Outcomes of extracorporeal life support for low cardiac output syndrome after major cardiac surgery

Sung Jun Park, MD, Joon Bum Kim, MD, Sung-Ho Jung, MD, PhD, Suk Jung Choo, MD, PhD, Cheol Hyun Chung, MD, PhD, and Jae Won Lee, MD, PhD

Objective: Extracorporeal life support (ECLS) is a widely accepted modality for the treatment of postoperative low cardiac output syndrome (LCOS) after major cardiac surgery by providing temporary circulatory support for the stunned myocardium. We sought to identify the factors that affect outcomes of ECLS for postoperative LCOS.

Methods: From 2005 to 2011, of a total of 9267 adult patients underwent major cardiac surgery, 93 patients (aged, 60.6 ± 13.8 years; 47 women) underwent ECLS to treat postoperative LCOS.

Results: Thirty-nine (41.9%) patients were weaned off ECLS successfully, and 1 patient underwent heart transplantation. A total of 23 patients (24.3%), including 1 heart transplantation recipient, survived until the end of the follow-up period (median, 611 days; range, 125-2247 days). On logistic regression analysis, old age (P < .001), a high blood lactate level before ECLS initiation (P < .001), cardiopulmonary bypass weaning failure after surgery (P < .001), and postoperative bleeding (P = .012) were independent factors associated with mortality. In contrast, administration of anticoagulant nafamostat mesilate (P = .040) was found to be associated with improved outcomes of ECLS. When the predictive value of pre-ECLS blood lactate level for mortality was assessed using the receiver operating characteristic curve, the greatest accuracy was obtained at the cutoff value of 7.9 mmol/L, with 63% sensitivity and 68% specificity.

Conclusions: High lactate level before ECLS is an independent predictor of mortality after ECLS, necessitating earlier ECLS implementations before profound lactic acidosis develops. Moreover, nafamostat mesilate should be considered as alternative to heparin to reduce the risk of bleeding in these high-risk patients. (J Thorac Cardiovasc Surg 2014;147:283-9)
cardiopulmonary life support, and (3) 33 patients with postoperative cardiopulmonary bypass (CPB) weaning failure. The study was approved by the institutional ethics committee/review board of the University of Ulsan, and the requirement for informed patient consent was waived in view of the retrospective nature of the study.

### ECLS Devices

In all 93 patients, venoarterial ECLS was administered via peripheral cannulation involving the common femoral artery and vein or internal jugular vein. The ECLS system consisted of a centrifugal pump, a hollow-fiber membrane oxygenator with an integral heat exchanger, and a heparin-bound circuit. Three types of ECLS system were used: the Capiox emergency bypass system (Terumo, Tokyo, Japan) was used for 80 (86%) patients, the PLS system (Maquet, Hirrlingen, Germany) for 6 (6.5%), and the Bio-Console 560 system (Medtronic, Minneapolis, MN) for 7 (7.5%) patients.

### Anticoagulation

Before cannulation, an intravenous heparin bolus of 100 U/kg was administered to achieve a citrate activated clotting time (ACT) (measured using a Hemochron 401 machine; Soma Technology, Bloomfield, Conn) of 300 seconds, except in patients with a high risk of bleeding or in patients who were actively bleeding. The latter 2 classes of patients received a half dose of heparin. After the patients were connected to the ECLS circuit, the ACT was normally maintained within a range of 180 to 200 seconds. However, when hemorrhage had occurred or was anticipated, an attempt was made to ensure a lower ACT of 160 to 180 seconds. During the weaning process, an ACT of less than 200 seconds was achieved by significantly reducing the pump flow rate. Whenever CPB weaning failed after surgery, ECLS was performed. Heparin was then replaced by protamine sulfate, which was administered at a dose 25% lower than normally used.

In 2010, we began to use nafamostat mesilate (Futhan; Torii Pharmaceutical, Tokyo, Japan), a synthetic serine protease inhibitor, as an alternative anticoagulant to heparin for actively bleeding patients immediately after surgery. For these patients, a half dose of heparin was administered before cannulation, and ACT was maintained between 160 to 180 seconds after the administration of a starting dose of 0.75 mg/kg nafamostat mesilate. The maintenance dose of nafamostat mesilate was adjusted between 0.5 mg/kg and 1 mg/kg according to hourly measurements of ACT.

### ECLS Management

The ECLS blood flow was maintained at a cardiac index of at least 2.4 L · min⁻¹ · m⁻². The mean arterial blood pressure was targeted at 60 to 70 mm Hg. To maintain the appropriate mean arterial pressure, we administered vasopressors as needed, rather than inotropic agents. The patients’ hematocrit values were maintained at 30% to 35%, and platelets were transfused when the platelet count was less than 100 × 10⁷/mm³ for high bleeding risk patients and 50 × 10⁷/mm³ otherwise. An antegrade perfusion catheter was routinely placed distal to the arterial cannulation site for distal limb perfusion, except in instances in which this placement failed owing to technical difficulties. If signs of ischemia in the distal limbs developed, we changed the arterial cannulation to the opposite side of the femoral artery.

Successful weaning was defined as the separation from ECLS without mortality over a 24-hour period without resumption of ECLS. Generally, the weaning process started with the prospect of the recovery of cardiac function when echocardiography showed adequate ventricular filling and an ejection fraction of greater than 30% to 35% at ECLS flow of a cardiac index of 1.0 L · min⁻¹ · m⁻². As ECLS weaning proceeded, the ECLS flow was gradually reduced to 0.5 L/min. If the hemodynamic parameters remained stable for 30 minutes at the ECLS flow of 0.5 L/min, ECLS was removed from the bedside.

### Statistical Analysis

Categorical variables are presented as frequencies and percentages and were compared using the χ² test or Fisher’s exact test. Continuous variables are expressed as mean ± standard deviation and were compared using the Student unpaired t test. For multivariable analyses of mortality data, a logistic regression model was used. Variables with a P value ≤ .20 in univariable analyses were candidates for the multivariable models. Multivariable analyses involved a backward elimination technique, and only variables with a P value ≤ .10 were used in the final model. Results were expressed as a hazard ratio (HR) with 95% confidence intervals (CIs). The predictive value of pre-ECLS lactate level for mortality was evaluated by analyzing areas under receiver operating characteristic curves, with their 95% CIs. The optimal cutoff value corresponded to the value with the greatest accuracy. All reported P values are 2-sided. Statistical analyses were performed with SPSS 18.0 for Windows Software (SPSS Inc, Chicago, Ill).

### RESULTS

The baseline characteristics of the patients are listed in Table 1. The patients who died were older and required a longer CPB time during surgery than those who survived. The preoperative echocardiographic data, however, showed no significant differences between the 2 groups.

Table 2 compares the variables related to ECLS management and complications in patients according to their final vital status. The levels of serum lactate level before ECLS were significantly higher in patients who died than in those in the group of survivors. Twenty-one (22.6%) patients were supported with an IABP before ECLS was begun. For 33 (35.4%) patients, ECLS commenced in the operating room, immediately after the main cardiac procedure, and as a result of CPB weaning failure. For the remaining 60 patients, ECLS commenced in the intensive care unit owing to delayed circulatory collapse after cardiac surgery. Among these 60 patients, 21 patients had cardiac arrest while ECLS was being instituted, and the median arrest time before the initiation of ECLS was 31 minutes (range, 3-142 minutes). Including these 21 patients, the median time interval from the end of the operation to the initiation of ECLS in the intensive care unit was 13.5 hours (range, 0.6-702.1 hours).

### Overall Outcomes

Details of complications that arose during ECLS are provided in Table 2. Twenty-five (26.9%) patients required...
reoperation owing to mediastinal bleeding, and 11 (11.8%) died of uncontrolled bleeding immediately after the operation, while on ECLS. Among 14 (15.1%) patients who had complications associated with distal limb ischemia, 2 underwent toe amputation. New-onset neurologic events occurred in 7 (7.5%) patients, including intracerebral hemorrhage in 3, subdural hemorrhage in 1, cerebral infarction in 2, and spinal infarct resulting in quadriplegia in 1 further patient. Six (6.5%) patients had complications that involved bowel infarction and all died of multiple organ failure, including 2 patients who underwent bowel resection.

Figure 1 summarizes the outcomes of ECLS. One patient underwent a successful HT and survived. The successful weaning rate was 41.9% (39/93). Fifteen patients died after successful weaning from ECLS in hospital. Of these 15 patients, 5 had multiple organ failure, 2 had profound cardiac failure, 2 had sepsis, 2 had panperitonitis, 2 had aortic rupture, 1 had intracerebral hemorrhage, and 1 had gastrointestinal bleeding. Hence, 24 patients survived until the time they were discharged. During follow-up, 1 patient died of sepsis owing to graft infection after an ascending aorta replacement 182 days after the operation. Another patient died of heart failure 742 days after coronary artery bypass grafting. A final total of 23 (24.3%) patients, including 1 HT recipient, survived until the end of the follow-up period (median follow-up duration, 611 days; range, 125-2,247 days).

The outcomes of ECLS were summarized according to 3 clinical situations in Figure 2. Notably, the results of the CPB weaning failure group were poor, showing a weaning rate of 21.2% and a survival of 15.1%. In contrast, successful weaning and survivals were 53.3% and 40.0%, respectively, in patients with other clinical setting requiring ECLS.

Both the successful weaning and survivals tended to improve over the course of 7 years of experience (Figure 3).

### Independent Predictors of Mortality

Multivariable analyses revealed that old age (HR, 1.04; 95% CI, 1.01-1.06; P = .001), a high serum lactate level before ECLS initiation (HR, 1.13; 95% CI, 1.06-1.20; P < .001), CPB weaning failure after surgery (HR, 3.22;
95% CI, 1.79-5.78; \( P < .001 \), and postoperative bleeding (HR, 2.00; 95% CI, 1.17-3.42; \( P = .012 \)) were independent factors associated with mortality. In contrast, the administration of the anticoagulant nafamostat mesilate (HR, 0.47; 95% CI, 0.23-0.97; \( P = .040 \)) was found to be associated with an improved outcome of ECLS. The independent predictors for weaning failure from ECLS were also summarized in Table 3.

The predictive value of the serum lactate level before initiation of ECLS for mortality was assessed using the receiver operating characteristic curve. The best accuracy for prediction of mortality was at the cutoff value of 7.9 mmol/L, with a sensitivity of 63% and a specificity of 68%, showing an area under the curve of 0.73 (95% CI, 0.61-0.84; \( P = .002 \)) (Figure 4). The patients whose serum lactate level was below the cutoff value of 7.9 mmol/L before the initiation of ECLS showed higher survivals than the patients whose serum lactate level was greater than 7.9 mmol/L (Figure 5).

**DISCUSSION**

Notwithstanding improvements in surgical techniques, cardiac anesthesia, and myocardial protection during major cardiac surgery over the past few decades, the incidence of LCOS that requires mechanical support has not decreased.\(^\text{10}\) This can be attributed to the extended indications of surgical candidates, many of whom are older and have impaired ventricular function and comorbidities.

ECLS is a widely accepted temporary mechanical support and is used as “rescue therapy” for emergency and unexpected cardiogenic shock owing to the ease and rapidity with which it can be applied and its ability to rapidly restore the circulation that supports biventricular and respiratory function. Nonetheless, ECLS is strongly associated with complications such as bleeding, limb ischemia, infection, and thromboembolic events,\(^\text{11}\) and the occurrence of these events appears to increase throughout the course of ECLS. Hence, when the failing heart is unlikely to recover after more than 48 to 72 hours of ECLS, it is advisable to bridge this procedure to either implantation of a VAD or HT before end-organ insults or complications arise.\(^\text{2,7}\)

Owing to the costs associated with implantable VADs, HT is currently the only solution to treat profound heart
failure in South Korea. Unfortunately, the number of patients waiting for heart transplants is many times greater than the supply of donor hearts, and fewer than 100 heart transplants are performed annually despite the recent increase in rates of organ donation. Hence, the primary intention of ECLS should be limited to improving cardiac recovery in patients with LCOS after cardiac surgery.

The successful weaning rate from ECLS was measured at 41.9% in the present study. However, given that 38.4% of the patients in our study cohort died in the hospital after successful weaning, the hospital survival was only 25.8%. This outcome is comparable with the results of previous studies of ECLS that reported early survival rates ranging from 16% to 41%. These reports also suggested that there has not been significant improvement in early survival over the past few decades, despite technical improvements in ECLS devices and better management skills. Similarly, a previous analysis of 517 patients who received ECLS has reported a relatively constant survival over the course of a 12-year period. In contrast, the survival after ECLS at our center appears to have increased over the past 7 years of the study period, with a rate of 40% for the past 2 years (Figure 2). A reduction in the frequency of bleeding complications, which is associated with the use of nafamostat mesilate for anticoagulation, may account for this better outcome. The low lactate levels in our patients before the initiation of ECLS also likely contributed to the result.

Recent studies have demonstrated that older age, evidence of organ system dysfunction, a history of cardiac surgery, extensive aortic operations, neurologic events, and failure to use an IABP are all predictors of mortality during ECLS. Our current findings, however, suggest that advanced age, high levels of serum lactate before ECLS initiation, CPB weaning failure at the end of the operation, postoperative bleeding, and nonuse of

nafamostat mesilate are also predictive of mortality during ECLS.

The discrepancies in the results between this study and the cited studies may be attributed to the differences in the subject patient population and discrepancies in analytic viewpoints. New-onset neurologic events, for instance, occurred in 7 patients during ECLS in the present study, and most of these patients died (n = 6, 85.7%). Although the neurologic events were strongly related to resultant mortality, we believe the causal relationship between the neurologic events and mortality is difficult to be proven in a limited number of patients. This particularly matters because the neurologic damage may be one of the consequences in the process of irreversible multiple organ damage rather than an independent risk factor of mortality. For these reasons, we did not include the neurologic events as one of the candidate risk covariates when determining the risk factors of mortality in this study. The concomitant usage of IABP during ECLS was believed to provide superior coronary perfusion potentially leading to more favorable outcomes.3,4,13 In the present study, however, there were no significant differences in overall clinical outcomes between the IABP group and the non-IABP group. Regarding this issue, we may find a clue from a recently published study that prospectively randomized patients to IABP support versus no IABP support in the setting of acute myocardial infarction presenting with shock.14 The study found no additional benefit from IABP in these patients. We believe that the sufficient coronary perfusion pressure can be achieved by maintaining mean arterial blood pressure over 60 mm Hg even without IABP in the setting of ECMO support. Moreover, IABP may carry further risks of complications related to vascular access. Risk versus benefit of additional IABP in the setting of ECMO support may need further verifications through prospective studies.

The early initiation of ECLS before the onset of profound cardiopulmonary collapse and secondary organ injuries is ideal. Outcomes of ECLS were significantly associated with the severity of pre-ECLS cardiogenic shock, as measured by lactate levels.3,15 Our data also suggest that high lactate levels are associated with adverse outcomes. We routinely measured the serum lactate level every 2 to 3 hours, and the value just before the initiation of ECLS was analyzed to determine the timing appropriate for the initiation of ECLS. Previous studies of ECLS after postcardiotomy cardiogenic shock indicated that postoperative mediastinal bleeding was the major problem in the management of this treatment.5,12,16 To reduce bleeding complications, we maintained blood cell components and coagulation factors at adequate levels and routinely administered aprotinin or tranexamic acid. Despite these efforts, the redo thoracotomy rate for the correction of excessive bleeding ranged from 40.0% to 87.3%.

In 2010, we began to administer nafamostat mesilate (Fu- than; Torii Pharmaceutical, Tokyo, Japan) to the ECLS regimen for patients with a tendency to bleed excessively. Nafamostat mesilate is a synthetic protease inhibitor that inhibits coagulation and fibrinolysis owing to its potent inhibitory activity toward thrombin, plasmin, trypsin, kallikrein, certain coagulation factors (XIIa, Xa), and certain complement factors (C1r, C1s).17,18 The use of nafamostat mesilate has been associated with fewer hemorrhagic complications than heparin during extracorporeal circulation during continuous venovenous hemodiafiltration.19 A favorable outcome from the use of nafamostat mesilate as an anticoagulant during ECLS was also reported previously.20 Abnormal bleeding after CPB may be the result of excessive fibrinolysis21,22 and/or a transient impairment of platelet function.23,24 Murase and colleagues25 have demonstrated that nafamostat mesilate inhibits fibrinolysis and preserves both platelet counts and platelet function during CPB and the postoperative course, and it contributes to the reduction of blood loss postoperatively. On the other hand, heparin enhances fibrinolytic activity during CPB, leading to the dissolution of clots and recurrence of bleeding. Fourteen patients in our present study cohort who received nafamostat mesilate for anticoagulation instead of heparin showed a lower occurrence of bleeding complication than patients who received heparin. Of these 14 patients, only 4 (28%) had mediastinal bleeding, compared with 32 (40.5%) of the 79 patients who received heparin and had mediastinal bleeding. However, the difference in frequencies of bleeding complications between the 2 groups was not statistically significant. This may be due to the small number of patients in the nafamostat mesilate group and the fact that the heparin group includes patients without a risk of bleeding complications, whereas the nafamostat mesilate group only contains patients at high risk of bleeding complications. The adequacy of ACT determinations to evaluate the need to monitor the extent of anticoagulation mediated by nafamostat mesilate remains to be established.

Limitations

This study is subject to the limitations inherent in retrospective studies of observational data from a single center. The nonrandomized design might have affected our results owing to unmeasured confounders, procedure bias, or detection bias. The study was conducted in the setting of a high-volume tertiary referral center in a country with unique medicosocial circumstances where availability of VAD or HT is very limited, and therefore the results may not be generalizable to other centers in different situations. Although the subject patient number was not small compared with previous studies of ECLS, the absolute number
of patients enrolled was small, particularly the number of patients who received nafamostat mesilate.

CONCLUSIONS

Owing to the lack of availability of implantable VAD and limited availability of donor hearts, ECLS has been intended to bridge to cardiac recovery. High lactate levels before ECLS and susceptibility to bleeding complications are independent predictors of mortality after ECLS. Hence, ECLS should be initiated before development of profound lactic acidosis. Moreover, nafamostat mesilate should be considered as an alternative to heparin to reduce the risk of bleeding-related complications in patients at high risk of this occurrence.
