Event recorder monitoring to compare the efficacy of a left versus biatrial lesion set in patients undergoing concomitant surgical ablation for atrial fibrillation

Simon Pecha, MD, Friederike Hartel, MD, Teymour Ahmadzade, MD, Muhammet Ali Aydin, MD, Stephan Willems, MD, Hermann Reichenspurner, MD, PhD, and Florian Mathias Wagner, MD

Objectives: Various lesion sets and subsequent success rates have been reported in patients receiving concomitant surgical ablation for atrial fibrillation. However, most of these results have been obtained by discontinuous monitoring. We report results using continuous event recorder rhythm monitoring to compare more accurately the efficacy of a left versus biatrial lesion set to treat patients with persistent atrial fibrillation.

Methods: Between July 2008 and December 2011, 66 patients with persistent or long-standing persistent atrial fibrillation underwent concomitant surgical atrial fibrillation ablation with a biatrial lesion set and subcutaneous event recorder implantation. The results and outcomes were compared with a propensity score–matched cohort of 66 patients with a left atrial lesion set and event recorder implantation. Event recorder interrogation was performed at 3, 6, and 12 months follow-up.

Results: The mean patient age was 70.2 ± 7.4 years, and 70.3% were male. No major ablation-related complications occurred. One-year survival was 94.8% with no statistically significant differences between the 2 groups. The overall rate of freedom from atrial fibrillation was 57.3% and 64.4% after 3 and 12 months follow-up, respectively. Three months postoperatively, patients in the biatrial group had a slightly higher rate of freedom from atrial fibrillation (63.6% vs 52.3% P = .22), but it did not reach statistical significance. At 12 months follow-up, a statistically significant higher rate of freedom from atrial fibrillation was observed in patients with a biatrial lesion set (74.4% vs 55.8%; P = .026). The mean atrial fibrillation burden in all patients was 15.1% ± 12.5% in the biatrial group and 21.2% ± 14.4% in the left atrial group 12 months postoperatively (P = .03).

Conclusions: Continuous rhythm monitoring by subcutaneous event recorder implantation was safe and feasible. In patients undergoing biatrial ablation, a statistically significant higher rate of freedom from atrial fibrillation was observed at 12 months follow-up. (J Thorac Cardiovasc Surg 2014;148:2161-6)

Atrial fibrillation (AF) is associated with an increased number of thromboembolic events, including stroke. Furthermore, it can lead to heart failure and results in an increased number of hospitalizations. Therefore, concomitant surgical AF ablation is recommended by guidelines for symptomatic patients and for asymptomatic patients at low risk for the surgical ablation procedure. Cox first reported his surgical AF ablation technique using the cut-and-sew principle in 1987, which was subsequently revised to the Cox-Maze III procedure.

Because of success rates greater than 90%, the Cox-Maze III procedure became the gold standard for surgical AF ablation. However, because of the complexity of the procedure, it was performed by only a few surgeons. After the cut-and-sew principle was recently replaced with the creation of transmural thermal lesions via the application of different energy sources, such as radiofrequency, high-frequency ultrasound, or cryotherapy, the use of the procedure has become widespread. This procedure is known as the “Cox-Maze IV” and contains a similar lesion set as in the initial Cox-Maze III procedure, including lesions in both atria.

Different modifications and simplifications of the original lesion set have been used over the years. In most patients, AF originates at the pulmonary veins, especially in patients with paroxysmal AF, and in such cases, a left atrial lesion set is considered sufficient by many specialists. However, in patients with persistent or long-standing persistent AF, there is an ongoing discussion about whether a biatrial lesion set results in higher success rates. All of the recent published studies comparing the efficacy of different lesion sets used discontinuous rhythm monitoring. However, studies comparing the efficacy of different follow-up
methods after surgical AF ablation have shown that short time rhythm monitoring, even with repeated 24-hour Holter electrocardiography (ECG), underestimates the rate of AF recurrence. The Reveal XT Performance Trial (XPECT) trial showed high sensitivity (96.1%) and negative predictive value (97.4%) for the detection of AF episodes by the Reveal XT (Medtronic Inc, Minneapolis, Minn) device, a subcutaneous implantable event recorder (ER). This device is programmed to detect arrhythmia episodes by analysis of irregularity and incoherence of R-R intervals. The Reveal XT is able to detect the duration of AF episodes and burden, defined as the percentage of time the patient is in AF during follow-up. The aim of our study was to compare the efficacy of left and bialtral lesion sets through continuous rhythm monitoring using subcutaneous ER implantation.

MATERIALS AND METHODS

From July 2008 to December 2011, 255 patients underwent concomitant surgical ablation because of persistent or long-standing persistent AF. Of those patients, 88 received bialtral ablation and 167 received left atrial ablation. Classification of persistent and long-standing persistent AF was according to Heart Rhythm Society/European Heart Rhythm Association/European Cardiac Arrhythmia Society expert consensus statement on catheter and surgical ablation of AF. Propensity score matching resulted in a group of 66 patients who received a bialtral lesion set and subcutaneous ER (Reveal XT) implantation and a control group of 66 patients who received a left atrial lesion set and ER implantation. All patients received implantation of the Reveal device during surgical ablation procedure. Patients were matched by age, gender, left ventricular ejection fraction, left atrial diameter, AF duration, surgical procedure, and energy source type.

In group 1, bialtral ablation was performed in 66 patients, including left atrial bilateral pulmonary vein ablation, box lesion, and left atrial appendage and ishmus isolation. Right sided-lesion set included intercal vein lesion and isolation of the cavotricuspid isthmus, right atrial appendage, and terminal crest. In group 2, only the left atrial lesion set was conducted. Applied energy sources included argon-based cryoaulation (cryoICE cryoaulation probe, AtriCure Inc, West Chester, Ohio; Cardioblate CryoFlex Surgical Ablation Probe, Medtronic Inc) in 21 patients (bialtrial, n = 12; left atrial, n = 9; P = .63), unipolar radiofrequency ablation (Cardioblate unipolar RF pen, Medtronic Inc) in 52 patients (bialtrial, n = 28; left atrial, n = 24; P = .37), and bipolar ablation (Cardioblate BP2 device and Cardioblate Surgical Ablation System Generator, Medtronic Inc; Atricure Isolator Synergy Ablation Clamp, AtriCure Inc) in 59 patients (bialtrial, n = 26; left atrial, n = 33). None of these energy sources were used in combination.

Statistical Analysis

All statistical analyses were performed using SPSS version 18.0 (SPSS Inc, Chicago, Ill). Continuous values are expressed as mean ± standard deviation and were compared using the Student t test or Mann–Whitney test as appropriate. Categoric variables are displayed as frequencies, and percentages were compared using the chi-square test or Fisher exact test as appropriate. Reported P values are 2-sided. A logistic regression model was used to generate a control group with a left atrial lesion set matched for the variables detailed earlier. Matching was performed by selecting a patient randomly from the bialtral group and identifying a partner in the control group with the nearest logit-transformed propensity score. Matching balance was assessed using statistical analysis with the Fisher exact test for categoric variables and the Student t test for continuous variables.

Follow-up

Follow-up with ER interrogation was conducted 3, 6, and 12 months postoperatively. AF recurrence was defined as an AF burden greater than 0.5% or a single stored AF episode with duration more than 30 seconds on ER interrogation. However, one needs to realize that the Reveal ER has a blanking period of 2 minutes because R-R intervals are analyzed within each 2-minute period of time. When there is an uncorrelated irregularity of the R-R intervals within the 2-minute interval, the heart rhythm in this period is classified as AF. All stored episodes were manually validated during follow-up visits. The primary end point of the study was freedom from AF after 12 months. To obtain success rate at 12 months, stored AF episodes from ER interrogation between 6 and 12 months were included. The postoperative and discharge rhythm results were obtained using 12-lead ECG. The antiarrhythmic drugs and anticoagulation regimens were maintained for 3 months postoperatively in all patients and then adapted according to the ER rhythm results. In patients without contraindications, amiodarone was used as the first-line antiarrhythmic drug therapy; otherwise, other class I or III antiarrhythmic drugs were used for at least 3 months postoperatively.

RESULTS

Baseline patient characteristics are shown in Table 1. Because of the matching process, there were no statistically significant differences between the 2 groups. The mean patient age was 70.1 ± 7.5 years in the left atrial group and 70.5 ± 7.3 years in the bialtral group. The mean left ventricular ejection fraction was 51.5% ± 10.9% in patients with a left atrial lesion set and 51.9% ± 10.8% in the bialtral group. The mean left atrial diameter was 53.6 ± 7.5 mm for patients with a left atrial lesion set and 54.9 ± 8.0 mm in patients with bialtral ablation. The mean AF duration was 3.9 ± 3.2 years in patients with a left atrial set and 4.5 ± 3.8 years for patients with a bialtral lesion set. Surgical procedures and applied energy sources were equally distributed between the 2 groups (Table 2).

No major ablation or ER-associated complications occurred in any of the patients. There were no cases of intraoperative death. The in-hospital mortality rate was 2.2% (3/132) (bialtral, 3.0% 2/66; left atrial, 1.5% 1/66; P = .25), whereas the 30-day mortality rate was 3.0% (4/132) (bialtral, 3.0%; left atrial, 3.0%). The 1-year survival was 94.8% (125/132), and there were no statistically significant differences between the 2 groups (bialtral, 95.6%; left atrial, 93.9% P = .68). Three of 125 patients (2.4%) experienced perioperative stroke (left atrial, 2/63 [1.8%]; bialtral, n = 1/62 [1.0%]). Postoperative new permanent pacemaker implantation rate was 11.2% (7/62) and 6.5% (4/63) (P = .5) in the bialtral and left atrial groups, respectively.
Rhythm Results

All patients underwent ER interrogation at 3 and 12 months of follow-up. Six-month follow-up was performed in 61.7% of patients (69/132). There was no statistically significant difference between the 2 groups in terms of freedom from AF immediately after the procedure and at the time of discharge (left atrial 51.4% [34/66] vs 62.1% [41/66], \(P = .28\) and left atrial 51.1% [33/65] vs 60.6% [41/64], \(P = .28\), respectively) (Figure 1). At 3 and 6 months of follow-up, there were no significant differences in freedom from AF between the left atrial and biatrial groups (left atrial 53.2% [33/62] vs 63.9% [39/61], \(P = .22\) and 56.3% [18/32] vs 67.3% [25/37], \(P = .20\), respectively). However, it must be considered that only 61.7% of the patients underwent a 6-month follow-up.

One-year follow-up revealed a significantly different rate of freedom from AF of 55.8% (35/63) for patients with left atrial ablation compared with 74.4% (46/62) for patients with a biatrial lesion set (\(P = .026\)) (Figure 1). The rate of freedom from AF at 12 months follow-up off class I and III antiarrhythmic drugs was 50.7% (32/63) and 68.1% (42/66), respectively (\(P = .033\)). However, freedom from oral anticoagulation at 12 months follow-up was only 25.4% (16/63) in the biatrial group and 24.1% (15/62) in the left atrial group.

Atrial Fibrillation Burden

The mean AF burden of all patients was 25% in the biatrial group and 39% in the left atrial group at 3 months of follow-up. At 12 months of follow-up, a reduced AF burden was seen in all patients irrespective of ablation success. The AF burden in the entire cohort was 15.1% ± 12.5% (n = 62) in the biatrial group and 21.3% ± 14.4% (n = 63) in the left atrial group 12 months postoperatively (\(P = .03\)). For patients in whom ablation failed, the mean AF burdens of 35% (n = 62) and 43% (n = 63) were seen in the biatrial and left atrial groups, respectively.

**DISCUSSION**

In the literature, no consensus has been reached about the appropriate lesion set for patients with different types of AF. Specifically, there is a controversial discussion on which patients should be treated with an additional right-sided lesion set. In our study, we showed a statistically higher rate of sinus rhythm after 12 months in patients with persistent or long-standing persistent AF treated with a biatrial lesion set. This finding is consistent with a previous published meta-analysis by Barnett and Ad\(^1\) that included 69 studies with an overall number of 5885 patients with AF who received cardiac surgery alone or cardiac surgery with concomitant surgical ablation. In their analysis, the patients who received surgical ablation had statistically significant higher rates of sinus rhythm at all points of follow-up to 3 years. Furthermore, patients who had received the biatrial lesion set had statistically

**FIGURE 1.** Sinus rhythm rates during follow-up.
higher rates of freedom from AF than those who received the left atrial lesion set. Similar results were shown in a meta-analysis by Cheng and colleagues,\(^\text{11}\) that included 4647 patients with persistent or long-standing persistent AF. However, a higher incidence of postoperative permanent pacemaker dependency for patients receiving biatrial ablation has been shown in previous published studies, and caution is recommended while performing right-sided lesions.\(^\text{12,13}\)

In contrast to the results published by Barnett and Ad\(^\text{1}\) and Cheng and colleagues,\(^\text{11}\) other studies have indicated no difference in rhythm results between patients who received left atrial and biatrial ablation. A recent study by Soni and colleagues\(^\text{14}\) showed the rates of freedom from AF in patients who underwent biatrial lesion set, left atrial lesion set, and pulmonary vein isolation were 80.0%, 76.1%, and 56.9%, respectively, at 12 months of follow-up. This analysis suggested no improvement in patients who underwent an additional right atrial lesion set.\(^\text{14}\) The limitation of this study is that the success rates were obtained using 12-lead ECG, but a more extensive follow-up with at least a 24-hour Holter ECG would probably show different results.

However, it needs to be stressed that in most of the previous published studies, ablation success was defined by use of 12-lead ECG or 24-hour Holter monitoring.\(^\text{4-6,12,15-17}\) Recent studies comparing the accuracy of rhythm detection using different follow-up methods after AF ablation showed that intermittent rhythm monitoring underestimates the actual AF recurrence rate.\(^\text{9,17}\) Furthermore, after AF ablation, even patients in whom ablation failed may have reduced AF burden, which makes the detection of AF recurrence with snapshot follow-up methods more difficult and unreliable. Our study was the first to assess success rates of bialtrial and left atrial lesion sets using continuous subcutaneous implanted ER monitoring. We demonstrated superior results concerning freedom from AF recurrence in patients receiving biatrial ablation after 1 year of follow-up. The use of continuous rhythm monitoring in our study allows for a more accurate comparison of the 2 different lesion sets, because the sensitivity to detect recurrent AF episodes is high with this method. However, the ER used in this study has a limited storage capacity of 49.5 minutes. Therefore, in patients with a high AF burden, not all stored episodes can be manually validated, and there is a certain risk to over- or underestimate the AF burden. Furthermore, the Reveal ER classifies the heart rhythm for each subsequent time interval of 2 minutes and can only detect AF episodes with a duration of at least 2 minutes. This means that every stored episode in the Reveal ER corresponds to an AF duration of more than 2 minutes and represents a failure of ablation according to the guidelines. Despite this 2-minute blanking period, in previous published studies it has been shown that the Reveal device is an excellent tool to predict freedom from AF because of its high negative predictive values.\(^\text{10}\) Despite these limitations, the ability to detect AF episodes is far better than with 24-hour, 7-day, or 30-day monitoring.\(^\text{9,18,19}\) and in our opinion, ER monitoring is the best available monitoring strategy to date.

An important observation in our study was the increase in the sinus rhythm rate between 3 and 12 months follow-up. The current study also showed a reduction of AF burden over time, even in patients in whom ablation failed. However, the impact of reduction in AF burden and the resulting consequences remain undefined. Future larger, prospective studies need to be performed to determine clinically relevant cutoff values for the AF burden in regard to the anticoagulation and antiarrhythmic drug regimens.

Our study did not show a survival benefit for patients with restored sinus rhythm. Furthermore, no significant differences were observed in the survivals of patients with a left or biatrial lesion set. These results may be due to the relatively short 12-month follow-up period and the limited number of included patients. Regardless, this finding is consistent with the results of the meta-analysis by Barnett and colleagues,\(^\text{4}\) in which similar survivals were reported for patients with and without successful ablation. In contrast, in a propensity score–matched analysis by Lee and colleagues,\(^\text{20}\) patients with AF receiving surgical ablation had similar survival compared with patients without a history of AF. Furthermore, they showed a survival benefit for patients with successful ablation compared with those in whom AF ablation failed.\(^\text{20}\) These first promising results have to be confirmed in larger, prospective, randomized trials to determine the impact of AF surgery on long-term survival.

After 1 year of follow-up, no statistically significant difference was observed between the left and biatrial ablation groups in regard to stroke-free survival in the current study. This finding may be the result of low incidences of postoperative stroke in both groups, which may be one of the advantages of left atrial appendage closure or excision, which can be easily done during surgical AF ablation.

Measurement of AF burden is a relatively new method to determine the time a patient spent in AF. If a patient has an AF burden of 0% over a certain period of time, we consider the ablation as successful and the patient as AF free. Nevertheless, the impact of reduction in AF burden and the resulting consequences remain undefined. Future larger prospective studies need to be performed to determine clinically relevant cutoff values for the AF burden.
in regard to the anticoagulation and antiarrhythmic drug regimen.

**Study Limitations**

The major limitation of this study is that we used a retrospective data analysis to compare the biatrial and left atrial lesion set groups. Although we minimized the differences between the 2 groups by matching the patients using a logistic regression model, the disadvantages of a retrospective, nonrandomized study, including unknown confounders and selection and detection bias, cannot be completely avoided.

Further limitations are due to technical aspects of ER with its limited storage capacity of 49.5 minutes. Therefore, in patients with a high AF burden, not all stored episodes can be validated manually, and there is a certain risk to over- or underestimate AF burden. Furthermore, the ER used in this study classifies the heart rhythm for each subsequent time interval of 2 minutes and only detects AF episodes with a duration of at least 2 minutes. This 2-minute blanking period of the ER may result in underestimation of AF episodes. Additional limitations of the study are that we did not use intraoperative electrophysiologic mapping and testing to confirm the quality of the applied lesions, and that no follow-up beyond 12 months is available.

We started to perform AF surgery in 2002 and initially used only left atrial lesions in all patients. As a result of the published data and our own experience, in 2008 we introduced the use of biatrial lesions in patients with persistent and long-standing persistent AF. Therefore, the results of the biatrial ablation may be influenced by a certain learning curve.

Moreover, the heterogeneity of the energy sources used is a limitation of the study. Furthermore, there was no consistent treatment of left atrial appendage (excision or to exclusion), and we did not routinely use transesophageal echocardiography postoperatively to control the success of left atrial appendage management.

**CONCLUSIONS**

In the current study, in which all rhythm results were obtained by ER monitoring, we showed that a biatrial lesion set in patients with persistent AF results in statistically significant higher sinus rhythm rates at 12 months follow-up. Furthermore, over time, patients showed a reduction of AF burden, even those in whom ablation failed.
