Ulceration is an important prognostic factor in melanoma whose biologic basis is poorly understood. Here we assessed the prognostic impact of pleckstrin homology domain-interacting protein (*PHIP*) copy number and its relationship to ulceration. *PHIP* copy number was determined using fluorescence *in situ* hybridization (FISH) in a tissue microarray cohort of 238 melanomas. Elevated *PHIP* copy number was associated with significantly reduced distant metastasis-free survival (DMFS; P = 0.01) and disease-specific survival (DSS; P = 0.009) by Kaplan–Meier analyses. *PHIP* FISH scores were independently predictive of DMFS (P = 0.03) and DSS (P = 0.03). Increased *PHIP* copy number was an independent predictor of ulceration status (P = 0.04). The combined impact of increased *PHIP* copy number and tumor vascularity on ulceration status was highly significant (P < 0.0001). Stable suppression of PHIP in human melanoma cells resulted in significantly reduced glycolytic activity *in vitro*, with lower expression of lactate dehydrogenase 5, hypoxia-inducible factor 1 alpha subunit, and vascular endothelial growth factor, and was accompanied by reduced microvessel density *in vivo*. These results provide further support for PHIP as a molecular prognostic marker of melanoma, and reveal a significant linkage between PHIP levels and ulceration. Moreover, they suggest that ulceration may be driven by increased glycolysis and angiogenesis.

Journal of Investigative Dermatology (2014) 134, 783–790; doi:10.1038/jid.2013.369; published online 10 October 2013

INTRODUCTION

Melanoma is an important clinical problem, with an estimated 76,250 new cases and 9,180 deaths in 2012 (Siegel *et al.*, 2012). The clinical behavior of melanoma can be unpredictable, making prognostic predictions difficult in individual patients. Although tumor thickness consistently emerges as the single most significant prognostic factor determining survival, and while ulceration increases the risk of death within a given thickness range, additional factors are required to refine the prognostic assessment of melanoma patients. Beyond histological factors that are reliably associated with decreased

survival, molecular markers represent the next frontier in the evaluation of melanoma outcome. Despite the identification of numerous putative molecular prognostic factors, no prognostic biomarkers are routinely used in the evaluation of melanoma patients (Gogas *et al.*, 2009). In addition, few biomarkers have been shown to retain prognostic impact, when measured on more than one platform (i.e., measurements at the DNA vs. RNA vs. protein level).

Recent studies performed by our group identified a previously unknown role for the pleckstrin homology domain-interacting protein (PHIP) in melanoma progression (De Semir et al., 2012). PHIP was identified as the top gene overexpressed in metastatic versus primary melanomas by gene expression profiling analysis (Haqq et al., 2005). Short hairpin RNA (shRNA)-mediated suppression of PHIP resulted in significant suppression of melanoma cell invasion and metastatic potential in both murine and melanoma cell lines. High levels of PHIP expression were associated with significantly reduced survival in both mouse models and human tissues. Specifically, high PHIP expression (as determined by immunohistochemical analysis) was independently predictive of distant metastasis-free survival (DMFS) and disease-specific survival (DSS). In this study, we analyze the role of PHIP copy number for its prognostic significance in primary cutaneous melanoma and explore the linkage between PHIP levels and ulceration development in melanoma.

RESULTS

Given the recent demonstration of a significant prognostic role for PHIP protein expression and the presence of elevated PHIP copy number in melanoma (De Semir et al., 2012), we aimed to determine the prognostic impact of PHIP copy number in primary cutaneous melanoma. PHIP copy number was analyzed using fluorescence in situ hybridization (FISH) on a tissue microarray (TMA) cohort of 238 specimens, with known immunohistochemical analysis of PHIP protein expression, by an observer blinded to patient outcomes. Overall, 22% of the cohort possessed a mean copy number of 3 or greater. See Figure 1a for representative examples of low versus high PHIP copy number. As the ratio of PHIP and probes representing the centromere of chromosome 6 in almost all of the cases was close to 1.0 (Supplementary Table S1 online), the primary attribute assessed was percentage of cells expressing three or more copies of the PHIP gene, in which there was a range from 0 to 87%, with a mean of 33.4%. There was a significant correlation between PHIP copy number and level of expression of the PHIP protein (P<0.0001, Supplementary Figure S1 online).

Initially, we analyzed the relationship between *PHIP* copy number and melanoma outcome using univariate analysis. High *PHIP* copy number was associated with decreased melanoma survival, when DMFS (P=0.01 by log-rank test) and DSS (P=0.009 by log-rank test) were assessed using Kaplan–Meier analysis (Figure 1b and c). In addition, there was a significantly increased risk of distant metastasis or death due to melanoma with the presence of high *PHIP* FISH scores. In all, 45.4% of patients with high copy number had distant metastasis, when compared with 25.5% with low copy number (Fisher's exact test, P=0.015). In total, 42.2% of patients with high copy number died of metastatic melanoma, when compared with 17.7% of patients with low copy number (Fisher's exact test, P<0.002).

Next, we examined the relationship between *PHIP* copy number and survival using multivariate Cox regression analysis. High *PHIP* FISH scores were significantly predictive of reduced DMFS (P=0.03, Table 1) and DSS (P=0.027, Table 2) in multivariate models that included tumor thickness, ulceration, age, gender, and tumor site. Thus, *PHIP* copy number was independently predictive of survival associated with melanoma, similar to the results obtained for PHIP protein expression (De Semir *et al.*, 2012).

Recently, high PHIP immunohistochemical scores were shown to correlate with ulceration status (De Semir *et al.*, 2012). We aimed to confirm this relationship at the DNA level. High *PHIP* copy number was significantly associated with ulceration status when analyzed by univariate logistic regression analysis (P=0.004). In addition, high *PHIP* copy number was associated with a significantly increased risk of developing ulceration. Thus, ulceration was present in 45.5% of cases with high *PHIP* copy number, when compared with 28.8% of cases with low *PHIP* copy number (P=0.013, Fisher's exact test).

Previously, we reported that ulceration was associated with increased tumor vascularity in the primary tumor, when assessed morphologically (Kashani-Sabet *et al.*, 2002).

Elevated tumor vascularity (as determined by melanomas with prominent vs. all lower degrees of vascularity) was significantly associated with ulceration status. Ulceration was present in 60.3% of the cases with prominent tumor vascularity, when compared with 22.2% of cases with lower degrees of tumor vascularity (P<0.0001, Fisher's exact test). This served to confirm the previously reported results in this TMA cohort. We then explored the combined impact of high *PHIP* copy number and elevated tumor vascularity on the development of ulceration. Ulceration was present in 20.2% of melanomas with both low *PHIP* copy number and low tumor vascularity. This increased to 38.8% of cases ulcerated with either prognostic factor elevated, and to 72.2% of melanomas ulcerated, when both factors were elevated (P<0.0001, χ^2 test of percentage differences).

We then assessed the relationship between *PHIP* copy number and ulceration status, using multivariate logistic regression analysis. Presence of ulceration in melanoma is also known to increase both with increasing tumor thickness and with increasing mitotic rate (Balch *et al.*, 2001b; Thompson *et al.*, 2011). A multivariate logistic regression analysis was performed, including low versus high *PHIP* copy number, low versus high tumor vascularity, tumor thickness, and mitotic rate. All four factors were significantly predictive of the incidence of ulceration (Table 3). Thus, *PHIP* FISH scores were independently predictive of

ulceration status, even with the inclusion of these other factors (P = 0.04).

Next, we explored cellular pathways regulated by PHIP expression potentially relevant to the development of ulceration. Targeted suppression of PHIP (using an anti-PHIP shRNA) in C8161.9 human melanoma cells (with elevated PHIP copy number) was previously shown to significantly suppress melanoma cell invasiveness and metastatic potential (De Semir et al., 2012). Given that PHIP functions in the IGF1 receptor pathway that is important in regulating glucose metabolism, we assessed whether suppression of PHIP activity resulted in altered glycolytic activity of melanoma cells. C8161.9 cells expressing the anti-PHIP shRNA produced significantly lower amounts of lactate than control cells expressing a shRNA targeting luciferase (anti-luciferase shRNA; Figure 2a). This was associated with decreased expression of lactate dehydrogenase 5 (LDH5), the most efficient isoenzyme of lactate dehydrogenase, which catalyzes the conversion of pyruvate to lactate in the final step of glycolysis (Figure 2b). In addition, culturing anti-PHIP shRNAexpressing cells in the presence of methylpyruvate, which bypasses glycolysis and directly enters the Krebs cycle, resulted in significantly increased invasion (Figure 2c). Thus, the pro-invasive role of PHIP in melanoma is mediated, at least in part, by activating the glycolytic pathway. Moreover, C8161.9 melanoma cells with reduced PHIP expression produced lower levels of vascular endothelial growth factor (VEGF), as determined by an ELISA assay of human VEGF secretion (Figure 2d). As VEGF expression is controlled by hypoxia-inducible factor 1 alpha subunit (HIF1A; Forsythe et al., 1996), melanoma cells with suppressed PHIP expression were also shown to express lower levels of HIF1A by western analysis (Figure 2b).

Finally, we assessed the effects of suppression of PHIP on the angiogenic potential of human melanoma cells *in vivo*. C8161.9 melanoma cells were inoculated subcutaneously into nude mice, and the resultant tumors examined for microvessel density using immunofluorescence of CD31 positivity. Although there was no significant difference in the tumor volume between the two groups (data not shown), tumors in the anti-*PHIP* shRNA-expressing group (Figure 3a, right panel) exhibited large areas of necrosis when compared with the control group (Figure 3a, left panel). Analysis of CD31 expression revealed that the control tumors were characterized by large, abnormal blood vessels, and

hemorrhage, apparent from autofluorescence of erythrocytes and lipofuscin (Baschong *et al.*, 2001; Figure 3b and c, left panels). By contrast, the vessels in the anti-*PHIP* shRNA-expressing tumors were smaller, with little or no hemorrhage evident (Figure 3b and c, right panels). Finally, the anti-*PHIP* shRNA-expressing tumors had significantly reduced microvessel density when compared with the control tumors (P<0.02 as assessed both by a *T*-test and by a two-sample randomization test, Figure 3d). Thus, increasing PHIP expression in human melanoma cells promotes angiogenic potential.

DISCUSSION

In this article, we describe a previously unreported role for *PHIP* copy number in the prognosis associated with melanoma. *PHIP* FISH scores were predictive of a significantly increased risk of both distant metastasis and death due to melanoma, and were independently predictive of DMFS and DSS. In addition, elevated *PHIP* FISH scores were associated with a higher incidence of ulceration and were independently predictive of ulceration status. The combined impact of *PHIP* copy number and tumor vascularity was additive, as cases with high levels of both factors had a significantly higher incidence of ulceration than cases with low levels of either or both factors. Finally, C8161.9 human melanoma cells with suppressed PHIP expression exhibited reduced glycolytic activity and angiogenic potential.

These results provide further support for the role of PHIP as a molecular prognostic marker for melanoma, as initially

described using immunohistochemical analysis of PHIP expression. High PHIP protein expression was associated with a significantly increased risk of distant metastasis and death due to melanoma, and was independently predictive of DMFS and DSS (De Semir *et al.*, 2012). Our analysis of *PHIP* copy number parallels the results obtained in human and murine melanoma cell lines, in which suppressed PHIP expression resulted in significantly reduced metastatic potential and increased survival in xenograft models.

To date, few markers have been shown to provide significant prognostic impact in melanoma when assessed on more than one platform. For example, SPP1 expression has been shown to have independent prognostic significance when assessed at the RNA and protein levels (Rangel *et al.*, 2008; Conway *et al.*, 2009). Our studies have demonstrated a significant prognostic role for PHIP at both the DNA and protein levels. Although the ratio of *PHIP* to chromosome 6 centromeric probe was close to 1.0 in the great majority of cases examined, changes in *PHIP* copy number, ranging from euploidy to three or greater copies, were highly correlated with increased PHIP expression. Additional studies of PHIP levels will be required in distinct cohorts in order to further validate its prognostic role.

Beyond an independent impact on survival, these studies confirmed a significant and independent relationship between PHIP levels and ulceration status. In addition, *PHIP* copy number combined markedly with tumor vascularity to increase the incidence of ulceration in primary melanoma specimens. Ulceration is an important

prognostic factor that has been incorporated into the American Joint Committee on Cancer staging classification for melanoma for over a decade (Balch *et al.*, 2001a, 2009). More recently, ulceration has been suggested as a potential predictive marker of benefit to adjuvant IFN alpha therapy (McMasters *et al.*, 2010; Eggermont *et al.*, 2012). However, the biologic basis for the development of ulceration is poorly understood.

Increasing incidence of ulceration in melanoma is associated with increasing tumor thickness, mitotic rate, and tumor vascularity (Balch *et al.*, 2001b; Kashani-Sabet *et al.*, 2002; Thompson *et al.*, 2011). In addition, gene expression profiling studies have identified a gene signature that correlates with ulceration (Winnepenninckx *et al.*, 2006). However, the specific cellular pathways and mechanisms by which ulceration develops are unclear. The linkage between PHIP levels and ulceration implies a role for the IGF1 receptor pathway in ulceration, given PHIP's involvement in this signal transduction pathway. In addition, our studies in human melanoma cells demonstrating that downregulation of PHIP expression results in significantly reduced glycolytic activity, VEGF secretion, and microvessel density provide mechanistic insights, identifying glucose metabolism and tumor angiogenesis as pathways by which ulceration may develop in melanoma.

Tumor cell growth is promoted by increased glucose consumption, a phenomenon known as the Warburg effect (Warburg 1956). The importance of glycolysis to melanoma progression has been amply reported in melanoma cell lines (Halaban et al., 1997, 2002; Bagheri et al., 2006) and is demonstrated clinically by the utility of positron emission tomography scanning in the radiologic assessment of melanoma both during initial staging (Reinhardt et al., 2006; Falk et al., 2007) and in response to targeted therapy (McArthur et al., 2012). Glycolysis in tumor cells is driven by AKT (Elstrom et al., 2004), and PHIP is a potent activator of AKT in melanoma (De Semir et al., 2012). Moreover, increased glucose metabolism can itself drive tumor angiogenesis, invasion, and metastasis (Lay et al., 2000; Tsutsumi et al., 2004). Thus, our studies on PHIP in melanoma describe a previously unreported link between PHIP, the Warburg effect, tumor angiogenesis, and ulceration development. As PHIP is activated through increased copy number in a subset of melanomas, additional markers of ulceration will need to be identified in melanomas without PHIP activation. However, the mechanistic analyses provided here should facilitate the identification of these additional markers in distinct molecular subsets of melanoma patients.

Finally, our investigation of PHIP in melanoma tissues and cell lines suggests an intriguing link between ulceration and LDH levels. These results imply that a common tumorpromoting pathway (i.e., IGF1 receptor), resulting in increased glycolysis, may underlie the biologic basis of two prominent prognostic markers incorporated into the American Joint Committee on Cancer staging classification, one that refines the prognosis of localized melanoma, the other the prognosis of disseminated melanoma. Elevated LDH5 expression in primary melanoma has been previously shown to be associated with reduced survival on univariate analysis, but was not independently predictive of melanoma outcome (Zhuang et al., 2010). Furthermore, LDH activity has been correlated to HIF1A expression and angiogenic potential (Koukourakis et al., 2003). However, further studies will be required in order to confirm the link between ulceration and LDH levels suggested by this analysis. In addition, high levels of angiopoietin-2 have been reported in multiple cancers, with a possible prognostic role (Bonner and Arbiser 2012), and are accompanied by upregulation of RAS-related C3 botulinum toxin substrate signaling pathways (Felcht et al., 2012). Thus, it is possible that elevated PHIP copy number

can modulate angiopoietin levels in melanoma, in part through mitrochondrial dysfunction, nicotinamide adenine dinucleotide phosphate oxidase induction, and increased generation of reactive oxygen species (which result in angiopoietin-2 activation). In conclusion, our studies support an important role for PHIP as a molecular marker of melanoma ulceration, metastasis and survival, and provide insights into the cellular pathways through which ulceration can develop.

MATERIALS AND METHODS

Study population

This study used a TMA cohort that was previously described according to REMARK guidelines (Rangel *et al.*, 2006; Kashani-Sabet *et al.*, 2009). The molecular prognostic factor analyses performed herein were approved by the appropriate ethics boards both at CPMC and UCSF.

Fluorescence in situ hybridization

FISH was performed as previously described (Wiegant and Raap 2001; Chin et al., 2003; De Semir et al., 2012) using bacterial artificial chromosome clones RP11-767O1, RP11-484L10, RP11-217L13, and CTD-2297E14 to detect the PHIP locus and clones RP11-26M18 and RP11-136K2 to detect 6q11.1 and 6p11.1 respectively (February 2009 freeze of the UCSC Genome Browser, http://genome.ucsc.edu). Bacterial artificial chromosome DNA's were prepared with the Large-Construct kit (Qiagen, Valencia, CA) and labeled by nick translation with Alexa Fluor 488 and 594 dUTPs (Life Technologies, Grand Island, NY) as described (Wiegant and Raap 2001). The quality and mapping of all probes were verified by hybridization to normal metaphase spreads in combination with a commercially available centromeric probe for chromosome 6 (Open Biosystems, Lafayette, CO) before tissue analysis. Hybridization on TMA's was performed as described previously (Wiegant and Raap 2001; Chin et al., 2003). Images were taken with a Zeiss Axio Imager Z2 controlled by AxioVision software (Zeiss, Jena, Germany). The FISH signals were assessed and counted manually from images with several Z stack layers acquired using a Zeiss Axio Image Z2 microscope controlled by AxioVision software (Zeiss, Jena, Germany). At least 30 nuclei from each case were evaluated, and the signals were interpreted according to guidelines described previously (Bayani and Squire 2004) and recorded as 1 through 5 or greater. Signals from bacterial artificial chromosome clones detecting 6q11.1 and 6p11.1 were interpreted as the centromeric signal for chromosome 6 and the count was used as control.

Cell culture studies

C8161.9 human melanoma cells stably expressing anti-*PHIP* shRNA and anti-*luciferase* shRNA were generated and propagated as described (De Semir *et al.*, 2012). Lactate production and invasion into matrigel were assayed as reported (De Semir *et al.*, 2012). C8161.9 cells were treated with 10 mM methylpyruvate (Sigma, St Louis, MO) for 48 hours before the invasion assay. VEGF secretion was measured by using an ELISA kit following the manufacturer's instructions (DY293B, R&D Systems, Minneapolis, MN). Western blotting was performed as described (De Semir *et al.*, 2012) using antibodies targeting HIF1A (ab16066, Abcam, Minneapolis, MN), LDH5 (ab1015, Abcam), and GAPDH (MAB374, Millipore, Billerica, MA).

Immunofluorescence

Groups of six nu/nu mice were inoculated subcutaneously with 1 million C8161.9 human melanoma cells expressing either control *luc* or anti-*PHIP* shRNA. On day 25, the mice were sacrificed and the tumors were assessed for microvessel density based on CD31 positivity by immunofluorescence, which was performed using a rabbit anti-CD31 antibody (ab28364, Abcam) and a secondary antibody labeled with Alexa Fluor 594 (Life Technologies) as described previously (Jalas *et al.*, 2011). Mosaic images were acquired with \times 20 magnification at a fixed exposure with a Zeiss Axio Imager Z2 microscope controlled by AxioVision software. After automatically stitching the images, the number of CD31-positive objects and area were determined using ImageJ software (NIH, Bethesda, MD). The number of CD31-positive vessels was quantitated and the microvessel density reported as the total CD31 count over the entire area of the tumor.

Statistical analysis

Statistical methods used to assess the significance of various prognostic factors on melanoma outcome were previously described (Rangel et al., 2006; Kashani-Sabet et al., 2009). The coding for clinical or pathological attributes was performed as described by the AJCC staging committee for melanoma (Balch et al., 2001b). The correlation between PHIP copy number and immunohistochemical score was tested by regression analysis using Data Desk software (Data Description, Ithaca, NY). For both DMFS and DSS, the definition of high PHIP FISH scores, as measured by percentage of cells harboring three or more copies of PHIP, was established as equal to or greater than 16%. A 16% cutoff served to maximize the average of the sensitivity and specificity in the prediction of both DMFS and DSS, analyzed separately. The same 16% cutoff was then uniformly and consistently used in all subsequent analyses of DMFS and DSS. The association between high PHIP copy number and DMFS or DSS was assessed using both Kaplan-Meier analysis and multivariate Cox regression. The association between high PHIP copy number and presence or absence of ulceration was assessed using both Fisher's exact test and multivariate logistic regression analysis. The association between a high degree of tumor vascularity and ulceration was also assessed using both Fisher's exact test and multivariate logistic regression. Assessment of the differential impacts of neither, either, and both of these two factors was done using both χ^2 analysis and Fisher's exact test. In predicting ulceration status, high PHIP copy number was uniformly defined as \geq 35% of tumor cells harboring three or more copies of the PHIP gene. This cutoff was similarly selected as the one that maximized the average of sensitivity and specificity in predicting ulceration. All P-values reported are two sided.

CONFLICT OF INTEREST

MK-S owns stock in Melanoma Diagnostics. Intellectual property covering the marker described in this study was licensed to Myriad Genetics Laboratories. The remaining authors state no conflict of interest.
