to describe the channel kinetics at sub-saturating [IP<sub>3</sub>] suggests that both channels transition between single open and closed states during drive mode with relatively constant kinetics and then are “parked” in a longer-lived closed state in the interburst intervals [79]. In the case of the IP<sub>3</sub>R1, increasing Ca<sup>2+</sup> and ATP facilitates bursting by facilitating both the transition out of the parked state and also by decreasing the likelihood it will return to this state. In contrast, [Ca<sup>2+</sup>] does not influence the time the IP<sub>3</sub>R2 spends in drive mode but simply destabilizes the parked state to initiate activity (Fig. 3). Increasing ATP then appears to markedly increase overall channel P<sub>o</sub> by prominently decreasing the amount of time in the parked state [79]. This unique property results in dissociation of the modulation of IP<sub>3</sub>R2 activity by ATP from the [Ca<sup>2+</sup>] in its immediate environment and likely allows added flexibility for tuning Ca<sup>2+</sup> signals to the needs of the cell.

**Fig. 3.** “Park and Drive” model for IP<sub>3</sub>R1 and IP<sub>3</sub>R2 gating. An increase in IP<sub>3</sub>R1 (A) and IP<sub>3</sub>R2 (B) channel activity in the presence of activating ligands is characterized by an increase in channel “bursting” without altering the intraburst kinetics. The bursts have subtype specific characteristics. A gating scheme for both channels can minimally be described by three states; one open state (in green) and two closed states (in red). Bursting activity is represented by rapid transitions between the open state (O) and a short-lived closed state (C<sub>1</sub>) representing the “Drive Mode” of the channel. In the interburst intervals, the channel is effectively “Parked” in a long-lived closed state (C<sub>2</sub>). For both IP<sub>3</sub>R1 (A) and IP<sub>3</sub>R2 (B) increasing the concentrations of activating ligands solely alters the transition from C<sub>2</sub> to C<sub>1</sub>. However, ligands both increase the likelihood that IP<sub>3</sub>R1 will leave the parked state to drive mode, as well as reciprocally decreasing the chances it will return to this state (A). In the case of IP<sub>3</sub>R2, ligands only destabilize the parked state resulting in an increase in bursting episodes of relatively constant duration (B).

#### 2.3.4. Dominance of IP<sub>3</sub>R2 ATP regulatory characteristics

An important question exists as to how the distinct features of individual IP<sub>3</sub>R subtypes are reflected in the overall characteristics of Ca<sup>2+</sup> release from heterotetrameric channels. Specifically, are the properties simply a blended integration of the individual subtypes or can a particular subtype dominate the overall characteristics? Studies investigating ATP regulation of Ca<sup>2+</sup> release in cells expressing multiple IP<sub>3</sub>R isoforms indicate that the latter possibility occurs, specifically when IP<sub>3</sub>R2 is expressed. For example, the characteristics of ATP regulation of IP<sub>3</sub>R2 (albeit the lack of regulation at saturating [IP<sub>3</sub>]) were observed in DT40 cells engineered to express only IP<sub>3</sub>R2, or in cells expressing both IP<sub>3</sub>R2 and IP<sub>3</sub>R1 or IP<sub>3</sub>R3 [48]. Similarly, in salivary and pancreatic acinar cells [80,81], which natively express IP<sub>3</sub>R2 and IP<sub>3</sub>R3 to approximately equal extents, the features of ATP regulation precisely match those documented for IP<sub>3</sub>R2 stably expressed in

isolation in either DT40 TKO [69] or in AR42J pancreatoma [80] cells (i.e. absence of regulation at saturating [IP<sub>3</sub>] and EC<sub>50</sub> for ATP ~40 μM). Notably, similar experiments in pancreatic and parotid acinar cells prepared from IP<sub>3</sub>R2 null animals revealed identical properties to IP<sub>3</sub>R3 (i.e. regulation at all [IP<sub>3</sub>] and EC<sub>50</sub> for ATP ~500 μM) [80,81]. Conversely, “rescue” experiments ectopically expressing IP<sub>3</sub>R2 in RINm5F insulinoma cells which predominately express IP<sub>3</sub>R3, converted IP<sub>3</sub>R3 characteristics to IP<sub>3</sub>R2 [80]. While these data clearly indicate the dominant influence of IP<sub>3</sub>R2 expression and are consistent with this occurring as a function of heterotetramer formation, these data could also formally be explained by an *intermolecular* interaction between clusters of homotetrameric IP<sub>3</sub>R. This issue has recently been tackled by generating tetrameric IP<sub>3</sub>R from concatenated IP<sub>3</sub>R dimers connected by short flexible linkers [82]. Expression of dimers results in the assembly of tetramers where the subunit composition can be unequivocally

defined. Expression of dimers of IP<sub>3</sub>R1 or IP<sub>3</sub>R2 exhibited the distinctive properties of ATP regulation typical of channels assembled from their respective monomeric parent subtype. Remarkably when heterodimers of IP<sub>3</sub>R1 and IP<sub>3</sub>R2 were expressed, resulting in assembly of channels consisting of equal numbers of IP<sub>3</sub>R1 and IP<sub>3</sub>R2 subunits, ATP regulation was indistinguishable from IP<sub>3</sub>R2, thus recapitulating the dominant effects seen in cells expressing native receptors [82]. These data indicate that IP<sub>3</sub>R2 in the context of a heterotetrameric channel exerts a dominant influence. Further work is needed to establish the number of monomers of IP<sub>3</sub>R2 necessary to exert this influence and whether IP<sub>3</sub>R2 similarly is the principle monomer that dictates the overall channel properties when subjected to other forms of regulation.

#### 2.4. Regulation by phosphorylation

Like for many other ion channels, phosphorylation/dephosphorylation reactions provide a versatile, reversible form of acute regulation of IP<sub>3</sub>R activity. IP<sub>3</sub>Rs have been shown to be biochemical substrates for numerous families of serine/threonine and tyrosine directed kinases. In a more limited number of cases, a comprehensive documentation of the phosphorylation event, including location of the substrate motif and the subsequent functional consequences have been detailed. These studies have largely focused on IP<sub>3</sub>R1 as a template. With some notable exceptions, for example the AKT/PKB site conserved in the C-termini of each IP<sub>3</sub>R [83,84], the amino acid motifs subject to phosphorylation events are not generally preserved between IP<sub>3</sub>R subtypes (Fig. 1). Therefore, this form of regulation has the capacity to provide modulation of activity in an IP<sub>3</sub>R sub-type specific manner. Below we highlight reports that have specifically focused on regulation of IP<sub>3</sub>R2 activity. The interested reader is directed to Vanderheyden et al. [23] and Betzenhauser and Yule [85] for detailed discussion of IP<sub>3</sub>R phosphorylation and its functional consequences.

##### 2.4.1. Regulation of IP<sub>3</sub>R2 by protein kinase A (PKA)

Historically, perhaps the most exhaustive investigation of IP<sub>3</sub>R modulation relates to PKA phosphorylation of IP<sub>3</sub>R1. Indeed, IP<sub>3</sub>R1 was identified as a major brain phosphorylated substrate even prior to the protein being appreciated as the receptor for IP<sub>3</sub> [86]. Subsequent studies demonstrated that IP<sub>3</sub>R1 is phosphorylated at serine residues within two canonical consensus motifs (Bas-Bas-Xaa-Ser/Thr, where Bas = a basic residue) [87,88] and phosphorylation is associated with markedly enhanced Ca<sup>2+</sup> release [89,90]. To complete the strong case for IP<sub>3</sub>R1 being a functionally important PKA substrate, mutation of Ser<sup>1589</sup> and Ser<sup>1755</sup> to non-phosphorylatable alanine residues completely abrogates phosphate incorporation and the functional effects of PKA activation [90–92]. However, while PKA activation in cells that predominately express IP<sub>3</sub>R2 such as hepatocytes, parotid acinar cells and AR42J similarly results in enhanced Ca<sup>2+</sup> release [93–95], the PKA substrate motifs present in IP<sub>3</sub>R1 are not conserved in IP<sub>3</sub>R2 [5]. In addition, while PKA activation results in IP<sub>3</sub>R2 phosphorylation, phosphate incorporation is non-stoichiometric and indeed much reduced in comparison to IP<sub>3</sub>R1 [96]. Nevertheless, IP<sub>3</sub>R2 contains approximately 30 serine or threonine residues, which constitute minimal PKA consensus motifs consisting of basic residues preceding the phosphorylated amino acid at the -2 and -3 positions (Bas-Bas-Xaa-Ser/Thr). Using an approach based on expressing consecutive domains of IP<sub>3</sub>R2 with N-terminal epitope tags, it was shown that PKA could only specifically phosphorylate *in vitro* a peptide fragment consisting of amino acids 920–1583 [97]. Mutation of Ser<sup>937</sup> to alanine (Ser<sup>937</sup>Ala) abrogated all phosphorylation of the fragment, pinpointing this residue as the PKA target site (Fig. 1). Subsequently, it was shown that an antibody raised against phospho-Ser<sup>937</sup> recognized IP<sub>3</sub>R2 after forskolin treatment in cells expressing IP<sub>3</sub>R2 but not cells expressing a mutant full-length receptor harbouring a Ser<sup>937</sup>Ala mutation [97]. Notably, Ser<sup>937</sup> was independently identified as a phosphorylated residue in a proteomic screen of hepatocytes [98]. Importantly, PKA activation markedly potentiated IP<sub>3</sub>-induced Ca<sup>2+</sup>

release in DT40 TKO cells expressing IP<sub>3</sub>R2 but not Ser<sup>937</sup>Ala IP<sub>3</sub>R2 thus establishing this motif as likely solely responsible for the PKA-mediated phospho-regulation of IP<sub>3</sub>R2 [97]. The Ca<sup>2+</sup> signalling machinery is a rich source of substrates responsible for cross-talk between cAMP and Ca<sup>2+</sup> signalling which ensure fine-tuning of the Ca<sup>2+</sup> signal and appropriate activation of effectors [99]. PKA phosphorylation of IP<sub>3</sub>R2 likely is an important site of this interaction in cells such as astrocytes, cardiac myocytes, hepatocytes and acinar cells that prominently express this family member.

##### 2.4.2. Regulation of IP<sub>3</sub>R2 by Ca<sup>2+</sup>/calmodulin-dependent protein kinase II (CaMKII)

CaMKII are a family of serine/threonine kinases assembled as either homo- or heteromultimers derived from the products of four closely related genes [100]. As a Ca<sup>2+</sup>/calmodulin-regulated enzyme, this kinase is an important primary effector of IP<sub>3</sub>R-induced Ca<sup>2+</sup> release and accordingly plays prominent roles in regulating various signal transduction pathways including the translocation of transcription factors and activity of ion channels [101,102]. Notably, IP<sub>3</sub>Rs are substrates for the kinase, which provides a regulatory loop following Ca<sup>2+</sup> release. Early work suggested that IP<sub>3</sub>R1 was a substrate for CaMKII *in vitro* and that the sites were distinct from those phosphorylated by PKA [103], however the functional consequences were poorly defined. Subsequently, studies based largely on pharmacology, concluded that Ca<sup>2+</sup> release from *Xenopus* oocytes and HeLa cells was attenuated following CaMKII activation [104,105]. More recently, a thorough characterization of the molecular sites and functional consequences of the CaMKII-mediated phospho-regulation of IP<sub>3</sub>R2 has been reported. Using a similar approach to that used to identify PKA sites, the ability of CaMKII to phosphorylate IP<sub>3</sub>R2 fragments *in vitro* was assessed. It was initially demonstrated that a candidate residue was present within a fragment encompassing the initial 1078 amino acids [106] and further refinement narrowed the potential phospho-acceptor residue to within residues 134–338 [107]. Subsequent mutagenesis of potential serines/threonine residues in CaMKII consensus motifs (Ser/Thr-Xaa-Asp) within this region [107] identified Ser<sup>150</sup> as phosphorylated by CaMKII (Fig. 1). This site is conserved in mammalian IP<sub>3</sub>R family members and ryanodine receptor (RyR) 2, suggesting a common mode of regulation in these channels. When incorporated in bilayers, CaMKII phosphorylation reduced the P<sub>o</sub> of IP<sub>3</sub>R2 and this effect was reversed by the CaMKII inhibitor KN62. Importantly, the reduced channel activity was absent in Ser<sup>150</sup>Ala IP<sub>3</sub>R2, indicating that the site was functionally relevant [107]. Notably, CaMKII colocalizes and interacts with IP<sub>3</sub>R2 in the nuclear envelope of cardiac myocytes [106,108]. This interaction has been proposed to be functionally important for cardiac remodelling during hypertrophy [109] (see Section 4).

##### 2.4.3. Regulation of IP<sub>3</sub>R2 by protein kinase C (PKC)

Cerebellar IP<sub>3</sub>R was also initially identified as a substrate for PKC with phosphorylation sites independent of those sites modified by PKA [103]. Interestingly, however, it was demonstrated that phosphorylation by PKC was enhanced by prior PKA phosphorylation indicating a potential additional layer of cross-talk between these prominent cellular signalling systems [110]. Similarly to CaMKII, because at least conventional PKC family members are regulated by an elevation in Ca<sup>2+</sup>, PKC phosphorylation provides a potential feedback loop to regulate IP<sub>3</sub>R activity. To date however, the functional effects of PKC phosphorylation and the sites of phosphorylation are relatively poorly defined. Unfortunately, despite the general appreciation of the amino acid motifs that constitutes a PKC consensus sequence and the presence of multiple such templates in IP<sub>3</sub>R, none have been experimentally defined. Furthermore, while PKC activation results in enhanced Ca<sup>2+</sup> release from liver nuclei, presumably reflecting IP<sub>3</sub>R1 and IP<sub>3</sub>R2 activity [111], Ca<sup>2+</sup> release is inhibited in AR42J cells, which predominately express IP<sub>3</sub>R2 [112]. These disparate findings may reflect subtype-specific regulation of IP<sub>3</sub>R given that the PKC consensus motif numbers and location are

different in each family member [9]. However an additional consideration is that numerous proteins in the signalling pathway from plasma membrane receptor occupation to the generation of  $\text{Ca}^{2+}$  signals are substrates for PKC and thus caution must be taken in interpreting data generated from indirect measurements of  $\text{IP}_3\text{R}$  activity. Our own experience is that  $\text{IP}_3\text{R}2$  single channel activity recorded in either DT40 cell nuclei or in DT40 plasma membranes was unaffected by phorbol ester treatment or recombinant PKC exposure (Wagner, Chandrasekhar and Yule; unpublished observations). These data might indicate that  $\text{IP}_3\text{R}$  is not a direct substrate for PKC. Yet, we cannot formally exclude the possibility that a scaffolding or anchoring protein necessary for activity is absent from the DT40 system. Hence, further work is required to characterize the impact of PKC on  $\text{IP}_3\text{R}$  activity in general and on  $\text{IP}_3\text{R}2$  in particular.

### 2.5. Other characteristics of $\text{IP}_3\text{R}2$

All the characteristics discussed above (see Sections 2.1–2.4) have been the subject of extensive investigations. There are however, a few less studied properties, which nevertheless might be very interesting for understanding the cellular function of  $\text{IP}_3\text{R}2$ .

#### 2.5.1. Regulation of $\text{IP}_3\text{R}2$ by cAMP

Similarly to the other  $\text{IP}_3\text{R}$  isoforms, many accessory proteins interact with, and modulate  $\text{IP}_3\text{R}2$  function. These proteins include regulatory and structural proteins, many of which were also reported to interact with  $\text{IP}_3\text{R}1$  and/or  $\text{IP}_3\text{R}3$  [1,2,14].

An interesting exception is the interaction described between  $\text{IP}_3\text{R}2$  and type 6 adenylate cyclase (AC6) [113]. In HEK 293 cells stably transfected with the type I parathyroid hormone receptor, a complex is formed between  $\text{IP}_3\text{R}2$ , AC6 and  $\text{G}\alpha\text{s}$  [113,114]. This close association facilitates an exquisite regulation of  $\text{IP}_3\text{R}2$  by cAMP, and in addition,  $\text{Ca}^{2+}$  released through  $\text{IP}_3\text{R}2$  may control AC6 in a negative feedback loop. Importantly, the regulation by cAMP does not require the canonical ATP-binding site or the activity of PKA. Moreover, although all  $\text{IP}_3\text{R}$  isoforms are potentially sensitive to cAMP, only  $\text{IP}_3\text{R}2$  has been unequivocally linked to a cAMP-producing enzyme (AC6) [114]. This mechanism can be of great general importance, since it provides a novel example of cross-talk between the cAMP- and the  $\text{Ca}^{2+}$ -dependent pathways.

#### 2.5.2. Clustering and mobility of $\text{IP}_3\text{R}2$

All  $\text{IP}_3\text{R}$  isoforms, including  $\text{IP}_3\text{R}2$  [115] are known to cluster in an agonist-dependent way [116] but a punctate distribution of  $\text{IP}_3\text{R}2$  has also been observed for native  $\text{IP}_3\text{R}2$  [117] and heterologously expressed  $\text{IP}_3\text{R}2$  [41] in resting cells. This property can be correlated to the higher affinity of  $\text{IP}_3\text{R}2$  for  $\text{IP}_3$  (see Section 2.1), which may allow the clustering to occur at basal, resting  $[\text{IP}_3]$ . Interestingly, also other differences in behaviour were found between the different  $\text{IP}_3\text{R}$  isoforms. A recent study performed in COS-7 cells confirmed that heterologously expressed  $\text{IP}_3\text{R}2$  showed a punctate distribution, in contrast to  $\text{IP}_3\text{R}1$  and  $\text{IP}_3\text{R}3$  that were uniformly distributed [118]. Moreover,  $\text{IP}_3\text{R}2$  appeared much less mobile than either the other  $\text{IP}_3\text{R}$  isoforms or than other proteins involved in intracellular  $\text{Ca}^{2+}$  handling, such as RyR1 or sarco/endoplasmic reticulum  $\text{Ca}^{2+}$  ATPase (SERCA) 1. In addition, its mobility depended on its intracellular localization with the  $\text{IP}_3\text{R}2$  located in the perinuclear region having the lowest mobility. As the  $\text{IP}_3\text{R}2$  has the highest sensitivity to  $\text{IP}_3$  (see Section 2.1), its lesser mobility may determine the initiation sites for intracellular  $\text{Ca}^{2+}$  signals.

## 3. The function of $\text{IP}_3\text{R}2$ in secretory cells

$\text{IP}_3\text{R}2$  exhibits prominent expression in classical secretory cells (Table 1), including exocrine cells of the pancreas [119–121], salivary glands [81,120–123], lacrimal gland [124], olfactory glands [125], liver [29], eccrine sweat glands [126] and the secretory epithelia of the biliary

tree [127] and the intestine [18] and the goblet cells of the small intestine [128]. A common feature of these epithelial cells is that they are morphologically and functionally polarized to secrete fluid and protein across their apical pole into a lumen forming a duct. Notably, the  $\text{Ca}^{2+}$  signal is centrally important to the primary secretory function of these cells by virtue of directly activating ion channels and the exocytotic machinery necessary for vectorial fluid and protein secretion [129,130]. In exocrine glands,  $\text{IP}_3\text{R}2$  and  $\text{IP}_3\text{R}3$  are expressed in approximately equal numbers [12] and both family members are co-localized to a region immediately below the apical plasma membrane [119,120]. This region has been termed “the trigger zone” because  $\text{Ca}^{2+}$  signals are invariably initiated in this region prior to the signal spreading as a  $\text{Ca}^{2+}$  wave towards the basal aspects of the cell [131–133]. There appears to be substantial functional redundancy between  $\text{IP}_3\text{R}2$  and  $\text{IP}_3\text{R}3$  in exocrine cells as mice *null* for either  $\text{IP}_3\text{R}$  in isolation have no obvious phenotype. However, compound knockouts of  $\text{IP}_3\text{R}2$  and  $\text{IP}_3\text{R}3$  have severe exocrine deficiency manifested as dry mouth [121], dry eye [124], pancreatic insufficiency [121] and attenuated mucus secretion [125]. As such, double knockouts are born normally but demise soon after weaning [121]. Indeed a detailed analysis of these mice have shown that  $\text{Ca}^{2+}$  signals in pancreatic, salivary, lacrimal and mucus glands are essentially unaltered in  $\text{IP}_3\text{R}3$  *null* mice [121,124,125] and only reduced to a modest degree at low  $[\text{IP}_3]$  in  $\text{IP}_3\text{R}2$  *null* mice [80,81,121,124,125]. These data suggest that  $\text{IP}_3\text{R}2$  is not generally essential for overall exocrine function.

A possible exception to this idea has been highlighted by a recent study, which investigated the cause of a severe congenital sweating defect in a Pakistani family [126].  $\text{Ca}^{2+}$  signalling is known to be important for sweat secretion and both  $\text{IP}_3\text{R}2$  and  $\text{IP}_3\text{R}3$  are expressed in the secretory cells of the sweat gland. A screen based on identifying regions of autozygosity in the genome of afflicted individuals revealed a mutation (Gly<sup>2498</sup>Ser) targeting an amino acid predicted to be critical to the function of the selectivity filter in the pore region of  $\text{IP}_3\text{R}2$ . This mutation rendered the channel completely inactive when expressed in DT40 TKO cells, thus potentially explaining the defect observed in the patients. Consistent with this idea, subsequent studies showed that mice lacking  $\text{IP}_3\text{R}2$  exhibited a decreased ability to sweat although the effect was more modest than observed in humans. The differences in severity between the phenotype observed between mouse and human may reflect the relative levels of these subtypes in mouse versus human. Alternatively, the relatively mild phenotype in the mouse might be related solely to the knockout of  $\text{IP}_3\text{R}2$ , reflecting some degree of compensation by the residual  $\text{IP}_3\text{R}3$ . In this scenario the more severe effect in human could be due to the combined effect of ablation of  $\text{IP}_3\text{R}2$  pore function and a possible dominant negative effect of the mutant  $\text{IP}_3\text{R}2$  when incorporated into heterotetramers containing  $\text{IP}_3\text{R}3$ .

The primary secretory function of hepatocytes is the secretion of bile and changes in intracellular  $\text{Ca}^{2+}$  play important regulatory roles in this process. Hepatocytes express predominantly  $\text{IP}_3\text{R}2$  (Table 1) with smaller amounts of  $\text{IP}_3\text{R}1$  and virtually no  $\text{IP}_3\text{R}3$ . However, in contrast to exocrine acinar cells, each isoform exhibits a distinct sub-cellular localization and therefore the isoforms appear not to have redundant functions.  $\text{IP}_3\text{R}2$  is enriched at the canalicular membrane, whereas  $\text{IP}_3\text{R}1$  has a more uniform distribution throughout structures in the cytosol [29]. Consistent with the sensitivity of  $\text{IP}_3\text{R}2$ , agonist-induced  $\text{Ca}^{2+}$  signalling is initiated through  $\text{IP}_3\text{R}2$  localized to the canalicular membrane [29,134,135] and  $\text{Ca}^{2+}$  release through this isoform is necessary for trafficking of the bile salt export pump to the canalicular membrane [134].

## 4. The function of $\text{IP}_3\text{R}2$ in the heart

As indicated (Table 1), cardiomyocytes are one of the cell types in which  $\text{IP}_3\text{R}2$  are highly expressed. Both atria and ventricles express  $\text{IP}_3\text{R}2$  [136] and consequently  $\text{IP}_3\text{R}2$  channels have been implicated in both physiological and pathophysiological signalling in the heart.

At the physiological level, Mikoshiba and co-workers showed that IP<sub>3</sub>R2 channels, together with IP<sub>3</sub>R1 channels, are critical for normal cardiogenesis [137]. Consistent with this, IP<sub>3</sub>R2 and IP<sub>3</sub>R1 are co-expressed in different parts of the embryonic heart, including atria, ventricle and atrioventricular canal, and in different cell types, including endothelial cells and cardiomyocytes, although timing differences in the appearance of IP<sub>3</sub>R2 versus IP<sub>3</sub>R1 exist. IP<sub>3</sub>R1/IP<sub>3</sub>R2 double knockout mice die *in utero* at embryonic stage E11.5 with major heart defects at the level of the ventricles (thin myocardial wall and poor trabeculation) and the atrioventricular canal (reduced number of cells). These defects were associated with a decrease in endocardial and myocardial cell proliferation. Furthermore, mesenchymal cells were lacking at the level of the developing atrioventricular canal. The authors hypothesized that this phenotype was due to the absence of IP<sub>3</sub>R-mediated Ca<sup>2+</sup> signalling, downstream of the activation of the Ca<sup>2+</sup>/calmodulin-dependent phosphatase calcineurin and of the translocation of NFATc to the nucleus. Indeed, in an *ex vivo* epithelial-mesenchymal transition (EMT) assay, the defect in EMT in atrioventricular explants derived from IP<sub>3</sub>R1/IP<sub>3</sub>R2 double knockout mice could be restored by transducing constitutively active calcineurin. Moreover, the phenotype of these mice resembled well the phenotypes of mice knockouts for calcineurin B [138] or for NFATc3/NFATc4 [139]. Interestingly, the defect in endocardial cells could also be observed in developing zebrafish exposed to calcineurin inhibitors, such as FK506 or cyclosporine A. Hence, from this study, it is clear that IP<sub>3</sub>R1 or IP<sub>3</sub>R2 channels are needed for activating calcineurin/NFATc signalling and endocardial cell proliferation in vertebrates. It is important to note that the presence of either IP<sub>3</sub>R1 or IP<sub>3</sub>R2 is sufficient to drive normal cardiac development, indicating redundant functions for these channels in this process. In addition to the cardiac crescent, or first heart field, giving rise to a linear beating tube, there is a second source of myocardial cells, which is termed the second heart field. However, with respect to the latter, it appears that there is a redundant role for IP<sub>3</sub>R1 and IP<sub>3</sub>R3 [140]. IP<sub>3</sub>R1/IP<sub>3</sub>R3 double knockout mice are characterized by hypoplasia of the outflow tract and the primitive right ventricle at E8.5–9.5, probably due to a defective Mef2c-Smyd1 transcriptional pathway.

At the functional level, IP<sub>3</sub>Rs were first shown to impact contractility and arrhythmias. Atrial myocytes express much higher levels of IP<sub>3</sub>R2 than ventricular myocytes [136]. They are activated in response to elevated extracellular agonist concentrations, e.g. after ischaemia or during disease. Endothelin-1-induced IP<sub>3</sub>R activation promotes the inotropy and the occurrence of arrhythmic events in atrial myocytes [141,142]. While in basal conditions, the cardiac function of IP<sub>3</sub>R2 knockout mice was similar to one of wild-type mice, the positive inotropic effect and the arrhythmic events induced by endothelin-1 were absent in IP<sub>3</sub>R2 knockout mice [143]. Hence, the presence of IP<sub>3</sub>R2 appears to be not essential for the normal functioning of the rodent heart, which is in line with the normal phenotype of the IP<sub>3</sub>R2 knockout mice generated by Chen and co-workers [143] and by Mikoshiba and co-workers [121].

In the ventricle, far fewer IP<sub>3</sub>Rs are present but may still contribute to Ca<sup>2+</sup> regulation under baseline conditions [144–147]. Moreover, a study by Roderick and co-workers revealed that increased IP<sub>3</sub>R2-mediated Ca<sup>2+</sup> signalling, in response to enhanced IP<sub>3</sub> signalling, is responsible for inducing hypertrophic pathways after prolonged endothelin-1 exposure of neonatal or adult rat ventricular cardiomyocytes [148]. Endothelin-1 triggered the expression of atrial natriuretic factor (ANF), a marker for hypertrophy. Endothelin-1-induced hypertrophy was independent of excitation-contraction coupling, but required IP<sub>3</sub> signalling and downstream IP<sub>3</sub>R-mediated Ca<sup>2+</sup> release. The latter occurred in the perinuclear region, but not in the cytosol, while Ca<sup>2+</sup> transients linked to excitation-contraction coupling occurred throughout the cardiomyocyte. Specifically buffering nuclear Ca<sup>2+</sup> by nuclear-targeted calbindin prevented endothelin-1-induced ANF expression. The nuclear Ca<sup>2+</sup> signal was mediated by IP<sub>3</sub>R2 channels, which were enriched in the

perinuclear region and led to the activation of calcineurin and downstream NFATc1, which accumulated in the nucleus.

The IP<sub>3</sub>R/calcineurin/NFATc1 hyperactivity also seems to be operative in response to prolonged  $\beta$ -adrenergic signalling, which occurs during workload-induced cardiac hypertrophy via enhanced excitation-contraction coupling. Interestingly, this model led to increased endothelin-1 signalling. This involved the release of endothelin-1 and autocrine/paracrine-mediated hyperactivation of its receptor (ET<sub>A</sub>R), thereby triggering downstream IP<sub>3</sub> signalling and Ca<sup>2+</sup>-dependent calcineurin activation. In hypertrophic cardiomyocytes (e.g. derived from spontaneous hypertrophic rats or from aortic-banded mice), IP<sub>3</sub>R2 not only played a role in the nucleus, where its hyperactivation via increased IP<sub>3</sub> signalling downstream of ET<sub>A</sub>R led to calcineurin/NFATc1 activation and ANF expression, but also became upregulated in the junctional sarcoplasmic reticulum [146]. Here, localization of IP<sub>3</sub>R2 coincides with RyR2 channels, thereby augmenting Ca<sup>2+</sup> transients associated with excitation-contraction coupling or endothelin-1 exposure. As a consequence, the IP<sub>3</sub>R2-mediated Ca<sup>2+</sup> rise during diastole may activate or sensitize RyR2 channels, resulting in spontaneous extra-systolic Ca<sup>2+</sup>-release events and the occurrence of arrhythmias [147]. This increased “extra-nuclear” expression of IP<sub>3</sub>R2 was also found in human heart samples derived from patients with heart failure after ischemic dilated cardiomyopathy [146].

The upregulation of IP<sub>3</sub>R2 channels during cardiac hypertrophy was mediated via a dynamic and Ca<sup>2+</sup>-dependent regulation of miRNA-133a [149]. In normal physiological conditions, miRNA-133a expression is highly expressed in cardiomyocytes, thereby targeting the 3' untranslated region of the IP<sub>3</sub>R2 mRNA. As a consequence miRNA-133a reduces the basal expression of IP<sub>3</sub>R2 and thereby avoids hypertrophy or arrhythmias resulting from excessive Ca<sup>2+</sup> signalling. Interestingly, limiting the expression of miRNA-133a using an antagomir led to hypertrophic signalling (evident from the increased ANF expression), which was dependent on IP<sub>3</sub>-induced Ca<sup>2+</sup> release, since degrading IP<sub>3</sub> using IP<sub>3</sub> 5-phosphatase limited the increase of ANF by miR-133a antagomir.

The role of miR-133a in controlling IP<sub>3</sub>R2 expression and the initiation of hypertrophic markers was found both *ex vivo* and *in vivo*. In isolated, hypertrophic cardiomyocytes from spontaneous hypertensive rats, IP<sub>3</sub>R2 levels were elevated, while miRNA-133a was downregulated [149]. Overexpression of miRNA-133a in these hypertrophic cardiomyocytes reduced ANF expression to levels similar as control cardiomyocytes. In addition, *in vivo* application of miRNA-133a antagomir caused IP<sub>3</sub>R2 upregulation and hypertrophic signalling. Interestingly, increased IP<sub>3</sub>-induced Ca<sup>2+</sup> release was also involved in the decreased miRNA-133a expression in hypertrophic models. Indeed, lowering IP<sub>3</sub> signalling by IP<sub>3</sub> 5-phosphatase transduction blunted the endothelin-1-induced decrease in miRNA-133a and the concomitant increase in IP<sub>3</sub>R2 protein levels. Collectively, these findings indicate that during pathophysiological conditions associated with increased endothelin-1, increased IP<sub>3</sub> signalling can lead to downregulation of miRNA-133a. The latter will lead to upregulation of IP<sub>3</sub>R2 protein levels, thereby further driving the downregulation of miRNA-133a by boosting IP<sub>3</sub>-induced IP<sub>3</sub>R2-mediated Ca<sup>2+</sup> signalling. This perpetual feedback cycle will establish a new signalling network that favours the expression of hypertrophic genes like ANF (via hyperactivation of calcineurin/NFATc1) and the occurrence of arrhythmic events.

The mechanism by which IP<sub>3</sub>-induced Ca<sup>2+</sup> release controls miRNA-133a expression seems to involve transcription factors like the serum response factor (SRF), which is negatively regulated by the homeodomain-only protein. SRF induces miRNA-133a expression and subsequent IP<sub>3</sub>R2 downregulation. However, during hypertrophy, IP<sub>3</sub>-induced Ca<sup>2+</sup> release may increase homeodomain-only protein expression, thereby recruiting class I histone deacetylase (HDAC) and limiting transcriptional activity of SRF.

The importance of IP<sub>3</sub> signalling and IP<sub>3</sub>R2 has also been elegantly addressed by Molkenin and co-workers by the generation of transgenic mice overexpressing an IP<sub>3</sub> sponge, which represents a mutated, high-

affinity form of the IP<sub>3</sub>-binding core (to blunt endogenous IP<sub>3</sub>-induced Ca<sup>2+</sup> release by trapping IP<sub>3</sub>), or overexpressing IP<sub>3</sub>R2 (to boost IP<sub>3</sub>-induced Ca<sup>2+</sup> release) in cardiomyocytes [150]. Mice overexpressing the IP<sub>3</sub> sponge displayed reduced cardiac hypertrophy in response to chronic β-adrenergic stimulation and angiotensin II stimulation. In contrast, IP<sub>3</sub>R2-overexpressing mice displayed only a mild cardiac hypertrophic phenotype under basal conditions. However, when cardiac hypertrophy was induced (e.g. using transverse aortic constriction, chronic β-adrenergic stimulation or overexpression of Gαq, an upstream phospholipase C activator) mice expressing high IP<sub>3</sub>R2 levels demonstrated increased hypertrophic responses. Under these conditions, mice expressing low levels of IP<sub>3</sub>R2 (except for transverse aortic constriction) also displayed enhanced cardiac hypertrophy. Moreover, IP<sub>3</sub>R2 channels, which already display high sensitivity to IP<sub>3</sub>, may be further sensitized by increased PKA signalling downstream of β-adrenergic receptor stimulation leading to hyperphosphorylation of IP<sub>3</sub>R2 at Ser<sup>937</sup> [97] (see Section 2.4.1). The increased sensitivity of IP<sub>3</sub>R2-expressing mice to cardiac hypertrophy-inducing conditions could be linked to increased calcineurin and NFAT signalling. Consistent with this, the augmented cardiac hypertrophic response in IP<sub>3</sub>R2-overexpressing mice were completely blunted when these mice were crossed with calcineurin B-knockout mice, indicating an essential role of calcineurin/NFAT signalling in response to hyperactive IP<sub>3</sub>R2-mediated Ca<sup>2+</sup> signalling. While from the above studies, calcineurin emerged as the downstream target of increased IP<sub>3</sub>R-mediated Ca<sup>2+</sup> signalling, it is important to note that also nuclear CaMKIIδ has been implicated in altered transcription in response to cardiac hypertrophic endothelin-1 signalling [109]. Increased IP<sub>3</sub> signalling in response to endothelin-1 triggers a unique nuclear Ca<sup>2+</sup> signalling that does not occur during excitation-contraction coupling but activates CaMKII, which together with protein kinase D results in the phosphorylation and nuclear export of class II HDAC5, a transcriptional repressor. In healthy conditions, nuclear HDAC5 forms a complex with the transcription factor MEF2, thereby preventing the transcription of hypertrophic genes. In hypertrophic conditions, HDAC5 is exported from the nucleus, leading to de-repression of MEF2 and the induction of hypertrophic genes. Interestingly, blocking IP<sub>3</sub>Rs using chemicals like 2-aminoethoxydiphenyl borate or using IP<sub>3</sub>R2-knockout mice, prevents the nuclear export of HDAC5 and subsequent activation of the hypertrophic transcription program.

All these studies are consistent with a critical role for Ca<sup>2+</sup> signalling via IP<sub>3</sub>R2 in cardiac hypertrophy, being in the nucleus and required for driving transcription of hypertrophic genes and in the junctional sarcoplasmic reticulum being responsible for driving extra-systolic Ca<sup>2+</sup> rises and contractions. Moreover, these studies all support the concept of distinct Ca<sup>2+</sup> signalling compartments in cardiomyocytes, either in the cytosol during physiological excitation-contraction coupling driven by RyR2 channels or in the nucleus during pathophysiological hypertrophic signalling driven by IP<sub>3</sub> and IP<sub>3</sub>R2 channels [151].

## 5. The role of IP<sub>3</sub>R2 in cell death and in senescence

Over the last 20 years, IP<sub>3</sub>R channels have emerged as key regulators that control cell death and survival in a variety of cellular systems [14, 152–154]. T cells deficient in IP<sub>3</sub>R1 are resistant to a variety of apoptotic triggers, including chemical stimuli, like corticoids, and biological stimuli, including excessive T-cell receptor stimulation and exposure to Fas ligand [155]. Interestingly, susceptibility to T-cell receptor stimulation could be restored by artificially rising the cytosolic [Ca<sup>2+</sup>] using the SERCA inhibitor, thapsigargin. Also, a role for IP<sub>3</sub>R3 has emerged in pro-apoptotic Ca<sup>2+</sup> signalling [156], because some studies proposed that this channel may be preferentially located in the mitochondrial ER-associated membranes. As such, IP<sub>3</sub>R3 channels are thought to be part of the “quasi-synaptic” Ca<sup>2+</sup>-transport complex between the ER Ca<sup>2+</sup> stores and the mitochondria that can involve IP<sub>3</sub>Rs, GRP75 and VDAC1 [157,158]. Nevertheless, it is becoming increasingly clear that

all IP<sub>3</sub>R isoforms participate in apoptotic Ca<sup>2+</sup> signalling and/or influence the susceptibility of cells towards apoptotic stimuli. This can mean two things: i) not only IP<sub>3</sub>R3, but also IP<sub>3</sub>R1 and IP<sub>3</sub>R2 channels can be part of the ER-mitochondrial junction complexes, and ii) not only direct Ca<sup>2+</sup> transfer into the mitochondria, but also other downstream Ca<sup>2+</sup>-dependent signalling pathways participate in triggering mitochondrial outer membrane permeabilization, the point-of-no-return in apoptosis. Furthermore, it is important to emphasize that a complex interaction exists between IP<sub>3</sub>Rs and proteins from the B-cell lymphoma (Bcl)-2 family involved in the control of apoptosis, whereby several interaction sites for such proteins have already been identified on the IP<sub>3</sub>R [159–162].

IP<sub>3</sub>R-mediated Ca<sup>2+</sup> release can lead to calcineurin activation, which dephosphorylates the pro-apoptotic “sensitizer” BH3-only protein, Bad [163,164]. Phosphorylated Bad is neutralized due to its scaffolding with 14-3-3 proteins and therefore it cannot form a complex with anti-apoptotic Bcl-XL [165]. Dephosphorylation of Bad by calcineurin, e.g. in response to increases in cytosolic [Ca<sup>2+</sup>] mediated by IP<sub>3</sub>Rs [164], results in Bad release from 14-3-3 proteins and its translocation from the cytosol to the mitochondrial membranes. Here, it can bind to and inhibit anti-apoptotic Bcl-XL proteins [163], thereby displacing Bim/tBid, which then can activate Bax/Bak and induce apoptosis.

These data indicate that dampening the IP<sub>3</sub>R-mediated Ca<sup>2+</sup> rise, either by lowering IP<sub>3</sub>R levels or altering the IP<sub>3</sub>R-expression profile, by inhibiting the Ca<sup>2+</sup>-flux properties of IP<sub>3</sub>Rs, or by lowering the ER Ca<sup>2+</sup> content, which decreases the driving force for Ca<sup>2+</sup> release into the cytosol upon IP<sub>3</sub>R activation, will be cytoprotective [162]. Not surprisingly, different pro-survival signalling mechanisms, which are often oncogenic, appear to have exploited this concept to promote cell survival, including the survival of malignant or altered cells. In many cases, different mechanisms can be simultaneously operative. For instance, oncogenic KRAS mutations appear to switch the expression from IP<sub>3</sub>R3 into IP<sub>3</sub>R1 and to lower the ER Ca<sup>2+</sup>-store content, together suppressing agonist-induced Ca<sup>2+</sup> release and mitochondrial Ca<sup>2+</sup> accumulation and thus protecting cells against menadione exposure [166]. AKT/PKB phosphorylates all three IP<sub>3</sub>R isoforms, thereby suppressing their pro-apoptotic Ca<sup>2+</sup>-release function [84,156]. This mechanism is also exploited by tumour suppressors like the promyelocytic leukemia protein, which enhance IP<sub>3</sub>R3 activity by counteracting PKB-mediated IP<sub>3</sub>R3 phosphorylation [167]. Other survival/anti-apoptotic proteins, like Bcl-2, have been reported to lower ER Ca<sup>2+</sup> store-content by sensitizing IP<sub>3</sub>Rs to basal IP<sub>3</sub> levels and to directly suppress IP<sub>3</sub>R-mediated Ca<sup>2+</sup> release, thereby preventing toxic mitochondrial Ca<sup>2+</sup> overload [168]. Evidently, these mechanisms will also result in reduced calcineurin activation, thereby limiting Bad dephosphorylation and its subsequent inhibitory effects on the anti-apoptotic Bcl-2 proteins.

While most studies have addressed the role of IP<sub>3</sub>R1 and IP<sub>3</sub>R3 channels in apoptosis, there is emerging evidence that IP<sub>3</sub>R2 channels play a crucial role in mediating pro-apoptotic Ca<sup>2+</sup> signalling. Definitely, IP<sub>3</sub>R2 with its high sensitivity to IP<sub>3</sub> (see Section 2.1) may actually be a very critical regulator of cell survival versus cell demise by rendering cells sensitive to basal IP<sub>3</sub> signalling. The role of IP<sub>3</sub>R2 in cell death has been elucidated in different studies and using different approaches.

First of all, there is evidence that cell death triggered by cellular exposure to cytotoxic compounds or agents that induce oxidative stress has been associated with an increase in IP<sub>3</sub>R2 levels and activity. Increasing oxidative stress in a neuronal cell line exposed to sub-lethal concentrations of tert-butyl hydroperoxide-mediated oxidative stress led to prominent upregulation of IP<sub>3</sub>R2 mRNA and protein levels, while IP<sub>3</sub>R1 and IP<sub>3</sub>R3-expression levels remained unaltered [38]. Consistent with elevated IP<sub>3</sub>R expression levels, Ca<sup>2+</sup> release from the nucleoplasm in response to a cell-permeable IP<sub>3</sub> ester was strongly potentiated in tert-butyl hydroperoxide-treated cells. Also, the nephrotoxic compound uranyl acetate has been shown to increase IP<sub>3</sub>R2 mRNA and protein levels in human epithelial kidney cells, thereby increasing

the basal cytosolic  $[Ca^{2+}]$  and apoptosis levels [169]. Similar findings have been reported in HeLa cells exposed to fast  $H_2S$  donors, although in this case  $IP_3R1$  expression levels were also increased [170]. Interestingly,  $IP_3Rs$  may also be directly affected by reactive oxygen species (ROS) [171]. In intact DT40 cells, superoxide anions caused  $Ca^{2+}$  release from the ER, likely via a mechanism that sensitizes  $IP_3Rs$  to basal levels of  $IP_3$  signalling. In these DT40 cells, the presence of  $IP_3R2$  and  $IP_3R1$  isoforms, but not of  $IP_3R3$ , was required for superoxide anion-induced  $[Ca^{2+}]$  rise in the cytosol.

The role of  $IP_3R2$  channels in apoptotic  $Ca^{2+}$  signalling was also identified in B-cell cancer cells, in particular in a subset of “primed to death” diffuse large B-cell lymphoma cell lines [172]. Cells expressing high  $IP_3R2$  levels seem “addicted” to the presence and recruitment of anti-apoptotic Bcl-2 proteins at the ER and especially in the  $IP_3R$  protein complex [173]. By interacting via its BH4 domain with the modulatory and transducing domain of the  $IP_3Rs$ , Bcl-2 inhibits  $IP_3$ -induced  $Ca^{2+}$  release [174–176]. The binding site for the BH4 domain of Bcl-2 (Fig. 1) has been identified [175] and is conserved between the three  $IP_3R$  isoforms [177]. Importantly, a peptide tool designed to disrupt  $IP_3R/Bcl-2$ -complexes by targeting Bcl-2’s BH4 domain (see [175–178]) was very effective in inducing intracellular  $Ca^{2+}$  overload and provoking cell death in DL-BCL cells that express high levels of  $IP_3R2$ , like SU-DHL-4 cells [172]. In contrast, cells that expressed very low levels of  $IP_3R2$  were virtually resistant to this peptide tool. The apoptotic resistance of these cells to this peptide was not due to a general defect in the initiation or execution of apoptosis, since staurosporine or BH3-mimetic drugs were very effective in these cells. We hypothesize that anti-apoptotic Bcl-2 is required at the ER to associate with the  $IP_3R2$  to prevent its hyperactivity in response to the ongoing  $IP_3$  signalling downstream of the B-cell receptor [173]. It remains to be elucidated whether these findings translate into primary B-cell cancer cells. In any case, disrupting  $IP_3R/Bcl-2$  complexes results in excessive  $Ca^{2+}$ -signalling patterns and apoptotic cell death in primary peripheral mononuclear blood cells (mainly B cells) isolated from chronic lymphocytic leukaemia patients [179]. Remarkably, a gene expression profile analysis using the GeneSapiens microarray database revealed an upregulation of  $IP_3R2$  at the mRNA level in chronic lymphocytic leukaemia samples [173].

$IP_3R2$  channels are not only implicated in apoptosis but also play a role in cellular senescence. Stable cell cycle arrest is a key feature of cellular senescence, which is activated in response to cellular stress. Factors include oncogenic stress following loss of PTEN function, DNA damage or telomere attrition, oxidative stress and replicative stress [180]. The arrest in proliferation depends on the major tumour suppressor pathways involving p53/p21 and p16/Rb [180,181]. At the physiological level, cellular senescence contributes to ageing at the level of the organism [182]. However, cellular senescence can also function as an important “health keeper” fighting pathophysiological conditions associated with oncogenic stress [183,184]. As such, cellular senescence, in addition to apoptosis, is one of the pathways that counteract cancer cell initiation and tumour development [185,186]. For instance, in pre-malignant hepatocytes, senescence led to the secretion of chemo- and cytokines, resulting in their clearance by  $CD4^+$  T cells [187]. Loss of immune surveillance caused the progression of the pre-malignant hepatocytes into hepatocellular carcinomas. Recently, Wiel et al. [188] performed an elegant shRNA-based screen to identify which “loss-of-function” genes can cause escape from oncogene-induced senescence in immortalized human mammary epithelial cells (HEC). Interestingly, the gene coding for  $IP_3R2$  was identified as a prominent modulator of this form of senescence. These findings correlated with an analysis performed by the authors using the Oncomine database, which indicated that many malignant tumours displayed a decrease in  $IP_3R2$  mRNA levels.  $IP_3R2$  shRNAs alleviated the growth arrest in HEC exposed to oncogenic stress. Prolonged incubation of these cells with cell-permeable  $IP_3$  repressed cell growth and induced pre-mature senescence. Oncogenic stress-induced senescence led to an increase in the  $Ca^{2+}$

accumulation in the mitochondria, a process that did not occur in the  $IP_3R2$  shRNA-treated cells, and also boosted  $IP_3$ -induced mitochondrial  $Ca^{2+}$  uptake. This mitochondrial  $Ca^{2+}$  uptake was proposed to be responsible for the decrease in mitochondrial potential observed during oncogene-induced senescence, because shRNA against the  $IP_3R2$  or against the mitochondrial  $Ca^{2+}$  uniporter prevented this decline in mitochondrial potential. Interestingly, chemical induction of mitochondrial depolarization blocked cell growth and induced pre-mature senescence. The role of  $IP_3R2$  and of the subsequent mitochondrial  $Ca^{2+}$  accumulation was linked to an increase in ROS production, since antioxidants promoted oncogene-induced senescence escape. Finally, these concepts may not be limited to oncogene-induced senescence, but may also be applicable in models of replicative senescence.  $IP_3R2$  knockdown counteracted the increase in mitochondrial  $Ca^{2+}$  and the decline in mitochondrial potential observed during replicative senescence, thereby delaying the occurrence of senescence in these models.

## 6. Conclusions

$IP_3R2$  is characterized by a number of important and specific properties, including, but not limited to, its high sensitivity to  $IP_3$  and ATP. Other properties such as its regulation by protein kinases, its interaction with adenylate cyclase to couple to cAMP production, its ability to recruit associated proteins and its low mobility in the ER, remain underexplored. At the functional level, it is clear that  $IP_3R2$  is not only important for regulating secretion, but also is implicated in health and disease, including prominent roles in cardiac function and tumour growth. The available evidence indicates that tumour cells either down-regulate  $IP_3R2$  expression or dampen its activity via Bcl-2, since  $IP_3R2$  can promote senescence and/or apoptosis. It is now anticipated that further research will elucidate additional important functions of  $IP_3R2$  in other tissues and organs and further that developing tools specifically targeting or impacting  $IP_3R2$  will allow modulating its function in disease states.

## Acknowledgments

Work performed on the topic in the laboratory of J.B.P. and G.B was supported by various grants of the Research Foundation-Flanders and of the Research Council of the KU Leuven as well as by the Interuniversity Attraction Pole Programs of the Belgian Science Policy. T.V. is the recipient of a fellowship of the “Vlaamse Liga tegen Kanker”. D.Y. is supported by grants from the NIH (R01-DE019245 and R01-DE041756).

The authors are indebted to past and present members of their laboratory, and especially to Professors H. De Smedt and L. Missiaen, for stimulating discussions. The authors wish also to acknowledge Professors C.W. Distelhorst, K. Mikoshiba, D. Bernard and P. Gailly for interesting discussions.
