SUMMARY

Hepatocellular carcinoma (HCC) is a slowly developing malignancy postulated to evolve from pre-malignant lesions in chronically damaged livers. However, it was never established that premalignant lesions actually contain tumor progenitors that give rise to cancer. Here, we describe isolation and characterization of HCC progenitor cells (HcPCs) from different mouse HCC models. Unlike fully malignant HCC, HcPCs give rise to cancer only when introduced into a liver undergoing chronic damage and compensatory proliferation. Although HcPCs exhibit a similar transcriptomic profile to bipotential hepatobiliary progenitors, the latter do not give rise to tumors. Cells resembling HcPCs reside within dysplastic lesions that appear several months before HCC nodules. Unlike early hepatocarcinogenesis, which depends on paracrine IL-6 production by inflammatory cells, due to upregulation of LIN28 expression, HcPCs had acquired autocrine IL-6 signaling that stimulates their *in vivo* growth and malignant progression. This may be a general mechanism that drives other IL-6-producing malignancies.

INTRODUCTION

Every malignant tumor is probably derived from a single progenitor that had acquired growth and survival advantages through genetic and epigenetic changes, allowing clonal expansion (Nowell, 1976). Tumor progenitors are not necessarily identical to cancer stem cells (CSCs), which maintain and renew fully established malignancies (Nguyen et al., 2012). However, clonal evolution and selective pressure may cause some descendants of the initial progenitor to cross the bridge of no return and form a premalignant lesion. Cancer genome sequencing indicates that most cancers require at least five genetic changes to evolve (Wood et al., 2007). How these changes affect the properties of tumor progenitors and control their evolution into a CSC is not entirely clear, as it has been difficult to isolate and propagate cancer progenitors prior to detection of tumor masses. Given these difficulties, it is also not clear whether cancer progenitors are the precursors for the more malignant CSC isolated from fully established cancers. An answer to these critical questions depends on identification and isolation of cancer progenitors, which may also enable definition of molecular markers and signaling pathways suitable for early detection and treatment. This is especially important in cancers of the liver and pancreas, which evolve over the course of many years but, once detected, are extremely difficult to treat (El-Serag, 2011; Hruban et al., 2007).

Hepatocellular carcinoma (HCC), the most common liver cancer, is the end product of chronic liver diseases, requiring

several decades to evolve (El-Serag, 2011). Currently, HCC is the third most deadly and fifth most common cancer worldwide, and in the United States its incidence has doubled in the past two decades. Furthermore, 8% of the world's population are chronically infected with hepatitis B or C viruses (HBV and HCV) and are at a high risk of new HCC development (El-Serag, 2011). Up to 5% of HCV patients will develop HCC in their lifetime, and the yearly HCC incidence in patients with cirrhosis is 3%–5%. These tumors may arise from premalignant lesions, ranging from dysplastic foci to dysplastic hepatocyte nodules that are often seen in damaged and cirrhotic livers and are more proliferative than the surrounding parenchyma (Hytioglou et al., 2007). However, the tumorigenic potential of these lesions was never examined, and it is unknown whether they contain any genetic alterations. Given that there is no effective treatment for HCC and, upon diagnosis, most patients with advanced disease have a remaining lifespan of 4–6 months, it is important to detect HCC early, while it is still amenable to surgical resection or chemotherapy. Premalignant lesions, called foci of altered hepatocytes (FAH), were also described in chemically induced HCC models (Pitot, 1990), but it was questioned whether these lesions harbor tumor progenitors or result from compensatory proliferation (Sell and Leffert, 2008). The aim of this study was to determine whether HCC progenitor cells (HcPCs) exist and if so, to isolate these cells and identify some of the signaling networks that are involved in their maintenance and progression.

We now describe HcPC isolation from mice treated with the procarcinogen diethyl nitrosamine (DEN), which induces poorly differentiated HCC nodules within 8 to 9 months (Verna et al., 1996). Although these tumors do not evolve in the context of cirrhosis, the use of a chemical carcinogen is justified because the finding of up to 121 mutations per HCC genome suggests that carcinogens may be responsible for human HCC induction (Guichard et al., 2012). Furthermore, 20%–30% of HCC, especially in HBV-infected individuals, evolve in noncirrhotic livers (El-Serag, 2011). Nonetheless, we also isolated HcPCs from *Tak1^{Δhep}* mice, which develop spontaneous HCC as a result of progressive liver damage, inflammation, and fibrosis caused by ablation of TAK1 (Inokuchi et al., 2010). Although the etiology of each model is distinct, both contain HcPCs that express marker genes and signaling pathways previously identified in human HCC stem cells (Marquardt and Thorgeirsson, 2010) long before visible tumors are detected. Furthermore, DEN-induced premalignant lesions and HcPCs exhibit autocrine IL-6 production that is critical for tumorigenic progression. Circulating IL-6 is a risk indicator in several human pathologies and is strongly correlated with adverse prognosis in HCC and cholangiocarcinoma (Porta et al., 2008; Soresi et al., 2006). IL-6 produced by in-vitro-induced CSCs was suggested to be important for their maintenance (Iliopoulos et al., 2009). Furthermore, autocrine IL-6 was detected in several cancers, but its origin is poorly understood (Grivnickov and Karin, 2008). In particular, little is known about the source of IL-6 in HCC. In early stages of hepatocarcinogenesis, IL-6 is produced by Kupffer cells or macrophages (Maeda et al., 2005; Naugler et al., 2007). However, paracrine IL-6 production is transient and does not explain its expression by HCC cells.

RESULTS

DEN-Induced Collagenase-Resistant Aggregates of HCC Progenitors

A single intraperitoneal (i.p.) injection of DEN into 15-day-old BL/6 mice induces HCC nodules first detected 8 to 9 months later. However, hepatocytes prepared from macroscopically normal livers 3 months after DEN administration already contain cells that progress to HCC when transplanted into the permissive liver environment of MUP-uPA mice (He et al., 2010), which express urokinase plasminogen activator (uPA) from a mouse liver-specific major urinary protein (MUP) promoter and undergo chronic liver damage and compensatory proliferation (Rhim et al., 1994). Collagenase digestion of DEN-treated livers generated a mixture of monodisperse hepatocytes and aggregates of tightly packed small hepatocytic cells (Figure 1A). Aggregated cells were also present—but in lower abundance—in digests of control livers (Figure S1A available online). HCC markers such as α fetoprotein (AFP), glypican 3 (*Gpc3*), and *Ly6D*, whose expression in mouse liver cancer was reported (Meyer et al., 2003), were upregulated in aggregates from DEN-treated livers, but not in nonaggregated hepatocytes or aggregates from control livers (Figure S1A). Thus, control liver aggregates may result from incomplete collagenase digestion, whereas aggregates from DEN-treated livers may contain HcPC. DEN-induced aggregates became larger and more abundant 5 months after carcinogen exposure, when they consisted of 10–50 cells that were smaller than nonaggregated hepatocytes. Using 70 μ m and 40 μ m sieves, we separated aggregated from nonaggregated hepatocytes (Figure 1A) and tested their tumorigenic potential by transplantation into MUP-uPA mice (Figure 1B). To facilitate transplantation, the aggregates were mechanically dispersed and suspended in Dulbecco's modified Eagle's medium (DMEM). Five months after intrasplenic (i.s.) injection of 10^4 viable cells, mice receiving cells from aggregates developed about 18 liver tumors per mouse, whereas mice receiving nonaggregated hepatocytes developed less than 1 tumor each (Figure 1B). The tumors exhibited typical trabecular HCC morphology and contained cells that abundantly express AFP (Figure S1B). To confirm that the HCCs were derived from transplanted cells, we measured their relative MUP-uPA DNA copy number and found that they contained much less MUP-uPA transgene DNA than the surrounding parenchyma (Figure S1C). Transplantation of aggregated cells from livers of DEN-treated actin-GFP transgenic mice resulted in GFP-positive HCCs (Figure S1D). Both experiments strongly suggest that the HCCs were derived from the transplanted cells. No tumors were ever observed after transplantation of control hepatocytes (nonaggregated or aggregated).

Only liver tumors were formed by the transplanted cells. Other organs, including the spleen into which the cells were injected, remained tumor free (Figure 1B), suggesting that HcPCs progress to cancer only in the proper microenvironment. Indeed, no tumors appeared after HcPC transplantation into normal BL/6 mice. But, if BL/6 mice were first treated with retrorsine (a chemical that permanently inhibits hepatocyte proliferation [Laconi et al., 1998]), intrasplenically transplanted with HcPC-containing aggregates, and challenged with CCl_4 to induce liver injury and compensatory proliferation (Guo et al., 2002), HCCs readily

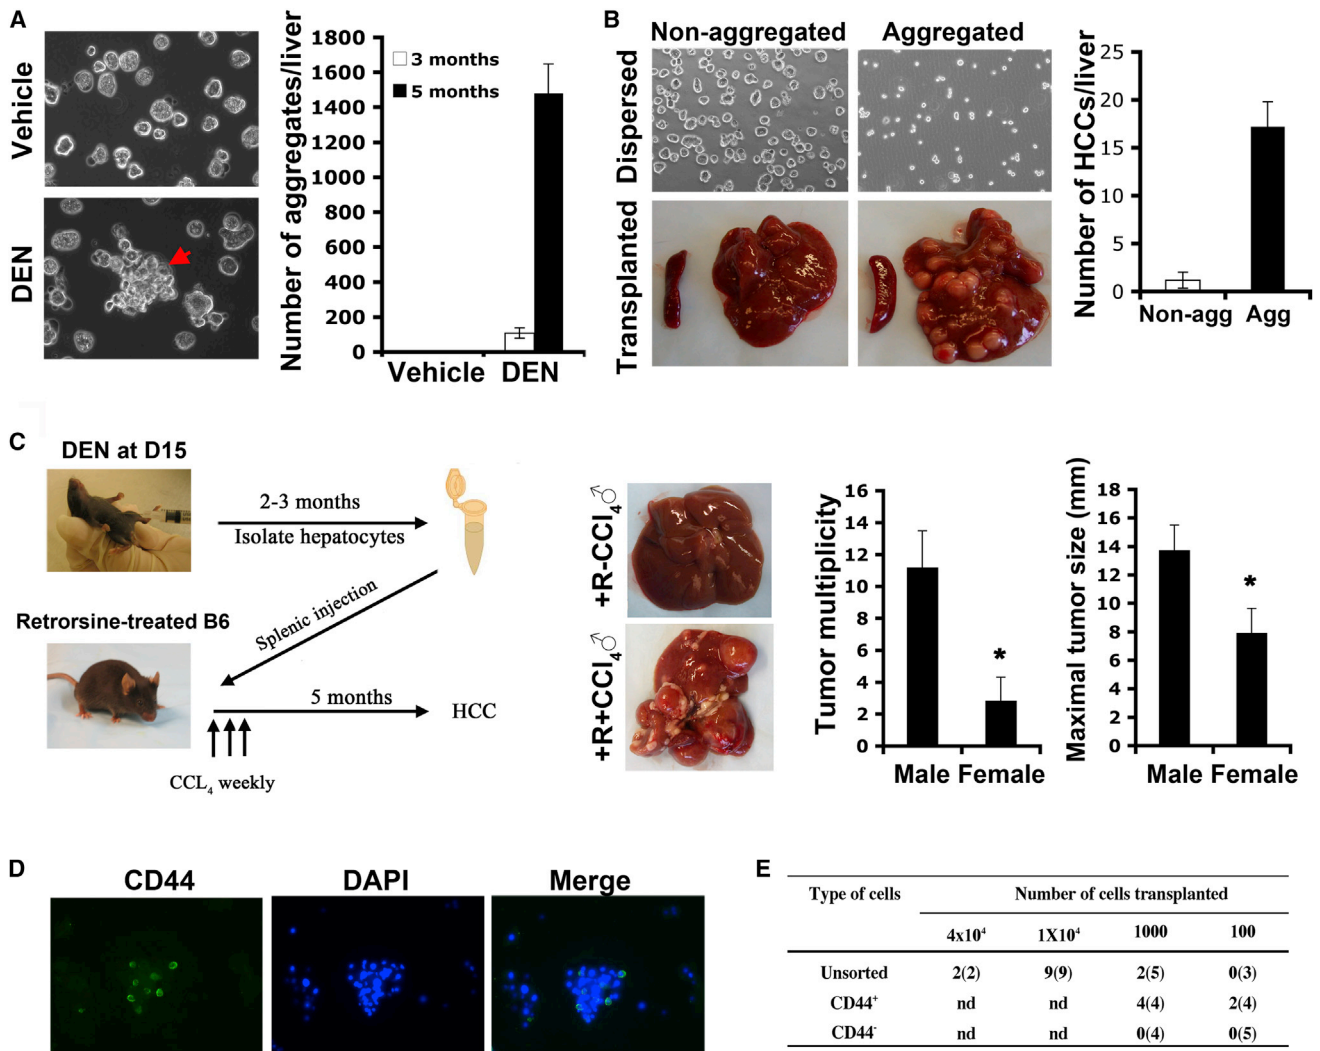

Figure 1. DEN-Induced Hepatocytic Aggregates Contain CD44⁺ HCC Progenitors

(A) Fifteen-day-old BL/6 males were given DEN or vehicle. After 3 or 5 months, their livers were removed and collagenase digested. Left: typical digest appearance (magnification: 400 \times ; 3 months after DEN). Red arrow indicates a collagenase-resistant aggregate. Right: aggregates per liver ($n = 5$; \pm SD for each point).

(B) Livers were collagenase digested 5 months after DEN administration. Aggregates were separated from nonaggregated cells and mechanically dispersed into a single-cell suspension (left upper panels; 200 \times). 10⁴ viable aggregated or nonaggregated cells were i.s. injected into MUP-uPA mice whose livers and spleens were analyzed for tumors 5 months later (left lower panels). The number of HCC nodules per liver was determined ($n = 5$; \pm SD).

(C) Adult BL/6 mice were given retrorsine twice with a 2 week interval to inhibit hepatocyte proliferation. After 1 month, mice were i.s. transplanted with dispersed hepatocyte aggregates (10⁴ cells) from DEN-treated mice and, 2 weeks later, were given three weekly i.p. injections of CCl₄ or vehicle. Tumor multiplicity and size were evaluated 5 months later ($n = 5$; \pm SD).

(D) Hepatocyte aggregates were prepared as in (A), stained with CD44 antibody and DAPI, and examined by fluorescent microscopy (400 \times).

(E) Hepatocyte aggregates were dispersed as above, and CD44⁺ cells were separated from CD44⁻ cells. The indicated cell numbers were injected into MUP-uPA mice, and HCC development was evaluated 5 months later. n values are in parentheses (n.d., not done).

See also Figure S1.

appeared (Figure 1C). CCl₄ omission prevented tumor development. Notably, MUP-uPA or CCl₄-treated livers are fragile, rendering direct intrahepatic transplantation difficult. The transplanted HcPC-containing aggregates formed more numerous and larger HCC nodules in male recipients than in females (Figure 1C), as observed in MUP-uPA mice transplanted with unfractionated DEN-exposed hepatocytes (He et al., 2010). Thus,

CCl₄-induced liver damage, especially within a male liver, generates a microenvironment that drives HcPC proliferation and malignant progression. To examine this point, we transplanted GFP-labeled HcPC-containing aggregates into retrorsine-treated BL/6 mice and examined their ability to proliferate with or without subsequent CCl₄ treatment. Indeed, the GFP⁺ cells formed clusters that grew in size only in CCl₄-treated host livers

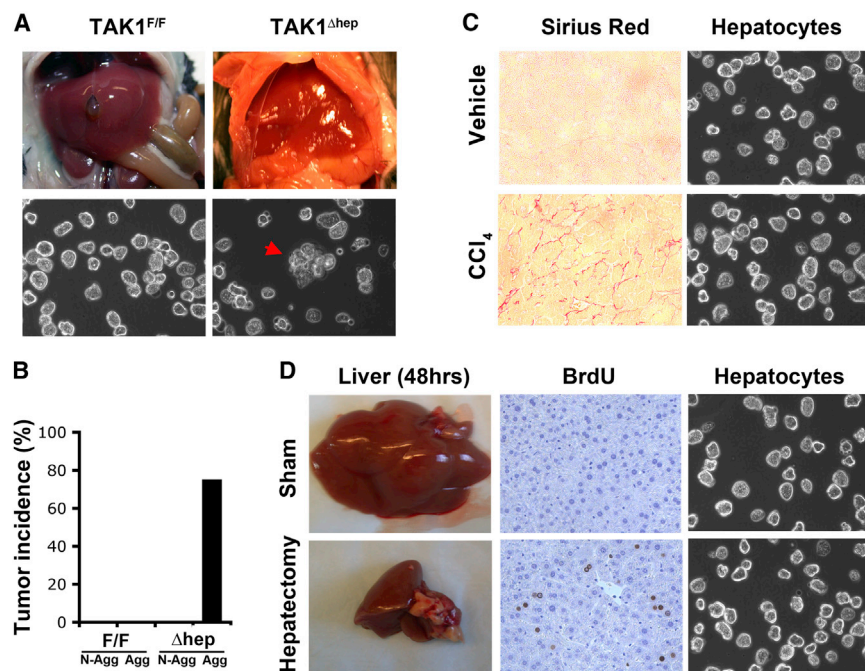

Figure 2. *Tak1*^{Δhep} Livers Contain Collagenase-Resistant HcPC Aggregates

(A) Livers, free of tumors (upper panels), were removed from 1-month-old *Tak1*^{F/F} and *Tak1*^{Δhep} males and collagenase digested (lower panels; red arrow indicates collagenase-resistant aggregate). (B) 10⁴ nonaggregated or dispersed aggregated hepatocytes from (A) were i.s. injected into MUP-uPA mice that were analyzed 6 months later to identify mice with at least one liver tumor (n = 5–8 mice per genotype).

(C) BL/6 males were injected with vehicle or CCl₄ twice weekly for 2 weeks. Hepatocytes were isolated by collagenase digestion and photographed (right panels; 400×). Liver sections were stained with Sirius red to reveal collagen deposits (left panels).

(D) 8-week-old BL/6 males were subjected to 70% partial hepatectomy, pulsed with BrdU at 46 and 70 hr, and sacrificed 2 hr later. Isolated hepatocytes were photographed. Liver sections were analyzed for BrdU incorporation (400×). See also Figure S2 and Table S1.

(Figure S1E). Omission of CCl₄ prevented their expansion. Unlike HCC-derived cancer cells (dih10 cells), which form subcutaneous (s.c.) tumors with HCC morphology (He et al., 2010; Park et al., 2010), the HcPC-containing aggregates did not generate s.c. tumors in BL/6 mice (Figure S1F).

Despite their homogeneous appearance, the HcPC-containing aggregates contained both CD44⁺ and CD44⁻ cells (Figure 1D). Because CD44 is expressed by HCC stem cells (Yang et al., 2008; Zhu et al., 2010), we dispersed the aggregates and separated CD44⁺ from CD44⁻ cells and transplanted both into MUP-uPA mice. Whereas as few as 10³ CD44⁺ cells gave rise to HCCs in 100% of recipients, no tumors were detected after transplantation of CD44⁻ cells (Figure 1E). Remarkably, 50% of recipients developed at least one HCC after receiving as few as 10² CD44⁺ cells. Mature CD44⁻ hepatocytes were found to engraft as well as or better than CD44⁺ small hepatocytic cells (Haridass et al., 2009; Ichinohe et al., 2012). Hence, livers of DEN-treated mice contain CD44⁺ HcPC that can be successfully isolated and purified and give rise to HCCs after transplantation into appropriate hosts. Unlike fully transformed HCC cells, HcPCs only give rise to tumors within the liver.

HcPC-Containing Aggregates in *Tak1*^{Δhep} Mice

We applied the same HcPC isolation protocol to *Tak1*^{Δhep} mice, which develop HCC of different etiology from DEN-induced HCC. Importantly, *Tak1*^{Δhep} mice develop HCC as a consequence of chronic liver injury and fibrosis without carcinogen or toxicant exposure (Inokuchi et al., 2010). Indeed, whole-tumor exome sequencing revealed that DEN-induced HCC contained about 24 mutations per 10⁶ bases (Mb) sequenced, with *B-Raf*^{V637E} being the most recurrent, whereas 1.4 mutations per Mb were detected in *Tak1*^{Δhep} HCC's exome (Table S1). By contrast, *Tak1*^{Δhep} HCC exhibited gene copy number changes.

Collagenase digests of 1-month-old *Tak1*^{Δhep} livers contained much more hepatocytic aggregates than *Tak1*^{F/F} liver digests (Figure 2A). Notably, HCC developed in 75% of MUP-uPA mice that received dispersed *Tak1*^{Δhep} aggregates, but no tumors appeared in mice receiving nonaggregated *Tak1*^{Δhep} or total *Tak1*^{F/F} hepatocytes (Figure 2B). Because *Tak1*^{Δhep} mice are subject to chronic liver damage and consequent compensatory proliferation, we wanted to ascertain that the HcPCs are not simply proliferating hepatocytes or expanding bipotential hepatobiliary progenitors using CCl₄ to induce liver injury and compensatory proliferation in WT mice. Although this treatment caused acute liver fibrosis, it did not augment formation of collagenase-resistant aggregates (Figure 2C). Similarly, few aggregates were detected in collagenase digests of livers after partial hepatectomy (Figure 2D). However, bile duct ligation (BDL) or feeding with 3,5-dicarbethoxy-1,4-dihydrocollidine (DDC), treatments that cause cholestatic liver injuries and oval cell expansion (Dorrell et al., 2011), did increase the number of small hepatocytic cell aggregates (Figure S2A). Nonetheless, no tumors were observed 5 months after injection of such aggregates into MUP-uPA mice (Figure S2B). Thus, not all hepatocytic aggregates contain HcPCs, and HcPCs only appear under tumorigenic conditions.

The HcPC Transcriptome Is Similar to that of HCC and Oval Cells

To determine the relationship between DEN-induced HcPCs, normal hepatocytes, and fully transformed HCC cells, we analyzed the transcriptomes of aggregated and nonaggregated hepatocytes from male littermates 5 months after DEN administration, HCC epithelial cells from DEN-induced tumors, and normal hepatocytes from age- and gender-matched littermate controls. Clustering analysis distinguished the HCC samples from other samples and revealed that the aggregated

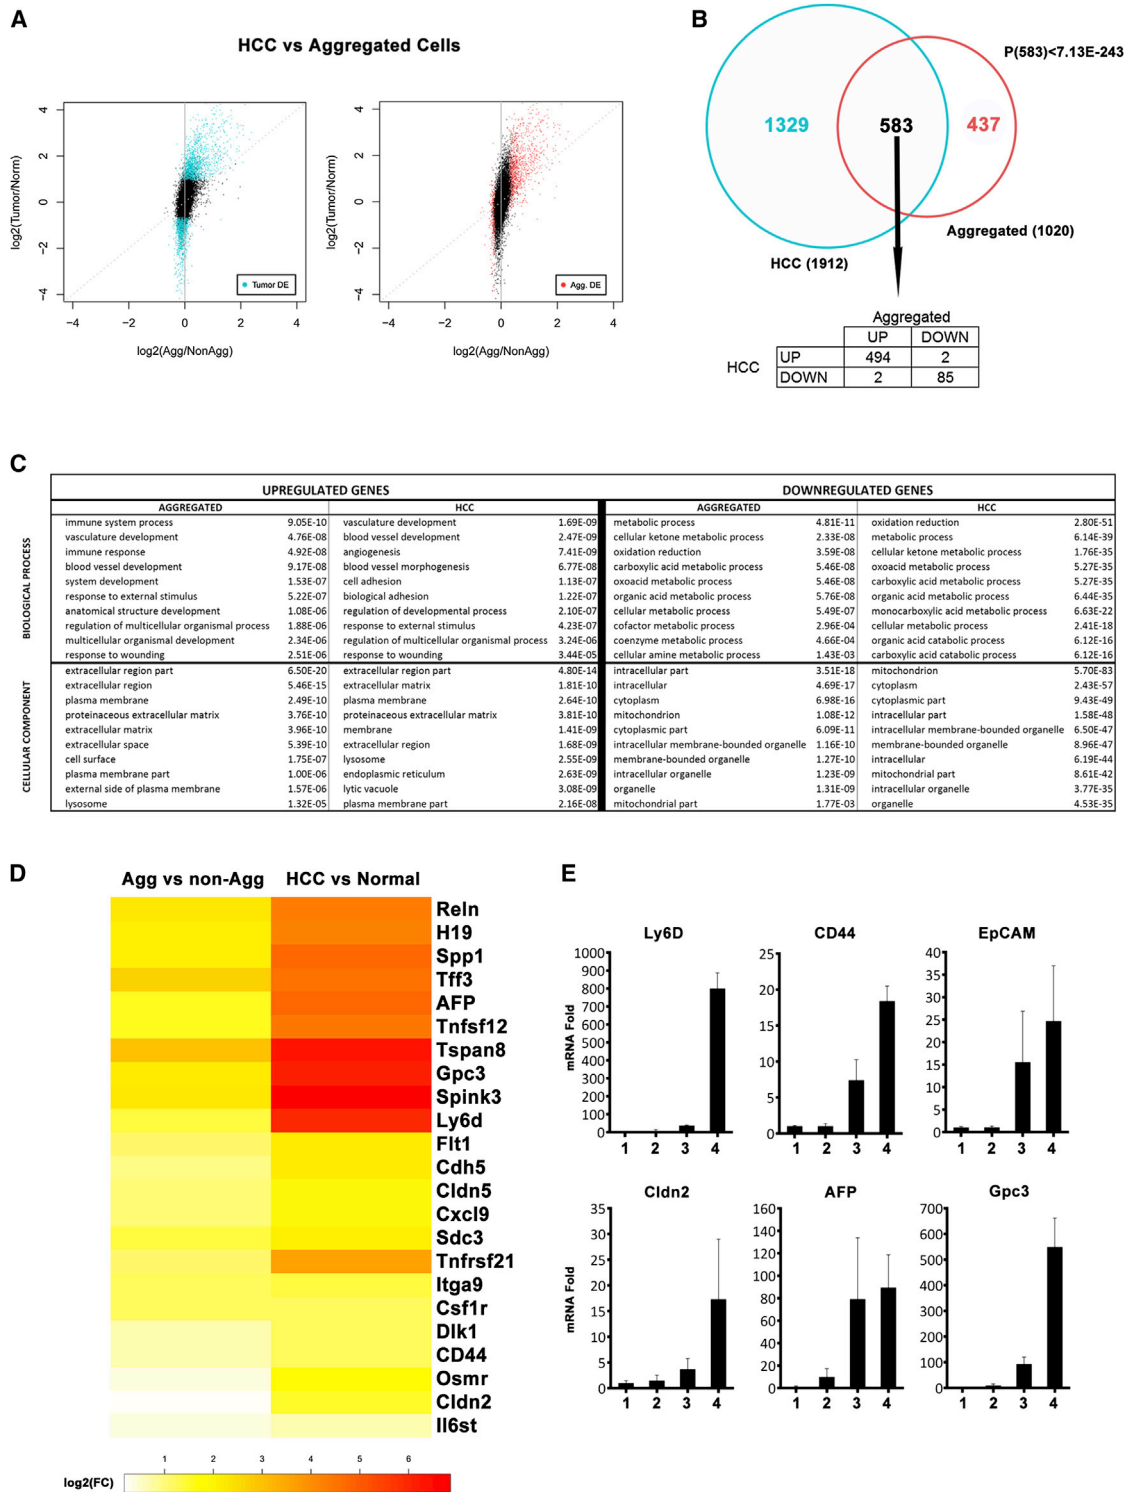

Figure 3. Aggregated Hepatocytes Exhibit an Altered Transcriptome Similar to that of HCC Cells

Aggregated and matched nonaggregated hepatocytes were isolated 5 months after DEN treatment. HCC cells were isolated from DEN-induced tumors, and normal hepatocytes were from age- and gender-matched control mice. RNA was extracted and subjected to microarray analysis (n = 3 for each sample).

(A) Scatterplot representing fold changes (log 2 of expression ratio) in gene expression for HCC versus normal (y axis) and aggregated versus nonaggregated (x axis) pairwise transcriptome comparisons. The plot is displayed twice: in the left panel, genes with an FDR < 0.01 in the aggregated versus nonaggregated

(legend continued on next page)

hepatocyte samples did not cluster with each other but rather with nonaggregated hepatocytes derived from the same mouse (Figure S3A). Interestingly, the aggregated cell transcriptome appeared closer to that of normal hepatocytes than to the HCC profile. This similarity may be due to the presence of ~70% nontumorigenic (or CD44⁻) hepatocytes within the purified aggregates (Figure 1D). Comparison of the HCC and normal hepatocyte transcriptomes revealed 1,912 differentially expressed genes (false discovery rate [FDR] < 0.01; Figure 3A, left, cyan dots). A similar comparison revealed 1,020 genes that are differentially expressed between aggregated and nonaggregated hepatocytes (FDR < 0.01; Figure 3A, right, red dots). The range of differential expression is wider for the HCC and normal hepatocyte pair than the aggregate versus nonaggregate pair, reflecting presence of normal, nontransformed hepatocytes within the aggregates, resulting in signal dilution. Interestingly, 57% (583/1,020) of genes differentially expressed in aggregated relative to nonaggregated hepatocytes are also differentially expressed in HCC relative to normal hepatocytes (Figure 3B, top), a value that is highly significant ($p < 7.13 \times 10^{-243}$). More specifically, 85% (494/583) of these genes are overexpressed in both HCC and HcPC-containing aggregates (Figure 3B, bottom table). Thus, hepatocyte aggregates isolated 5 months after DEN injection contain cells that are related in their gene expression profile to HCC cells isolated from fully developed tumor nodules.

To gain insight into the functional differences between the transcriptomes of the four populations, we examined which biological processes or cellular compartments were significantly overrepresented in the induced or repressed genes in both pairwise comparisons (Gene Ontology Analysis). As expected, processes and compartments that were enriched in aggregated hepatocytes relative to nonaggregated hepatocytes were almost identical to those that were enriched in HCC relative to normal hepatocytes (Figure 3C). Upregulated genes were related to immune response, angiogenesis, development, and wound healing, and many encoded plasma membrane or secreted proteins. By contrast, downregulated genes were highly enriched for metabolic processes, and many of them encoded mitochondrial proteins or had functions associated with differentiated hepatocytes (Figure 3C). Several human HCC markers, including AFP, Gpc3 and H19, were upregulated in aggregated hepatocytes (Figures 3D and 3E). Aggregated hepatocytes also expressed more Tetraspanin 8 (Tspan8), a cell-surface glycoprotein that complexes with integrins and is overexpressed in human carcinoma

(Zöller, 2009). Another cell-surface molecule highly expressed in aggregated cells is Ly6D (Figures 3D and 3E). Immunofluorescence (IF) analysis revealed that Ly6D was undetectable in normal liver but was elevated in FAH and ubiquitously expressed in most HCC cells (Figure S3C). A fluorescent-labeled Ly6D antibody injected into HCC-bearing mice specifically stained tumor nodules (Figure S3D). Other cell-surface molecules that were upregulated in aggregated cells included syndecan 3 (Sdc3), integrin α 9 (Itga9), claudin 5 (Cldn5), and cadherin 5 (Cdh5) (Figure 3D). Aggregated hepatocytes also exhibited elevated expression of extracellular matrix proteins (TIF3 and Reln1) and a serine protease inhibitor (Spink3). Elevated expression of such proteins may explain aggregate formation. Aggregated hepatocytes also expressed progenitor cell markers, including the epithelial cell adhesion molecule (EpCAM) (Figure 3E) and Dlk1 (Figure 3D). Elevated expression of cytokines and cytokine receptors was also detected, including tumor necrosis factor superfamily members 12 and 21, colony-stimulating factor 1 receptor, FMS-like tyrosine kinase 1, chemokine (C-X-C motif) ligand 9, the STAT3-activating cytokine osteopontin, IL-6 receptor (IL-6R) signal transducing subunit (gp130), and oncostatin M (OSM) receptor, which also activates STAT3 (Figure 3D).

Aggregated hepatocytes expressed albumin, albeit less than nonaggregated hepatocytes (Figure 4A). Some aggregated cells were positive for cytokeratin 19 (CK19) and A6, markers for bile duct epithelium and oval cells (Figure 4A). Most cells in the DEN-induced aggregates were AFP positive, and some of them expressed EpCAM (Figure 4A). However, not all markers were expressed by every cell within a given aggregate, suggesting that the aggregates contain liver cells that are related to bipotential hepatobiliary progenitors/oval cells as well as more differentiated progeny and normal hepatocytes. To confirm these observations, we compared the HcPC and HCC (Figure 3A) to the transcriptome of DDC-induced oval cells (Shin et al., 2011). This analysis revealed a striking similarity between the HCC, HcPC, and the oval cell transcriptomes (Figure S3B). Despite these similarities, some genes that were upregulated in HcPC-containing aggregates and HCC were not upregulated in oval cells. Such genes may account for the tumorigenic properties of HcPC and HCC.

We examined the aggregates for signaling pathways and transcription factors involved in hepatocarcinogenesis. Many aggregated cells were positive for phosphorylated c-Jun and STAT3 (Figure 4A), transcription factors involved in DEN-induced

comparison are highlighted in red, and in the right panel, genes with an FDR < 0.01 in the HCC versus normal comparison are highlighted in cyan. DE, differentially expressed.

(B) Venn diagram showing overlap between genes that are differentially expressed between aggregated and nonaggregated hepatocytes and between HCC cells and normal hepatocytes with an FDR < 0.01 (cyan and red dots from A). The probability to find 583 overlapping genes is $< 7.13 \times 10^{-243}$. From these 583 common genes, only 4 behaved differently.

(C) The ten most enriched biological processes (upper table) and cellular compartments (lower panel) represented by genes that are significantly upregulated (left panel) or downregulated (right panel) in HCC relative to normal hepatocytes (HCC) or in aggregated relative to nonaggregated hepatocytes (aggregated).

(D) Heatmap displaying positive fold changes (FC) in expression of genes of interest in aggregated versus nonaggregated HcPCs (left) and in HCC versus normal hepatocytes (right).

(E) Expression of selected genes was examined by real-time PCR and is depicted as fold change relative to normal hepatocytes given an arbitrary value of 1.0 ($n = 3; \pm$ SD). (1) Normal hepatocytes; (2) nonaggregated hepatocytes from DEN-treated liver; (3) HcPC aggregates from DEN-treated liver; and (4) DEN-induced HCCs.

See also Figure S3.

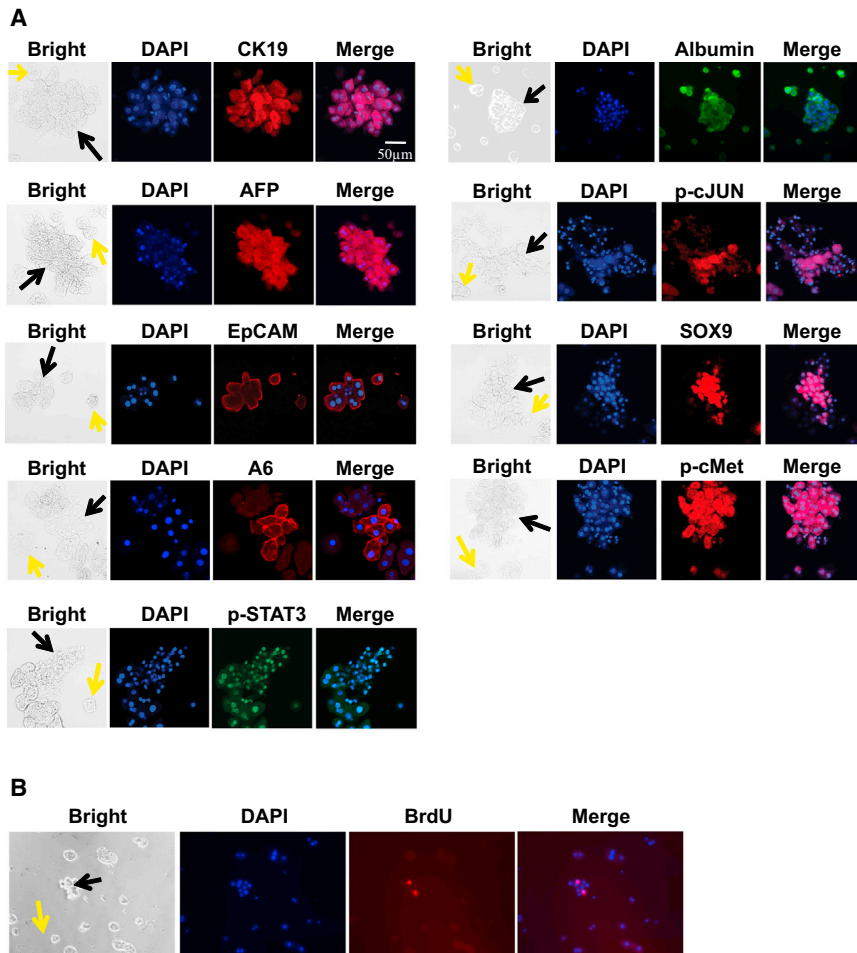

Figure 4. DEN-Induced HcPC Aggregates Express Pathways and Markers Characteristic of HCC and Hepatobiliary Stem Cells

(A) Cytospin preps of collagenase-resistant aggregates from 5-month-old DEN-injected mice were stained with antibodies to CK19, AFP, EpCAM, A6, phospho-Y-STAT3 (Tyr705), albumin, phospho-c-Jun, Sox9, and phospho-c-Met. Black arrows indicate aggregates, and yellow arrows indicate nonaggregated cells (magnification: 400 \times). (B) 5-month-old DEN-treated mice were injected with BrdU, and 2 hr later, collagenase-resistant aggregates were isolated and analyzed for BrdU incorporation (400 \times).

See also Figure S4.

HcPC-Containing Aggregates Originate from Premalignant Dysplastic Lesions

FAH are dysplastic lesions occurring in rodent livers exposed to hepatic carcinogens (Su et al., 1990). Similar lesions are present in premalignant human livers (Su et al., 1997). Yet, it is still debated whether FAH correspond to premalignant lesions or are a reaction to liver injury that does not lead to cancer (Sell and Leffert, 2008). In DEN-treated males, FAH were detected as early as 3 months after DEN administration (Figure 5A), concomitant with the time at which HcPC-containing aggregates were detected. In females, FAH development was delayed. In both genders, FAH

were confined to zone 3 and consisted of tightly packed small hepatocytic cells, some of which were proliferative based on BrdU incorporation (Figure 5B). BrdU⁺ cells were first detected in DEN-treated males and were confined to FAH and rarely detected in age-matched control mice. FAH contained cells positive for the same progenitor cell markers and activated signaling pathways present in HcPC-containing aggregates, including AFP, CD44, and EpCAM (Figure 5C). FAH also contained cells positive for activated STAT3, c-Jun, and PCNA (Figure 5C). Many cells within FAH exhibited strong upregulation of YAP (Figure 5C), a transcriptional coactivator that is negatively regulated by the Hippo pathway and a liver cancer oncoprotein (Zheng et al., 2011). FAH were also enriched in F4/80⁺ macrophages (Figure 5C). These results suggest that the HcPC-containing aggregates may be derived from FAH.

hepatocarcinogenesis (Eferl et al., 2003; He et al., 2010). Sox9, a transcription factor that marks hepatobiliary progenitors (Dorell et al., 2011), was also expressed by many of the aggregated cells, which were also positive for phosphorylated c-Met (Figure 4A), a receptor tyrosine kinase that is activated by hepatocyte growth factor (HGF) and is essential for liver development (Bladt et al., 1995) and hepatocarcinogenesis (Wang et al., 2001). Few of the nonaggregated hepatocytes exhibited activation of these signaling pathways. Aggregates from bromodeoxyuridine (BrdU)-pulsed DEN-treated mice contained BrdU-positive cells (Figure 4B), indicating that they were actively proliferating prior to isolation. Hepatocyte aggregates from 1-month-old *Tak1*^{Δhep} mice also contained cells positive for AFP, Sox9, phosphorylated c-Met, and EpCAM, but not A6-positive cells (Figure S4A). Many of the cells also exhibited partially activated β -catenin, phosphorylated STAT3, and phosphorylated c-Jun. Thus, despite different etiology, HcPC-containing aggregates from *Tak1*^{Δhep} mice exhibit upregulation of many of the same markers and pathways that are upregulated in DEN-induced HcPC-containing aggregates. Flow cytometry confirmed enrichment of CD44⁺ cells as well as CD44⁺/CD90⁺ and CD44⁺/EpCAM⁺ double-positive cells in the HcPC-containing aggregates from either DEN-treated or *Tak1*^{Δhep} livers (Figure S4B).

were confined to zone 3 and consisted of tightly packed small hepatocytic cells, some of which were proliferative based on BrdU incorporation (Figure 5B). BrdU⁺ cells were first detected in DEN-treated males and were confined to FAH and rarely detected in age-matched control mice. FAH contained cells positive for the same progenitor cell markers and activated signaling pathways present in HcPC-containing aggregates, including AFP, CD44, and EpCAM (Figure 5C). FAH also contained cells positive for activated STAT3, c-Jun, and PCNA (Figure 5C). Many cells within FAH exhibited strong upregulation of YAP (Figure 5C), a transcriptional coactivator that is negatively regulated by the Hippo pathway and a liver cancer oncoprotein (Zheng et al., 2011). FAH were also enriched in F4/80⁺ macrophages (Figure 5C). These results suggest that the HcPC-containing aggregates may be derived from FAH.

HcPCs Exhibit Autocrine IL-6 Expression Necessary for HCC Progression

In situ hybridization (ISH) and immunohistochemistry (IHC) revealed that DEN-induced FAH contained IL-6-expressing cells (Figures 6A, 6B, and S5), and freshly isolated DEN-induced aggregates contained more IL-6 messenger RNA (mRNA) than nonaggregated hepatocytes (Figure 6C). We examined several

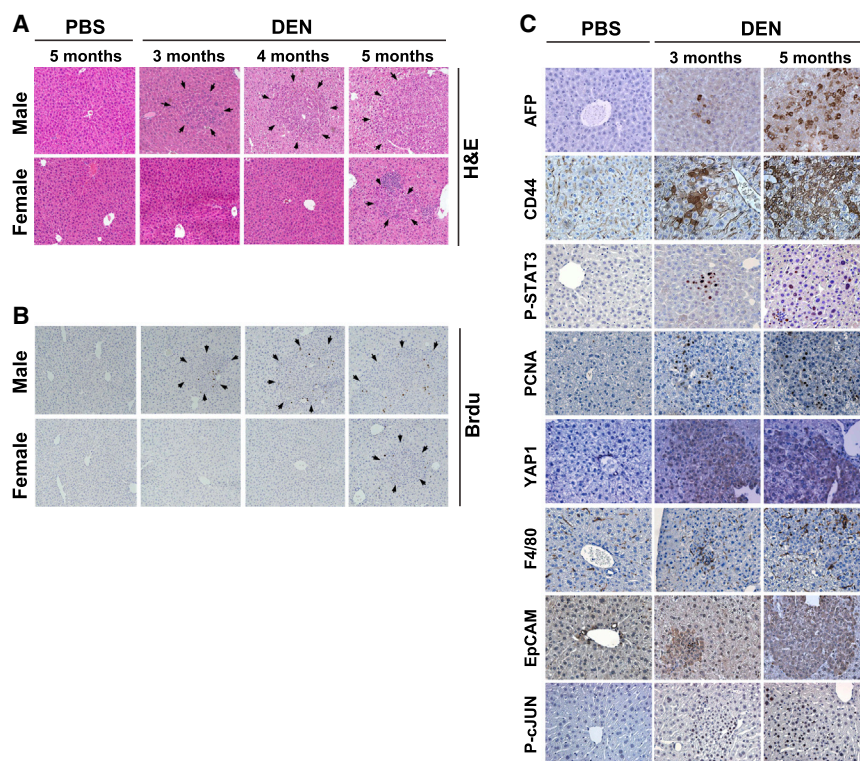

Figure 5. HcPC-Containing Aggregates May Originate from Liver Premalignant Lesions

(A and B) Male and female mice were injected with PBS or DEN at 15 days. At the indicated time points, BrdU was administered, and livers were collected 2 hr later and stained with H&E (A) or a BrdU-specific antibody (B). Arrows indicate borders of FAH (magnification: 200 \times).

(C) Sections of male livers treated as above were subjected to IHC with the indicated antibodies (400 \times).

factors that control IL-6 expression and found that LIN28A and B were significantly upregulated in HcPCs and HCC (Figures 6D and 6E). LIN28-expressing cells were also detected within FAH (Figure 6F). As reported (Iliopoulos et al., 2009), knockdown of LIN28B in cultured HcPC or HCC cell lines decreased IL-6 expression (Figure 6G). LIN28 exerts its effects through downregulation of the microRNA (miRNA) Let-7 (Iliopoulos et al., 2009). Accordingly, miRNA array analysis of aggregated and nonaggregated hepatocytes from DEN-treated mice indicated that the amount of Let-7, along with other miRNAs that also inhibit IL-6 expression (miR194 and miR872), was lower in aggregated cells than in nonaggregated cells (Table S2).

To determine whether autocrine IL-6 production is needed for HCC growth, we silenced IL-6 expression with small hairpin RNA (shRNA) in diH10 HCC cells (He et al., 2010). This resulted in nearly a 75% decrease in IL-6 mRNA (Figure 7A) but had little effect on cell growth in the presence of growth factors, including EGF and insulin (Figure S6A). IL-6 mRNA silencing, however, diminished the ability of diH10 cells to form s.c. tumors (Figures S6B and S6C) and inhibited their ability to form HCCs and proliferate after transplantation into MUP-uPA mice (Figures 7B and S6D). To investigate the importance of autocrine IL-6 production at an earlier step, we isolated HcPC from DEN-treated WT and *Il6*^{-/-} mice. Although IL-6 ablation attenuates HCC induction (Naugler et al., 2007), we still could isolate collagenase-resistant aggregates from livers of DEN-injected *Il6*^{-/-} mice. Notably, IL-6 ablation did not reduce the proportion of CD44⁺ cells in the aggregates (Figures S7A and S7B). We introduced an identical number of WT and *Il6*^{-/-} aggregated hepatocytes into MUP-uPA mice and scored HCC development 5 months later. The

within the MUP-uPA liver (Figure 7E). We also ablated IL-6 expression in mouse hepatocytes and found that this led to a marked reduction in DEN-induced tumorigenesis (Figure 7F). Thus, autocrine IL-6 production by DEN-initiated HcPC is important for HCC development. To investigate whether autocrine IL-6 signaling also occurs in human premalignant lesions, we examined needle biopsies of normal liver tissue and HCV-infected livers with dysplastic lesions. We found that 16% of all ($n = 25$) dysplastic lesions exhibited coexpression of LIN28 and IL-6 and contained activated STAT3 (Figure 7G). These markers were hardly detected in normal liver or nontumor portion of HCV-infected livers.

DISCUSSION

The isolation and characterization of cells that can give rise to HCC only after transplantation into an appropriate host liver undergoing chronic injury demonstrates that cancer arises from progenitor cells that are yet to become fully malignant. Importantly, unlike fully malignant HCC cells, the HcPCs we isolated cannot form s.c. tumors or even liver tumors when introduced into a nondamaged liver. Liver damage induced by uPA expression or CCl₄ treatment provides HcPCs with the proper cytokine and growth factor milieu needed for their proliferation. Although HcPCs produce IL-6, they may also depend on other cytokines such as TNF, which is produced by macrophages that are recruited to the damaged liver. In addition, uPA expression and CCl₄ treatment may enhance HcPC growth and progression through their fibrogenic effect on hepatic stellate cells. Although HCC and other cancers have been suspected to arise from

Figure 6. Liver Premalignant Lesions and HcPCs Exhibit Elevated IL-6 and LIN28 Expression

(A and B) Livers of 5-month-old DEN injected mice were analyzed for IL-6 expression by IHC (magnification: 400 \times) (A) and ISH (magnification: 100 \times , top; 400 \times , bottom) (B).

(C and D) Quantification of IL-6 (C) and LIN28 (D) mRNA in aggregated versus nonaggregated hepatocytes from 5-month-old DEN-treated livers and in normal versus tumor-bearing livers ($n = 6$; \pm SEM) (ND, not detected).

(E) Immunoblot analyses of LIN28A in normal (NL) and tumor-bearing (TU) livers.

(F) DEN-treated livers were subjected to IHC with a LIN28A antibody. Broken lines indicate borders of FAH (400 \times).

(G) LIN28B was silenced with shRNA in HCC (dih) cells and cultured HcPCs, and LIN28B and IL-6 mRNAs were quantitated by qRT-PCR ($n = 3$; \pm SEM).

See also Figure S5 and Table S2.

dysplastic lesions and mouse FAH and HcPC exhibit autocrine IL-6 signaling. HcPC are not unique to DEN-treated mice, and similar cells were isolated from *Tak1^{Δhep}* mice in which HCC development resembles cirrhosis-associated human HCC (Inokuchi et al., 2010).

HcPC Origin and Relationship to Liver and HCC Stem Cells

Transcriptomic analysis indicates that DEN-induced HcPCs are related to both normal hepatobiliary bipotential stem cells/oval cells and HCC cells. Although HcPCs are not fully transformed, they express several markers—CD44, EpCAM, AFP, SOX9, OV6, and CK19—found to be expressed by HCC stem cells and oval cells (Guo et al., 2012; Mikhail and He, 2011; Terris et al., 2010; Yamashita et al., 2008; Zhu et al., 2010). However,

premalignant/dysplastic lesions (Huban et al., 2007; Hytiroglou et al., 2007), a direct demonstration that such lesions progress into malignant tumors has been lacking. Based on expression of common markers—EpCAM, CD44, AFP, activated STAT3, and IL-6—that are not expressed in normal hepatocytes, we postulate that HcPCs originate from FAH or dysplastic foci, which are first observed in male mice within 3 months of DEN exposure. Indeed, the cells that are contained within the FAH are smaller than the surrounding parenchyma and are similar in size to isolated HcPCs. Importantly, FAH or premalignant dysplastic foci are not unique to DEN-treated rodents (Ban-nasch, 1984; Rabes, 1983), and similar lesions were detected in human cirrhotic livers (Hytiroglou et al., 2007; Seki et al., 2000; Takayama et al., 1990) in which the rate of HCC progression is 3%–5% per year (El-Serag, 2011). We found that human

unlike oval cells, which do not express albumin or AFP and do not give rise to liver tumors upon transplantation into MUP-uPA mice, HcPCs give rise to HCC after intrasplenic transplantation. Yet, unlike dih10 HCC cells, which express high levels of the HCC stem cell markers AFP, CD44, and EpCAM, HcPCs do not form s.c. tumors.

At this point, it is not clear whether HcPCs arise from oval cells or from dedifferentiated hepatocytes. Given that DEN is metabolically activated by Cyp2E1 that is expressed only in fully differentiated zone 3 hepatocytes (Tsutsumi et al., 1989) and that *Cyp2E1^{-/-}* mice are refractory to DEN (Kang et al., 2007), DEN-induced HcPC are most likely derived from dedifferentiated hepatocytes. Consistent with this hypothesis, DEN-induced FAH and proliferating cells were found in zone 3 and not near bile ducts or the canals of Hering, sites at which oval cells reside

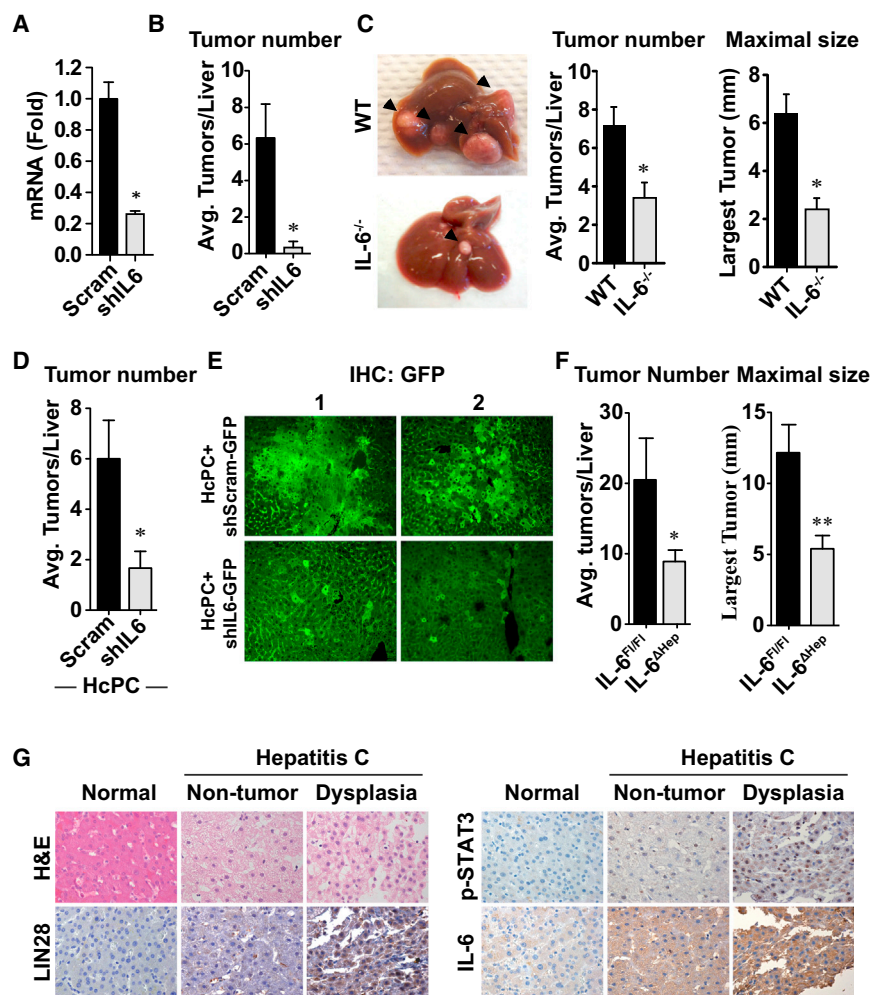

Figure 7. HCC Growth Depends on Autocrine IL-6 Production

(A) HCC cells (dih10) were transduced with lentiviruses containing scrambled or IL-6-specific shRNA. IL-6 mRNA was analyzed by qRT-PCR.

(B) Dih10 cells (1.2×10^5) transduced as above were i.s. injected into MUP-uPA mice that were analyzed 6 months later for HCC development ($n = 3$; \pm SEM).

(C) HcPCs from WT and *Il6*^{-/-} mice were injected (1×10^4 cells/mice) into MUP-uPA mice and analyzed 5 months later for HCC development ($n = 5$; \pm SEM).

(D) HcPCs isolated from DEN-treated WT mice were transduced with shRNA against IL-6 or scrambled shRNA, cultured for 3 to 4 days, i.s. transplanted (1×10^4 cells/mice) into MUP-uPA mice, and analyzed 6 months later ($n = 3$; \pm SEM). (E) Livers of MUP-uPA mice from (D) were immunostained with GFP antibody 6 months after transplantation (200 \times). The bicistronic lentivirus in this experiment expresses GFP along with control or IL-6 shRNA, allowing tracking of the infected cells.

(F) DEN-treated *Il6*^{Δhep} and *Il6*^{Fl/Fl} mice were sacrificed after 9 months to evaluate tumor multiplicity and size ($n = 6-10$, \pm SEM).

(G) IHC analysis of autocrine IL-6 signaling in human premalignant lesions in HCV-infected livers. Expression of LIN28, p-STAT3, and IL-6 was analyzed in 25 needle biopsies of dysplastic nodules, and representative positive specimens ($n = 4$) are shown. The dysplastic nodules and paired nontumor tissue were obtained from the same HCV-infected patient ($n = 25$). Nontumor tissue of metastatic liver cancer was used as normal control.

See also [Figures S6](#) and [S7](#).

(Duncan et al., 2009). Notably, GO analysis revealed that many of the genes whose expression is downregulated in HcPC-containing aggregates are involved in xenobiotic and organic acid metabolism, characteristics of differentiated hepatocytes. The same types of genes are also downregulated in HCC. However, final identification of the origin of HcPC will be provided by ongoing lineage-tracing experiments.

The Significance of Autocrine IL-6 Expression

Elevated IL-6 was detected in at least 40% of human HCCs, where it is expressed by the cancer cells (Soresi et al., 2006). More recent studies have confirmed upregulation of IL-6 in human HCC and suggested that it plays a central role in a gene expression network that drives tumor development (Ji et al., 2009). Elevated IL-6 was also found in viral and alcoholic hepatitis and liver cirrhosis, but in these conditions, IL-6 is expressed mainly by myeloid cells/leukocytes rather than parenchymal cells (Devieire et al., 1989; Kakumu et al., 1993; Soresi et al., 2006). Our studies indicate that the critical site of IL-6 expression shifts from myeloid cells to epithelial cells during the course of DEN-induced liver tumorigenesis. Initially, DEN administration rapidly induces IL-6 in Kupffer cells through NF- κ B activation

(Maeda et al., 2005). This initial surge in IL-6 is required for DEN-induced hepatocarcinogenesis (Naugler et al., 2007). Although IL-6 decays within 2 weeks of DEN administration, it reappears several months later, but at that time, it is expressed within FAH. IL-6 expression is also elevated in isolated HcPCs and is maintained in fully transformed HCC cells. Furthermore, autocrine IL-6 is important for HcPC to HCC progression and for tumorigenic growth. Autocrine IL-6 in both HcPC and HCC cells depends on elevated expression of LIN28, an RNA-binding protein that exerts its protumorigenic activity through downregulation of Let-7, an miRNA that inhibits IL-6 expression (Viswanathan and Daley, 2010). Accordingly, HcPCs exhibit downregulation of both Let-7f and Let-7g, and elevated LIN28 is found not only in isolated HcPCs but also within FAH and human HCV-induced dysplastic lesions.

A similar LIN28-Let-7-IL-6 epigenetic switch is important for in vitro programming and maintenance of cancer stem cells (Iliopoulos et al., 2009). IL-6 also induces malignant features in human ductal carcinoma stem cells (Sansone et al., 2007). In fact, autocrine IL-6 signaling was suggested to play a key role in STAT3-dependent tumor progression (Grivnenkov and Karin, 2008). Another miRNA-driven autoregulatory circuit involved in

hepatocarcinogenesis accounts for elevated IL-6R expression (Hatzia Apostolou et al., 2011). Yet, HcPC-containing aggregates also express several other STAT3-activating cytokines and receptors. Accordingly, silencing or ablation of IL-6 results in incomplete inhibition of HcPC to HCC progression. Nonetheless, our results demonstrate that autoregulatory circuits/epigenetic switches play an important role in the very early stages of tumorigenesis. Given that such circuits are already activated in pre-malignant cells, pharmacological agents that disrupt their function may be useful in cancer prevention. Prevention is of particular importance in cancers such as HCC, which is often detected at a stage that is refractory to currently available therapeutics.

EXPERIMENTAL PROCEDURES

Mice, HCC Induction, HcPC Isolation, and Transplantation

MUP-uPA transgenic mice (Weglarz et al., 2000) were maintained on a pure BL/6 background. Because homozygous females frequently die when pregnant, MUP-uPA heterozygotes were generated by backcrossing homozygous MUP-uPA males with BL/6 females to be used as recipients for hepatic transplantation. *Tak1^{Δhep}* (Inokuchi et al., 2010) and *Il6^{F/F}* (Quintana et al., 2013) mice were also in the BL/6 background. *Il6^{Δhep}* mice were generated by crossing *Il6^{F/F}* and *Alb-Cre* mice. C57BL/6 actin-GFP mice were from the Jackson Laboratories. BL/6 mice were purchased from Charles River Laboratories.

To induce HCC, 15-day-old mice were injected i.p. with 25 mg/kg DEN (Sigma). A pool of DEN-injected BL/6 mice was maintained and used in most experiments. Hepatocytes were isolated using a two-step procedure (He et al., 2010). Cell aggregates were isolated by filtration through 70 and 40 μm sieves. To disperse the aggregates into single cells, they were subjected to gentle pipetting in Ca/Mg-free PBS on ice. Single-cell suspensions of aggregated and nonaggregated hepatocytes were transplanted via an i.s. injection into 21-day-old male MUP-uPA mice (He et al., 2010). Alternatively, single-cell suspensions of aggregated hepatocytes were enriched for CD44⁺ HcPC using magnetic beads. As few as 100 viable CD44⁺ cells mixed with 1 × 10⁵ normal hepatocytes from normal males were transplanted into MUP-uPA mice. Alternatively, BL/6 mice were pretreated with retrorsine (70 mg/kg i.p.) (Sigma), a cell-cycle inhibitor, 1 month prior to transplantation. Transplanted mice were allowed to recover for 1 week and then injected weekly with 3 × 0.5 ml/kg CCl₄ i.p. to induce liver injury and hepatocyte proliferation (Guo et al., 2002). Mice were sacrificed 5 to 6 months later, and tumors bigger than 1 mm in diameter on the liver surface were counted. Tumors bigger than 5 mm across were dissected for biochemical and molecular analyses.

ACCESSION NUMBERS

Raw gene expression array data have been deposited to NCBI's Gene Expression Omnibus under the GSE50431 study.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Extended Experimental Procedures, seven figures, and three tables and can be found with this article online at <http://dx.doi.org/10.1016/j.cell.2013.09.031>.

AUTHOR CONTRIBUTIONS

G.H. identified, isolated, and characterized HcPCs; D.D. and H.N. optimized the HcPC isolation and purification procedure; D.D. found the mechanism of their dependence on autocrine IL-6 controlled by LIN28, characterized them using flow cytometry (with S.S.), and conducted miR analyses (with M.H. and D.I.); H.N. and D.D. used *Il6^{Δhep}* mice to demonstrate in vivo HCC dependency on autocrine IL-6; H.N. (with R.T. and K.K.) found IL-6, LIN28, and P-STAT3 in human dysplastic lesions; J.F.-B. conducted the transcriptome

analysis and exome sequencing (with S.E.Y., K.J., and O.H.) and with H.O. examined oncogenic potential of oval cells; H.O. examined HcPC proliferative potential and performed IF analysis of isolated HcPC (with A.S. and R.M.H.); Y.J. assisted with IHC and ISH staining; E.S. contributed to the experiments involving *Tak1^{Δhep}* mice; G.H., D.D., J.F.-B., H.O., and M.K. wrote the manuscript.

ACKNOWLEDGMENTS

We acknowledge the Biogen facility at UCSD for their assistance with transcriptome analysis and A. Arian, K. Iwaisako, Y. Hiroshima, and H. Matsui for technical assistance. We thank Dr. J. Hidalgo (Universitat Autònoma de Barcelona, Spain) for the *Il6^{F/F}* mice. Research was supported by the Superfund Basic Research Program (P42ES010337), NIH (CA118165 and CA155120), Wellcome Trust (WT086755), American Diabetes Association (7-08-MN-29), the Center for Translational Science (UL1RR031980 and UL1TR000100), the National Center for Research Resources IMAT program (N12R1CA155615), and postdoctoral research fellowships from the Damon Runyon Cancer Research Foundation (G.H.), American Liver Foundation (D.D.), Daiichi Sankyo Foundation of Life Science (H.N.), California Institute for Regenerative Medicine Stem Cell Training Grant II (TG2-01154) fellowship (J.F.-B.), Kanzawa Medical Research Foundation (H.O.), the German Research Foundation (DFG, SH721/1-1 to S.S.), and a Young Investigator Award from the National Childhood Cancer Foundation, "CureSearch" (D.D.). M.K. is an ACS Research Professor and is a recipient of the Ben and Wanda Hildyard Chair for Mitochondrial and Metabolic Diseases.
