arising from the central hydrophobic core, and precipitated by the residues belonging to the N-terminal region. Adaptive biasing force based potential of mean force (PMF) calculations estimating the free energy changes as the peptide strands collapse towards each other demonstrate that the SWCNT causes the ‘open’ and the ‘collapsed’ states to be in near equilibrium, by bringing down the energetic cost of ‘loop opening’. The observed phenomena of peptide localization and decreased propensity for loop collapse could have important implications for site-directed drug delivery and for altering the kinetics of the peptide’s self-assembly.

Several proteins possess a segment of amino acids composed of successive glutamines. In many, this segment affects the native folding when expanded above 35 to 40 glutamines. Such effect is associated to neurodegenerative diseases such as Huntington’s in which the huntingtin protein misfolds. As the huntingtin protein has over 3000 amino acids, it is easier to focus on the glutamine sequence alone as well as part of the neighboring amino acids to this segment.

Several experiments characterized the folding of polyglutamate with various amino acid lengths, yielding somewhat contradictory structural and dynamical information. It is safe to say that, at the moment, the early oligomerization is still not clearly understood at an atomic level. To address this question, we present molecular dynamical simulations on various polyglutamine segments from 30 to 40 glutamines with and without neighboring amino acids to assess their importance on folding and fold stability. To reach relevant time-scales, we combine simulations using a coarse-grained model as well as an all-atom model with explicit solvent.

Understanding the aggregation mechanism of amyloid fibrils is a critical step in the investigation of several neurodegenerative disorders associated with the misfolding of proteins. In a previous study (Rojas et al., JMB 2010 404, 537–552), the growth mechanism of β-amyloid peptide fibrils which is associated with Alzheimer’s disease (AD), was successfully modeled by using a physics-based coarse-grained united-residue model and molecular dynamics (MD) simulations. We report a simulation study of coherent two-dimensional chiral signals based on the trajectories obtained by Rojas et al. to monitor this growth mechanism at different simulation times. Far ultraviolet signals (FUV)(λ = 190–250 nm) originated from the backbone ππ* and ππ* transitions, and near ultraviolet signals (NUV) (λ > 250 nm) are associated with aromatic side-chains (Phe and Tyr). These signals display distinct cross peak patterns in the two-dimensional spectra that can be used, in combination with MD, to monitor local dynamics and conformational changes in the secondary structure of AB peptides during the aggregation process. 2DUV total chiral signals in the aggregation process are combinations of subset of chiral signals from a monomer Aβ peptide, an amyloid fibril and the interactions between them.

Large-scale conformational changes in proteins involve barrier-crossing transitions on the complex free energy surfaces of high-dimensional space. Here we show that, by combining the on-the-fly string method and the multi-state Bennett acceptance ratio (MBAR) method, the free energy profile of a conformational transition pathway in Escherichia coli adenylate kinase can be accurately determined. The minimum free energy paths (MFEPs) of adenylate kinase were searched by the on-the-fly string method in 20-dimensional space spanned by the 20 largest-amplitude principal modes, and the free energy and various kinds of average physical quantities along the MFEPs were successfully evaluated by the MBAR method. The influence of ligand binding on the MFEPs was characterized in terms of rigid-body motions of the LID and AMPβd domains. It was found that the LID domain was able to partially close without the ligand while the closure of the AMPβd domain required the ligand binding. The transition state ensemble of the ligand bound form was identified as those structures characterized by highly specific binding of the ligand to the AMPβd domain, and was validated by unrestrained MD simulations. It was also found that complete closure of the LID domain required the dehydration of solvents around the P-loop. These findings suggest that the interplay of the two different types of domain motion is an feature in the conformational transition of the enzyme.

Conventional and Accelerated Molecular Dynamics Simulations of Staphylococcus Aureus Sortase A
Kalik Kappel, Jeff Wernick, and Andew McCammon.
University of California, San Diego, San Diego, CA, USA.
The targeting of surface proteins to the cell wall, necessary for the full virulence of Gram positive bacteria, can be traced back to the actions of sortase enzymes. These enzymes recognize a specific sorting sequence in proteins destined to be displayed on the surface of the bacteria, and catalyze the transpeptidation reaction that results in the attachment of the protein to a cell wall precursor molecule. With the rise of antibiotic resistant strains of bacteria, sortase enzymes are promising new drug targets. Specifically, in light of the growing emergence of methicillin resistant Staphylococcus aureus (MRSA), we are looking at Staphylococcus aureus Sortase A (SrrA). SrrA cleaves proteins at the LPXTG sorting signal and attaches them to lipid II. Here, we have used both conventional and accelerated molecular dynamics simulations to simulate the enzyme in its apo and holo (bound to the LPATG sorting signal) states. Results reveal the importance of loop motions of which are situated proximal to the active site, specifically the B6/B7 and B7/B8 loops, and suggest dual functionality of the catalytic arginine residue. Additionally, in a subset of the holo simulations we observe movement of the sorting signal away from the active site to distinct metastable states and find that motions of the enzyme in the accelerated molecular dynamics simulations suggest an induced fit binding mechanism. These results improve our understanding of the functioning of SrrA and will ultimately aid in the development of new drugs to combat MRSA infections.

Classical Force Field Development and Molecular Dynamics of [NiFe] Hydrogenase
Dayle Smith, Thomas C. Squier, T.P. Straatsma.
Pacific Northwest National Lab, Richland, WA, USA.

An understanding of the force-field parameters necessary to describe metal clusters in [NiFe]-hydrogenase enzymes currently limits an ability to use classical molecular dynamics (MD) simulations to understand how changes in the coordination geometry around the metal centers promote catalysis. Using density functional theory (DFT), we have developed force-field parameters for three catalytic states of the [NiFe] active site as well as the reduced and oxidized states of the three Fe/S clusters. Calculations were made using small model clusters that approximate the protein environment, respectively replacing cysteinate and histidine coordinating side-chains with thiolates and imidazole. Parameters were tested using 25 ns MD simulations of gas-phase model clusters and classical harmonic frequency analysis. Matching of DFT and MD normal modes verified that the derived force field parameters reproduce the DFT modes and frequencies, even the low-frequency torsion modes that couple with protein backbone motion. The utility of the determined force-field parameters was further established in situ using explicit-solvent, all-atom, 25 ns MD simulations of [NiFe] hydrogenase in three catalytic states (Ni-A, Ni-B, and Ni-C). These results establish the utility of the derived force-field parameters, and provide the basis for testing current models that suggest changes in the coordination geometry of the active site metals promotes catalysis.
