**OBJECTIVES:** To validate a software, for an optical pencil toll, to calculate psoriasis patients’ Body Surface Area (BSA) and to demonstrate that the new developed method is been valid and reliable to quantify the BSA.

**METHODS:** Multicentre prospective study at Dermatology centres (Five Spanish Hospitals and one Portuguese Hospital). In each hospital two dermatologists visited the same patients twice (second visit 3 days after first), 60 dermatologists included ≥10 consecutive patients with psoriasis. Socio-demographical and clinical variables (PASI, time since diagnosis, current treatment) and BSA scores were collected for each patient in the two visits. To calculate BSA scores traditional method (visual grading following the nine rule of Wallace method’s) and the optical pencil method (BSA software developed) were used. Inter-intra observers reliability, variability between BSA scores regarding the new tool, versus the traditional method, and the tool’s usefulness will be assessed.

**RESULTS:** Fifty-six patients were included. Mean (SD) age was 48.93 (16.76) years. Mean (SD) time since diagnosis was 18.77 (14.28). Pearson’s correlation coefficient between both methods was 0.91 (p < 0.01). Intraobserver correlation for each of the methods was 0.91. The correlation among both methods was in the first visit 0.92 and 0.90 in the second visit. The ICC was higher than 0.85 independently of which of the two methods were used firstly. The investigators considered that the new method is easy to use (94%), it guides towards the disease management (64%) and standardizes the calculation of the body surface area (86.4%).

**CONCLUSION:** These results can prove that the software to assess BSA has shown to be valid to be used both in clinical practice and in clinical studies. Therefore, the optical pencil method to quantify BSA can be used as standard for the assessment of involved body surface area in the management of psoriatic patients.

**QUANTITATIVE ASSESSMENT OF PATIENT-DEFINED BENEFIT IN DERMATOLOGY**

Schafer I, Rustenbach Sj, Reich C, Augustin M

University Clinics of Hamburg, Hamburg, Germany

**OBJECTIVES:** In an increasing number of European countries patient-defined benefit is considered important in the valuation of therapy. So far, most procedures used for benefit assessment do not cover the broad spectrum of benefits relevant to patients nor do they allow for an individual weighting of preferences. In this context a patient-reported benefit questionnaire was developed and validated.

**METHODS:** Initially, open questioning of n = 100 dermatological patients generated a pool of 213 benefit items which were converted into a 24 item-list by an expert panel of dermatologists, psychologists and patients. This pilot version of the questionnaire was evaluated in a group of n = 500 patients with 10 dermatological diagnoses. Basic principle of the instrument is pre/post data-collection. Prior to therapy, individually perceived needs (Patient Needs Questionnaire, PNQ) are obtained: For each of the 24 standardized items patients rate its importance on a Likert scale ranging from 0 (“not important at all”) resp. “doesn’t apply to me”) to 4 (“very important”). At the end of therapy the degree to which these benefits (Patient Benefit Index, PBI) also ranges from 0 to 4.

**RESULTS:** Besides good acceptance and feasibility the PBI showed construct validity and the PNQ a high internal consistency with Cronbach’s alpha > 0.94. Diagnostic groups presented different and clinically plausible outcome-patterns: Whereas the PBI was rather low for all vitiligo-therapies (mean = 1.03, SD 1.13, n = 711) wound-patients undergoing vacuum-assisted therapy (n = 172) showed a mean PBI of 2.75 (SD = 0.89).

**CONCLUSION:** The PBI is a valid and reliable instrument to obtain patient-defined and individually weighted therapeutic benefits in clinical and public health studies.
