Anomalous coronary arteries: Depiction at dual-source computed tomographic coronary angiography

Hai Xu, MD, Yinsu Zhu, MD, Xiaomei Zhu, MD, Lijun Tang, MD, PhD, and Yi Xu, MD

Objective: To retrospectively determine the imaging features of coronary artery anomalies depicted at dual-source computed tomographic coronary angiography (DSCT-CA).

Methods: We reviewed the case histories of 12,145 patients with suspected coronary arterial disease who underwent DSCT-CA at our institution. Multiplanar reformation, maximum-intensity projection, and volume-rendered imaging were performed on an offline workstation. Each study was assessed retrospectively for the origin and course of the anomalous coronary artery by a minimum of 2 cardiovascular radiologists; decisions were made in consensus.

Results: There were 124 (1.02%) patients with coronary anomalies. Fifty-one patients demonstrated an anomalous origin of the right coronary artery from the left sinus of Valsalva or the left main artery. An anomalous origin of a left circumflex artery from the right sinus of Valsalva or the right coronary artery was depicted in 17 patients. An anomalous origin of a left main artery from the right sinus of Valsalva was depicted in 1 patient. A single coronary artery was shown in 4 patients, and congenital transposition of the great arteries was associated with this anomaly in 1 patient. In the remaining 50 patients, coronary artery fistulas were identified. Eight patients were referred after an equivocal conventional coronary angiogram.

Conclusions: DSCT-CA is a reliable noninvasive tool that allows accurate delineation of coronary arterial anomalies in an appropriate clinical setting and provides detailed 3-dimensional anatomic information that may be difficult to obtain with invasive coronary angiography. (J Thorac Cardiovasc Surg 2012;143:1286-91)

Coronary artery anomalies are rare. Most of these anomalies produce no clinical symptoms during life. Approximately 20% of these anomalies produce life-threatening symptoms, including arrhythmias, syncope, myocardial infarction, or sudden death. Indeed, congenital coronary artery anomalies are the common cause of sudden death in young competitive athletes, accounting for 13% of cases, which is second in frequency to hypertrophic cardiomyopathy.

For several decades, conventional invasive coronary angiography has been used for premorbid diagnosis of coronary artery anomalies. However, this technique is not only invasive, but expensive, and cannot always adequately provide the precise information about the abnormal vessels. Noninvasive coronary angiography has become feasible as temporal and spatial resolution improves with the development of electrocardiographically gated multi-detector row computed tomography (MDCT). However, MDCT imaging can be limited by motion artifacts caused by limited temporal resolution in patients with high heart rates as well as patients with arrhythmia.

The recently introduced dual-source computed tomography (DSCT) scanner uses 2 x-ray tubes and detectors to achieve an improved temporal resolution up to 83 ms. It is now possible and practical to have high-quality cardiac imaging without beta-blocker premedication even in patients with high heart rates.

The aim of this article is to retrospectively determine the imaging features of coronary artery anomalies depicted at DSCT coronary angiography (DSCT-CA).

PATIENTS AND METHODS

Patients

Between July 2006 and June 2011, 12,415 case studies of DSCT-CA were conducted in our institution. All patients had known or suspected coronary artery obstructive disease with atypical chest pain or stable angina. Contraindications for the examination were previous allergy to iodinated contrast medium, nonsinus rhythm, renal insufficiency, and cardiac insufficiency. A retrospective evaluation was performed to identify all patients with anomalous coronary vessels.

DSCT-CA: Scan Protocol and Reconstruction

All patients were examined with a DSCT system (Somatom Definition; Siemens Medical Systems, Erlangen, Germany). Before scanning was performed, the procedure was explained to the patients in detail and nitroglycerin (0.5 mg) was administered sublingually to induce coronary vasodilatation. Between 40 and 110 mL of nonionic contrast medium (Schering Ultravist, Iopromide, 370 mg iodine per milliliter) was injected...
intravenously at a flow rate of 2.3 to 7.4 mL/s followed by a 40-mL saline flush at the same rate of contrast. Beta-blocker premedication was not used in any patient before the DSCT examination for heart rate regulation.

Bolus tracking was used to trigger data acquisition by placing a region of interest over the descending aorta and setting the trigger threshold to 100 Hounsfield units above baseline. Scanning was performed in a craniocaudal direction covering the region from the aortic root above the ostium of the left coronary artery to the diaphragm. Scanning parameters were as follows: detector collimation, 2 × 0.6 mm; slice collimation, 2 × 64 × 0.6 mm by means of a z-flying focal spot; gantry rotation time, 330 ms; heart rate–dependent pitch, 0.20 to 0.42; tube current, 380 to 400 mAs; tube voltage, 120 kV. The scan time was about 7.9 to 14.1 seconds for a single breath hold.

The coronary arteries were reconstructed retrospectively at best diastolic or best systolic phases with the fewest motion artifacts. Axial images were reconstructed with 0.75-mm slice thicknesses and 0.5-mm increments using a medium soft-tissue convolution kernel (B26). Further reconstructions were obtained with 2-dimensional multiplanar reformation (MPR), 3-dimensional maximum-intensity projection (MIP), and 3-dimensional volume-rendered (VR) imaging were performed on an offline workstation (Syngo Multimodality Workstation; Siemens, Erlangen, Germany).

**Image Review**

All images were assessed in a blinded manner by a minimum of 2 cardiovascular radiologists. The determination of coronary artery origin and course of the anomalous vessel was reached by consensus.

**RESULTS**

DSCT-CA was performed successfully without any complication in all patients. There were 124 patients (80 male and 44 female) with coronary anomalies. The patients ranged in age from 5 to 86 years (mean age, 57.6 years). The effective radiation dose ranged from 10.5 to 22.3 mSv (mean dose, 13.6 mSv). The heart rate ranged from 45 to 126 beats/min (mean heart rate, 81 beats/min).

Among the 80 (64.5%) men and 44 (35.5%) women, there were 69 anomalies with origin of the coronary artery or branch from the opposite or noncoronary sinus and an anomalous course (Figures 1, A and B, and 2), 4 anomalies with a single coronary artery (Figure 1, C), 1 anomaly associated with congenital transposition of the great arteries, and 50 anomalies with coronary artery fistula (Figure 3). In 1 of these, a complex coronary artery–pulmonary artery fistula with conus artery aneurysm was clearly delineated using a 3-dimensional VR image (Figure 3, B), which was misdiagnosed as a thrombus in the right atrium by echocardiography.

Incidences of coronary anomalies and patterns were summarized in Table 1. Origin and drainage sites of coronary artery fistulas in 50 patients were summarized in Table 2.

Among 69 patients with anomalous origin of the coronary artery from the opposite sinus, 50 anomalous arteries ran between the aorta and the pulmonary artery and took an interarterial course (Figures 1, A, and 2), 18 anomalous arteries passed posterior to the aortic root and took a retroaortic course (Figure 1, B), and 1 anomalous artery extended around the front of the pulmonary artery and took a prepulmonic course.

Among the 50 patients with an interarterial course in our series, all patients had symptoms: chest pain (37/50), syncope (11/50), or dyspnea on exertion (11/50). Fifteen patients had significant coronary artery stenosis (stenosis rate ≥ 70%), 14 mild or moderate coronary artery stenosis (stenosis rate < 70%), and 21 had an absolutely normal coronary artery (no stenosis). Myocardial bridge was found in 8 of these 21 patients without any plaque within the coronary arteries.

Overall, conventional coronary angiography could not confidently identify the precise anomaly in 8 patients with anomalous arteries (Figure 1, A and C).

In each case, DSCT-CA unequivocally demonstrated the origin of the anomalous coronary artery and its course in relation to the great vessels.

**DISCUSSION**

Coronary artery anomalies were classified as hemodynamically significant or hemodynamically insignificant. Hemodynamically significant anomalies include an anomalous interarterial course between the pulmonary artery and the aorta, an anomalous origin of either the left or right coronary artery from the pulmonary artery, occasional myocardial bridge, and coronary artery fistula.

It is widely documented that coronary insufficiency and sudden death are associated with some of these variants, specifically those that have a course that runs between the 2 great arteries. The exact pathophysiologic mechanisms that cause ischemia have not been determined. In our series, there were 13 symptomatic patients who had an anomalous interarterial course with no other concomitant obstructive coronary disease or myocardial bridge. The finding suggests that the important factor for presentation symptoms is the interarterial course itself, which is consistent with the study by Gulati and associates.

Coronary artery anomalies are usually diagnosed during invasive coronary angiography. However, conventional coronary angiography sometimes is inadequate to delineate the precise course of the anomalous vessel because of a complex 3-dimensional geometry displayed in a relatively restricted 2-dimensional view. The low incidence of these
anomalies also results in limited experience for many angiographers and causes a large percentage of coronary artery anomalies to be categorized incorrectly at invasive coronary angiography. Among 26 patients undergoing invasive coronary angiography in our study, the anomaly was incorrectly classified after an equivocal coronary angiogram in 8 patients (Figure 1, A and B).

Noninvasive imaging techniques, including echocardiography, magnetic resonance (MR), electron-beam computed tomography, and MDCT, were introduced in the past few years and have proven to be reliable. Improvements in noninvasive diagnostic techniques have also increased the ability to easily and safely screen for the coronary congenital anomaly, leading to increased rates of diagnosis.

Transesophageal echocardiography may clinically detect coronary anomalies, but this method is not totally noninvasive and is too costly for screening large populations. In our study, 1 patient with a complex coronary artery–pulmonary artery fistula with conus artery aneurysm received an incorrect diagnosis of thrombus in the right atrium (Figure 3, B). In a continuous series of 2388 transthoracic echocardiograms obtained in children, Davis and associates observed 1 false-negative echocardiographic finding followed by sudden death related to a coronary anomaly newly found at necropsy, raising doubts about this method’s predictive value.

Substantial investigative works have been performed with regard to the use of MR angiography in the evaluation of the coronary artery anomalies. MR angiography holds the
greatest appeal because it avoids radiation and iodinated contrast agents. As shown in several studies, MR angiography provides an accurate assessment of the origin and proximal course of anomalous coronary arteries. Nevertheless, MR angiography has several limitations in the assessment of the coronary arteries. MR angiography can be limited by low spatial resolution and artifacts and can be technically challenging. Therefore, this technique is less helpful in evaluating fistulas and coronary origination outside the normal sinuses (eg, from a pulmonary artery). 

FIGURE 2. Images obtained in a 68-year-old man with a mean heart rate of 110 beats/min. A and B, Five-millimeter maximum-intensity projection and volume-rendered images clearly show the RCA originating from the LSV in the patient with a mean heart rate of 110 beats/min. For abbreviations, see Figure 1.

FIGURE 3. Images obtained in 2 patients with a coronary artery fistula. 1A, 1B, and 1C, Three-dimensional volume-rendered and 2-dimensional maximum-intensity projection images show the markedly enlarged and tortuous LCX coursing along the posterior cardiac surface. LM and LCX are markedly dilated while the LAD is of normal caliber. 2A, 2B, and 2C, Three-dimensional volume-rendered and 10-mm maximum-intensity projection images show an abnormal complex coronary artery to pulmonary artery fistula with LAD and RCA aneurysms. A plexus of tortuous vessels (black arrows) arising from the proximal RCA is clearly delineated. For abbreviations, see Figure 1.

Furthermore, MR angiography cannot be performed for patients with pacemakers or defibrillating devices, and it may be difficult to perform for claustrophobic patients and patients with tachycardia or certain arrhythmias.1
Electron-beam computed tomography has a high temporal resolution of 100 ms, however, its clinical application is limited by relatively poor z-axis resolution.1 Electrocardiographically gated MDCT systems were introduced in 1999. This is a most significant development for evaluation of the coronary artery disease. It enables rapid coverage of the coronary territory in a single breath hold and improved longitudinal resolution, approaching the ideal of "isotropic" spatial resolution.16 It has been reported that MDCT is superior to conventional angiography in delineating the ostial origin and proximal path of the anomalous coronary artery.17 However, MDCT imaging can be limited by motion artifacts caused by limited temporal resolution in patients with high heart rates as well as patients with arrhythmia. Therefore, beta-blocker administration is routinely used to reduce the heart rate, minimizing residual heart motion in all patients with a heart rate of more than 65 beats/min. Nevertheless, some patients with chronic obstructive pulmonary disease, bronchial asthma, second-and third-degree heart block, and severe peripheral vascular disease have contraindications to the use of beta-blocker drugs, and administration of beta-blocker drugs to patients scheduled for MDCT-CA might be logistically difficult.
With the recently introduced DSCT, which mainly improves the temporal resolutions, it is now possible and practical to have high-quality cardiac imaging without beta-blocker premedication even in patient with high heart rates.6,7 The DSCT system is equipped with 2 x-ray tubes and 2 corresponding detectors, which are mounted onto the rotating gantry with an angular offset of 90°. The temporal resolution is as high as 82.5 ms. The better temporal resolution and the ability to choose the optimal cardiac phase result in a near cessation of physiologic motion. As the spatial resolution of data collected is isotropic, images can be reviewed by 2-dimensional MPR and 3-dimensional reconstruction techniques including VR and MIP.18 The 3-dimensional reconstruction with viewing at an unlimited angle allows us to demonstrate anomalous vessels at the best projection, without repeated radiation exposure and an additional contrast load, and makes assessment of the size and exact location of the anomalous vessel feasible. Although these images were not crucial in the diagnosis of the anomaly, they were valuable for depicting the relationships among the coronary vessels, great vessels, and ventricles. Such images could be helpful for planning future cardiovascular intervention and give the surgeons a better understanding of the complex anatomy before operation.1,18 In our study, DSCT-CA unequivocally demonstrated the origin of the anomalous coronary artery and its course in relation to the great vessels in all cases, even in 1 patient with a mean heart rate of 110 beats/min (Figure 2). In addition, data obtained during DSCT-CA are often used to evaluate obstructive coronary disease, as well as cardiovascular function.19,20 Among the 50 patients with an interarterial course in our series, 15 patients had significant coronary artery stenosis (stenosis rate ≥ 70%). Such information was also useful to help the surgeons to make the decision of which surgical techniques to use to repair the anomaly.
DSCT-CA also has its own drawbacks. Allergy, renal, or cardiac insufficiency may prevent the use of intravenous contrast material in some patients. MR angiography is considered as a supplement in these patients. Another drawback is the high effective radiation dose to which a patient undergoing DSCT angiography is exposed. In our study, the mean effective radiation dose was 13.6 mSv. By comparison, the mean effective radiation dose with diagnostic coronary arteriography is 2.1 to 2.5 mSv as reported by Hunold and associates.21 Fortunately, investigators have shown that DSCT has the potential to reduce radiation dose exposure to as low as 3.8 mSv if the optimized and individual scan protocol is used.22 With the recent advent of second-generation DSCT equipped with two 128-slice acquisition detectors, the prospectively electrocardiographically gated step-and-shoot and the high-pitch mode data acquisition significantly lowers the radiation dose to less than 1 mSv.23

Limitations

We acknowledge the following study limitations. The most notable limitation is lack of a reference standard technique to prove that our DSCT-CA findings were correct. The direct visualization at surgery was considered to be the reference standard. Unfortunately, this “confirmatory” information was obtained in only 3 patients with coronary anomalies who underwent surgery. It is also reported that even surgery cannot be considered a consistently reliable standard reference technique because the anomalous coronary course is often obscured by epicardial fat.1 Another limitation is incomplete statistics of coronary anomalies. Myocardial bridges, duplication of arteries, high takeoff, and multiple ostia of coronary arteries were not counted in our study. One of the reasons is that, at the time of writing, there are no clear diagnostic criteria and no unified classification of the multiple variations. The greatest confusion in this regard is about myocardial bridges. Angelini24 suggests that they may be a normal variant.

Coronary arterial anomalies should be suspected in any young patient with symptoms of angina pectoris, near-fatal arrhythmias, or recurrent syncope.25 DSCT-CA is a reliable noninvasive imaging tool in the delineation of coronary anomalies, and it is superior to conventional invasive coronary angiography in delineating the origin and course of an anomalous coronary artery.
