National Audit Project (MINAP) database and patient notes. Mortality data was confirmed using the Office of National Statistics database with follow-up ranging from 3 to 44 months.

Results: The mean age was 60.2 years and 80.3% patients were male. The incidence of previous coronary disease in the cohort was 27.8%, 32.8% patients were hypertensive, 37.7% smokers, 24.6% hypercholesterolaemic and 8.2% had known diabetes. 45% patients had a witnessed arrest and 43.6% were directly conveyed to the PCI centre. Mean arrest-to-arrival time in the cohort was 115±24mins with a mean call-to-balloon time of 168±24mins. The rate of successful pPCI in the cohort was 85% with 21.7% having 3-vessel disease. Shock was present in 16% and severe left ventricular impairment in 32% of patients. The therapy mortality within the cohort was 21%. Of the patients who died 14 were cardiovascular deaths, 3 being shortly after return of spontaneous circulation in the catheterisation laboratory, and 6 of all deaths were secondary to hypoxic brain injury in Intensive Care. 79% of all patients survived to discharge. Of the patients who survived 92% were discharged with no neurological deficit. At follow-up (12-44 months in survivors) 100% of patients who survived to discharge were still alive.

Conclusions: Here we present descriptive data of a large, contemporary cohort of STEMI admissions for pPCI that are complicated by OHCA. Here we show a 7% survival rate to discharge, a higher proportion than previously reported, with good long term prognosis after discharge.

Predictors Of Outcome In Patients With ST-elevation Myocardial Infarction Presenting With Out Of Hospital Cardiac Arrest
Fizah Choudry1, Roshan Weerackody1, Andrew Wragg2, Peter Mills3, Ajay Jain1
1Barts and the London, London, United Kingdom

Background: ST elevation myocardial infarction (STEMI) complicated by out of hospital cardiac arrest (OOHCA) is associated with significant mortality. Small observational studies have shown survival benefit with primary percutaneous coronary intervention (pPCI) in this setting. We sought to identify clinical characteristics and predictors of outcome in STEMI complicated by OHCA in a large patient cohort in the era of pPCI. Methods: From January 2008 to October 2011, STEMI admissions to a regional cardiac centre were retrospectively analysed. 122 patients with OHCA in the context of STEMI were identified. Clinical and procedural data was collected from the UK Myocardial Ischaemia National Audit Project (MINAP) database and patient notes. All cause mortality data was confirmed using the Office of National Statistics mortality database with follow-up ranging from 3 to 44 months.

Results: The mean age of patients was 60.2±14 years, 80.3% were male and 43% were direct admissions via the ambulance service, 57% being transferred from district hospitals. The in-hospital mortality within the cohort was 21% with 96/122 patients surviving to discharge. There were no significant differences in patient demographics, previous cardiac history, arrest rhythm or referral source between patients who survived to discharge compared with those who died. Patients who died had significantly higher incidence of cardiogenic shock (p=0.0289), 3-vessel coronary disease (p=0.0125), severe left ventricular (LV) impairment (p=0.0273) and renal dysfunction (p=0.0001). Shorter arrest-to-arrival time (p=0.0001), shorter call-to-balloon time (p=0.015), successful pPCI (p=0.0247) and witnessed arrest were strongly associated with survival in this patient cohort.

Conclusions: We show that in this large, contemporary cohort of STEMI admissions for pPCI that are complicated by OHCA, 79% of patients survive to discharge, a higher proportion than previously reported. Predictors of poor outcome include: unwitnessed arrest, delay from arrest to arrival, delay in call-to-balloon, cardiogenic shock, 3-vessel coronary disease, failure of pPCI, severe LV impairment and renal dysfunction.

National Trends in Case Fatality based on Anatomical Location of ST-elevation Myocardial Infarction in Hospitalized Patients, 1993-2009
Kaushtub Dabhadkar1, Abhishik Deshmukh1, Ambar Kulshreshtha1, Apurva Badheka3, Rajesh Sachdeva4
1Kaival Hospital, Thane, India, 2Maulana Azad Medical College, New Delhi, India, 3St. John’s Medical College, Bangalore, India, 4Apollo Hospitals, Chennai, India

Background: Although mortality due to ST elevation myocardial infarction (STEMI) has declined in the past few decades, it is unknown if this decline is uniform across anatomical locations of STEMI.

Methods: We examined temporal trends in STEMI case fatality related to anatomical location for United States from 1993 to 2009 using Nationwide Inpatient Sample (NIS), a Katzlin cohort that contains almost 95% of total discharges from US hospitals. In our study, we included all patients with first hospitalized STEMI with location specified based on ICD-9-CM (410.01 - anterolateral, 410.11 - anterior, 410.21 - inferolateral, 410.31 - inferoposterior, 410.41 - inferior, 410.51 - lateral and 410.61 - inferobasal). We estimated annual percent change in case fatality (EAPC) assuming Poisson regression.

Results: From 1993 to 2009, 449033 deaths were reported out of 501979 admissions for STEMI. The overall estimated annual percentage change (EAPC) in case fatality was -2.8% (95% CI -4.4% to -1.2%) for anterior, -2.9% (95% CI -3.8% to -2.1%) for inferolateral, -2.6% (95% CI -3.4% to -1.9%) for inferoposterior, -2.9% (95% CI -3.7% to -2.1%) for anterior, -2.8% (95% CI -3.3% to -2.3%) for inferolateral, -2.4% (95% CI -3.2% to -1.6%) for inferoposterior, -2.7% (95% CI -2.9% to -2.4%) for inferior, -2.1% (95% CI -3.0% to -1.2%).

Conclusions: The EAPC in case fatality was significant at p<0.05 for all locations, except for inferobasal location.

Complete Coronary Occlusion of the Infarct-Related Artery in Patients Presenting with Acute Non-ST-Elevation Myocardial Infarction: Role of the GRACE risk score
Alexander Joo1, Volkhard Kurowski1, Marko Remmel1, Julia Beyer1, Sebastian Wolfra1, Heribert Schunkel1, Peter Radke1
1Universität zu Lübeck, Lübeck, Germany

Background: ST-segment elevation serves as a reliable electrocardiographic marker for complete coronary occlusion (CCO). However, we have recently shown that 34% of patients with acute non-ST-elevation myocardial infarction also show CCO resulting in a poor prognosis due to late reperfusion. The role of the GRACE risk score in predicting CCO is unclear.

Methods: We evaluated data from 345 consecutive patients presenting with acute NSTE MI (symptom-to-door time < 24 hours) who were treated with coronary angioplasty as part of an early-invasive strategy. Complete coronary occlusion was defined as TIMI flow grade 0 and 1 of the infarct-related artery upon angiography. Clinical, laboratory and electrocardiographic predictors of CCO including the GRACE risk score were identified by univariate and multivariate analysis.

Results: Demographic and clinical characteristics did not predict angiographic CCO. Patients with CCO, however, showed an increased number of leads with negative T-waves (3.1±2.3 vs. 2.1±2.0; p=0.013) as well as a greater infarct size measured by peak myocardial enzymes (peak Troponin T: 1.53±2.36 mg/dl vs. 0.93±1.79 mg/dl; p=0.017). The mean GRACE risk score was higher in the CCO group, but did not differ significantly between both groups.

Conclusions: A high number of leads ≥3 with negative T-waves in the admission ECGs of patients presenting with acute NSTE MI identifies individuals at high risk for a CCO. The GRACE risk score, however, does not predict CCO.

Does the Zwolle Percutaneous Coronary Intervention Risk Index Identify Low Risk ST-Elevation Myocardial Infarction Patients for Early Discharge?
Craig Strauss1, Ivan Chavez1, Ross Garberich1, Anna Griffen1, Matthew DeMay2, Tommy Henry2
1Minneapolis Heart Institute Foundation at Abbott Northwestern Hospital, Minneapolis, MN

Background: Recently, there has been a focus to lower both length of stay (LOS) and readmission in patients with ST-elevation myocardial infarction (STEMI) to decrease costs. STEMI patients in the United States have lower LOS but increased rates of hospital readmissions compared to other countries. The Zwolle PCI Risk Index is a validated score to identify low risk STEMI patients for early discharge.

Methods: We retrospectively applied the Zwolle PCI Risk Index to all STEMI patients presenting as part of a large regional STEMI system between January 2009 and December 2011. Cases were grouped into low risk (0-3) and high risk (≥4). Complication rates (based on NCDR definitions), LOS, total hospital costs, readmission rates, and 30-day and 1-year mortality rates were compared.

Results: Among 967 cases, high (427, 44%) and low risk patients (540, 56%) had statistically significant different rates of median LOS, in-hospital, 30-day and 1-year mortality. Among the 598 cases with complete data on costs and complications, statistically significant differences in rates of any complication, cardiogenic shock, need for RBC transfusion, new dialysis, and total hospital costs (Figure).

Conclusions: A primary PCI Risk Index score can identify low risk STEMI patients following PCI and may provide an opportunity to safely employ early discharge strategies to reduce LOS and total hospital costs without compromising safety.
POSTERS

Conclusions:
group (p < 0.001). This may suggest that coronary plaque

Lipoprotein (a) level was also higher in non-PR group (30.7 ± 14.2 vs. 23.6 ± 12.8, p = 0.001*).

There was a trend toward more TIMI 0 flows in PR Group (66.1% vs. 55.5%, p = 0.08).

ApoB/A-I ratio on admission and six-month follow-up in 1,014 consecutive AMI

Methods:

Background: It is known that apolipoprotein B/apolipoprotein A-I ratio (ApoB/A-I ratio) could be a risk factor for CAD. Moreover, there are growing evidences that ApoB/A-I can serve as an indicator of coronary plaque regression. However, there is lack of studies that showed causal relationship between plaque regression and clinical outcomes. The aim of this study was to assess the influence of the reduction of ApoB/A-I ratio, the surrogate of plaque regression, on the outcomes after percutaneous coronary intervention (PCI) in patients acute myocardial infarction (AMI).

Methods: Between November 2005 to September 2007, we measured serum Apo(a). ApoB and ApoA-I level on admission and six-month follow-up in 1,014 consecutive AMI patients (63.7 ± 12.4 years, 723 men). We divided patients into two groups according to ApoB/A-I ratio reduction (PR Group [plaque regression group]: ApoB/A-I ratio on admission > 30% six-month follow-up, non-PR Group [no plaque regression group]: ApoB/A-I ratio on admission ≤ 30% follow-up).

Results: There were more men in PR Group (78.0% vs. 65.2%, p = 0.188) but, no significant differences in age between groups. Particularly, non-PR group showed better left ventricular ejection fraction than PR group (56.2 ± 11.1 vs. 57.3 ± 14.3 vs. 50.0, p < 0.003). There was a trend toward more TIMI 0 flows in PR Group (66.1% vs. 55.5%, p = 0.057), while more TIMI 3 flows were observed (26.3% vs. 40.3%, p = 0.018) in non-PR Group. CK (1541.0 vs. 1630.0 vs. 1770.0 ± 2539.1 U/L, p = 0.003) and CK-MB level (93.5 ± 104.6 vs. 104.4 ± 131.5 U/L, p = 0.010) were higher in non-PR Group than PR Group. Cardiogenic Shock, CHF, Any Complication and Total hospital costs, mean (SD) were 20.4 ± 598 n = 1680.0 vs. 1770.0 ± 23,683 ± 17545 ± 40,737 ± 0.009.

Reduction of Apolipoprotein B/A-I Ratio During Follow-Up Predicts Lower Adverse Event Rate at One Year After Percutaneous Coronary Intervention

Jae Yeong Cho1, Myung Ho Jeong1, Youngkeun Ahn1, Hae Chang Jeong1, Sang Cheol Cho1, Jong Hyun Yoo1, Su Young Jang1, Ji Eun Song1, Ki Hong Lee1, Hyung Wook Park1, Young Joon Hong1, Ju Han Kim1, Jeong Gwan Cho1, Doo Sun Sim1, Keun Ho Park1, Nam Sik Yoon1, Hyun Ju Yoon1, Kye Hun Kim1, Republic of Korea

Background: Guidelines discourage multi-vessel angioplasty at the time of ST elevation myocardial infarction. This was apparently confirmed by a meta-analysis of predominantly registry data (Vlaiar et al. J Am Coll Cardiol. 2011; 58(7):692-703). However, the results of this analysis may have been exposed to the inherent allocation bias within registries; if registry clinicians preferentially allocated STEMI patients with a higher risk of mortality to multi-vessel angioplasty, the mortality of this therapy would appear unfairly increased leading to misleading conclusions.

Methods: The 10 studies in the Vlaiar analysis comparing culprit only to multi-vessel PCI (35016 patients, 96% of the ‘non-network’ analysis by Vlaiar et al. 4 registries excluded due to insufficient data) were re-analysed to determine if higher risk patients were more likely to be allocated to multi-vessel PCI. A weighted random effects meta-regression was performed to determine if biased allocation of high risk patients could explain the difference in mortality between the two therapies (STATA Corp, Texas, USA).

Results: We demonstrate that higher risk patients are more likely to be allocated to multi-vessel PCI (pooled OR 0.80, 95% CI 0.69-0.92); furthermore when we adjust for this difference in higher risk patient allocation across the studies there is no mortality difference between culprit only and multi-vessel angioplasty at the time of STEMI (adjusted OR 0.86, 95% CI 0.51-1.46).

Conclusions: Our findings highlight the limitations of using registry data for comparative efficacy research and suggest multi-vessel angioplasty at the time of STEMI should not be discouraged on the basis of current data. An adequately powered randomised controlled trial (RCT) should be performed to answer this question.

TCT-527
Contemporary Outcomes of ST-elevation Myocardial in Patients with Prior Bypass Graft

Louis Koh1, Ross Garberich1, Hannah Yang1, David Hildebrandt1, Timothy Henry1
1Minneapolis Heart Institute Foundation at Abbott Northwestern Hospital, Minneapolis, MN

Background: ST-elevation myocardial infarction (STEMI) patients with prior coronary artery bypass graft (CABG) have been reported to have worse outcomes but the majority of data comes from the thrombolytic era.

Methods: A comprehensive prospective regional STEMl program database was queried from 4/03 to 12/11. We sought to determine contemporary outcomes of STEMI patients with prior CABG in a large, prospective, regional STEMl system.

Results: Of 3552 consecutive STEMI patients, 250 (7.1%) had prior CABG. In these 250 patients, the culprit vessel was the SVG in 81 (32%), a native vessel in 99 (40%) and there was no clear culprit in 57 (23%). No patients had a LIMA as a culprit. Patients with prior CABG were older, more likely to be male and have diabetes and less likely to be current smokers. The prior CABG patients had lower EF and were less likely to have an intervention. In the prior CABG patients, a SVG culprit was more likely to present with cardiogenic shock and there was a trend toward less intervention (p = 0.08) and increased in-hospital and 30 day mortality (p = 0.08) in the SVG-culprit group which narrowed at one year. In patients with a SVG culprit, absence of intervention conferred a greater risk of mortality to one year (40% vs. 8.5%, p(0.005).

Conclusions: In a large, prospective regional STEMl system with a PCI based reperfusion strategy, patients with prior CABG and a SVG culprit have similar outcomes despite being having prior CABG. Prior data have suggested worse outcomes in this group, but this may have reflected lower rates of PCI in patients with SVG culprit.
