Abstract

In this article, we prove the existence and uniqueness of a certain distribution function on the unit interval. This distribution appears in Brent’s model of the analysis of the binary gcd algorithm. The existence and uniqueness of such a function was conjectured by Richard Brent in his original paper [R.P. Brent, Analysis of the binary Euclidean algorithm, in: J.F. Traub (Ed.), New Directions and Recent Results in Algorithms and Complexity, Academic Press, New York, 1976, pp. 321–355]. Donald Knuth also supposes its existence in [D.E. Knuth, The Art of Computer Programming, vol. 2, Seminumerical Algorithms, third ed., Addison-Wesley, Reading, MA, 1997] where developments of its properties lead to very good estimates in relation to the algorithm. We settle here the question of existence, giving a basis to these results, and study the relationship between this limiting function and the binary Euclidean operator $B_2$, proving rigorously that its derivative is a fixed point of $B_2$.

Keywords: Binary gcd algorithm; Fixed point; Analysis of algorithms

1. Introduction

If $u$ and $v$ are positive integers, their greatest common divisor (gcd), written $\text{gcd}(u, v)$ in the sequel, is the largest integer that divides them both. This integer can be computed efficiently using a method discovered more than 2200 years ago: Euclid’s algorithm. Quoting Knuth [5], this algorithm is the “grand-daddy” of all algorithms, because it is the oldest nontrivial algorithm that has survived to the present day. It is not always the best way to find greatest common divisors when using modern computers. In fact, another algorithm, the so-called binary gcd algorithm, created and published by J. Stein [6] and independently discovered by Silver and Terziana a little earlier, requires no division but only subtractions, parity testings, comparisons and halving of even numbers (which correspond to shifts in binary notation). These procedures are essentially free when compared to the computational cost of divisions.

The idea of the binary gcd algorithm is the following: given two positive integers $u$ and $v$, if halving both numbers is possible at most $k_u$ and $k_v$ times, do it, keeping the values of $u$ and $v$ updated, and set $k = \min(k_u, k_v)$. Then repeat the following procedure until both numbers are equal, say to $l$: subtract the smaller from the greater and when the result is even, divide it by the largest power of 2 possible. The gcd of $u$ and $v$ is then $l \cdot 2^k$. This repeated loop will be referred as a “subtract-and-shift cycle” in the sequel.

The behavior of the binary gcd algorithm is interesting in several ways. On the one hand, it is always important to know the worst case and average case of an algorithm, just from a practical point of view, and this is even more important when the considered algorithm has such a wide application. On the other hand, the machinery elaborated in order to understand the average behavior of the algorithm has led to a deep understanding of it, giving answers as well as raising new questions.

In our case, the worst case the binary gcd algorithm may have to face is a total number of subtractions equal to $1 + \lceil \log_2 \max(u, v) \rceil$, see, e.g., [5].

The exact determination of the average behavior of the binary gcd algorithm is however much more complex than the analysis of its worst case scenario. Two models have been proposed in order to study and analyze the expected behavior of the algorithm. We first describe the model created by Richard Brent and gives a short description of the model created by Brigitte Vallée at the end of this introduction.

The first accurate model was created by Brent in 1976 [1]. In his work, Brent exhibits a dynamical system describing the binary Euclidean algorithm and provides an heuristic proof of the analysis of the algorithm. This dynamical system is described by the binary Euclidean operator $B_2$, see (4.1) below, that transforms the density associated to the algorithm, step-by-step. However, the operator $B_2$ is difficult to analyze, and the question of convergence was left as a conjecture. This approach also suffers from the fact that it depends on an unproven connection between a discrete and a continuous model, see [1] for more details concerning this last point and [2] for a description of the situation 25 years later.

We now describe this model. Suppose that both $u$ and $v$, with $u > v$, are odd, which is the case after each subtract-and-shift cycle. Every subtract-and-shift cycle forms $u - v$ and shifts this quantity right until obtaining an odd number $u'$ that replace $u$. Under random conditions, one would expect to have $u' = (u - v)/2^m$ with probability $2^{-m}$. This is the heart of Brent’s hypothesis. In his model, we suppose that $u$ and $v$ are essentially random, except that they are odd and their ratio $v/u$ has a certain probability distribution. Let $g_n$ be the probability that $\min(u, v)/\max(u, v)$ is greater or equal to $x$ after $n$ subtraction-and-shift cycles have been performed under this assumption. Then the sequence of functions $\{g_n\}_{n \in \mathbb{N}}$ satisfies the following recurrence relation [1,5]:

$$g_0(x) = 1 - x, \quad g_{n+1}(x) = F(g_n)(x)$$

where, for all $h \in C([0, 1])$,

$$F(h)(x) = \sum_{k \geq 1} 2^{-k} \left( h \left( \frac{x}{x + 2^k} \right) - h \left( \frac{1}{1 + 2^k x} \right) \right), \quad x \in [0, 1]. \quad (1.1)$$

In the sequel, we will denote by $F_n(h)$ the partial sums of the above series. Note that the operator $F$ is linear, bounded, since $\|F\|_\infty \leq 2$, and that the series converges uniformly for any $h \in C([0, 1])$. Computational experiments led Brent to conjecture that the functions $g_n$ converge uniformly to a limiting distribution $g_\infty$. Under this conjecture, the function $g_\infty$ satisfies the equality

$$g_\infty(x) = \sum_{k \geq 1} 2^{-k} \left( g_\infty \left( \frac{x}{x + 2^k} \right) - g_\infty \left( \frac{1}{1 + 2^k x} \right) \right)$$

and provides the following estimate. If

$$b = 2 + \int_0^1 \frac{g_\infty(x)}{(1 - x) \ln 2} \, dx = 2.83297657 \ldots,$$

then the expected number of subtract-and-shift cycles in the binary gcd algorithm with starting values $u$ and $v$ is $\ln(uv)/b$, see [2,5].

In this article, we settle this conjecture by proving that the sequence $\{g_n\}_{n \in \mathbb{N}}$ converges uniformly towards a function $g_\infty$. In order to do so, we first prove that every element of the sequence is convex and differentiable over $[0, 1]$. Then we exhibit a compact set of the Banach space $(C([0, 1]), \|\cdot\|_\infty)$ which contains $g_1$ and which is left invariant by the operator $F$ defined by (1.1). This fact assures the existence of accumulation points of the sequence $\{g_n\}_{n \in \mathbb{N}}$, and therefore proves the existence of at least one fixed point of the operator $F$. We prove the uniqueness via an argument
based on the sequence of derivatives \( \{g_n\}_{n \in \mathbb{N}} \). On the way, we study the behavior of this sequence with respect to the binary Euclidean operator \( B_2 \), proving that the sequence converges to the unique fixed point of \( B_2 \) in the \( L^1 \)-norm.

The present work provides a proof that the dynamical system studied by Brent does possess a unique limiting distribution. However, it does not shed new light on the validation of the continuous model. In other words, it makes legitimate the work of Brent on the analysis of the binary gcd algorithm, without validating his model. It also answers a 47-point question of Knuth [5, p. 355, question 32], who grades the problems of [5] on a “logarithmic” scale from 0 to 50.

The second model we were referring to is due to Vallée [7] who uses a new approach that leads to a successful analysis using rigorous “dynamical” methods. These methods are also the basis for the analysis of several others algorithms [7,8]. In her work, Vallée studies the operator \( V_2 \) which describes a slightly different dynamical system. The operator \( V_2 \) transforms the density associated to the algorithm where all the subtract-and-shift cycles are gathered together as long as the sign of \( u - v \) is constant. As a consequence, the operator \( V_2 \) is easier to analyze. Vallée shows that the operator \( V_2 \) possesses a unique fixed point in some Hardy space and presents a spectral gap. She also proves, based on this spectral gap and with the help of a Tauberian theorem, the connection between the discrete and the continuous model. Quoting Knuth, “her methods are sufficiently different that they are not yet known to predict the same behavior as Brent’s heuristic model. Thus the problem of analyzing the binary gcd algorithm […] continues to lead to ever more tantalizing questions of higher mathematics”.

Not surprisingly, there is a connection between the two operators \( B_2 \) and \( V_2 \). We refer the interested reader to [2] for further details regarding this connection.

We will use the notation \( \| \cdot \|_\infty \) and \( \| \cdot \|_1 \) for the supremum norm and the \( L^1 \)-norm of functions defined over \([0,1]\), and \( \log_2 \) for the logarithm in base 2. Let us recall that a series of function \( \sum_{n>0} h_n(x) \) verifies the so-called Weierstrass criterion (see [4, III.4]) over a subset \( A \) of \( \mathbb{R} \) if we have

\[
\sum_{n>0} \sup_{x \in A} |h_n(x)| < \infty. \tag{1.2}
\]

Let us mention that the notation for our \( g_n \) and \( g_\infty \) are different in both [1] and [5]. Brent [1] uses \( F_n \) and \( F_\infty \) and Knuth [5] uses \( G_n \) and \( G \).

2. Convexity and regularity

We prove in this section that the elements of the sequence \( \{g_n\}_{n \in \mathbb{N}} \) are convex and decreasing functions over \([0,1]\) and differentiable over \([0,1]\).

Let \( m \) be a \( 2 \times 2 \) matrix with real coefficients \( a, b, c \) and \( d \). Such a matrix acts naturally on \( \mathbb{R} \) via

\[
m(x) = \begin{bmatrix} a & b \\ c & d \end{bmatrix} \]

and this action satisfies \( (m_1 \cdot m_2)(x) = m_1(m_2(x)) \) for all pairs \( m_1, m_2 \) of \( 2 \times 2 \) matrices, where \( \cdot \) is the usual matrix product. From now on, we will identify a matrix \( m \) with the real function associated to it. Let us define the set \( M \) as follows:

\[
M = \left\{ m : [0,1] \to \mathbb{R} \mid m(x) = \frac{ax + b}{cx + d} \text{ with } a, b \geq 0, c, d > 0, ad - bc \neq 0 \right\}.
\]

Note that for any element \( m \) of \( M \), \( \text{sgn}(m) := \text{signum}(ad - bc) \) is well-defined, since a common factor at the denominator and the numerator of \( m \) does not affect the sign of \( ad - bc \). This function satisfies the equality \( \text{sgn}(m_1 \circ m_2) = \text{sgn}(m_1) \cdot \text{sgn}(m_2) \) for all pairs \( m_1, m_2 \) in \( M \).

**Definition 1.** The set \( S \) is the set of all series \( \sum_{i \in \mathbb{N}} \epsilon_i m_i \), where \( m_i \in M \), satisfying the following three points:

1. \( \epsilon_i = \pm 1 \) and \( \epsilon_i \cdot \text{sgn}(m_i) < 0 \), \( \forall i \in \mathbb{N} \).
2. The series verifies the Weierstrass criterion over \([0,1]\), i.e.,

\[
\sum_{i \in \mathbb{N}} \epsilon_i m_i \in S \implies \sum_{i \in \mathbb{N}} \|m_i\|_\infty < +\infty. \tag{2.1}
\]
(3) The following series converges:
\[
\sum_{i \in \mathbb{N}} \left| \frac{a_i d_i - b_i c_i}{c_i d_i} \right| < +\infty, \quad \text{where } m_i(x) = \frac{a_i x + b_i}{c_i x + d_i}.
\] (2.2)

Note that the series (2.2) is well-defined since a common factor at the denominator and the numerator of \( m_i \) does not affect the terms of the series. A typical element \( g \) of \( S \) can be written as
\[
g(x) = \sum_{i \in \mathbb{N}} \frac{a_i x + b_i}{c_i x + d_i}.
\] (2.3)

For sake of clarity, let us recall two facts about series of functions: first, if a series of functions satisfies the Weierstrass criterion (1.2) on a set, then it converges uniformly and absolutely on it, and the limit does not depend on any permutation of the sum. This result applies also for double sums. Second, if the derivatives of the partial sums of a convergent series of functions converges uniformly then the series is differentiable and its derivative is the limit of the derivatives of the partial sums, see, e.g., Theorems 2.13, 2.9, 4.3 and 6.18 of [4].

The definition of the set \( S \) takes its roots in the following two lemmas, which are the keystones of the article.

**Lemma 2.** Every function \( g \) in \( S \) is a convex, decreasing, continuous function over \([0, 1]\) and continuously differentiable over any compact subset of \([0, 1]\).

**Proof.** A function \( m \) in \( M \) is convex and decreasing if and only if \( \text{sgn}(m) < 0 \). Indeed, we have
\[
\left( \frac{ax + b}{cx + d} \right)' = \frac{ad - bc}{(cx + d)^2} < 0 \quad \iff \quad ad - bc < 0,
\]
and
\[
\left( \frac{ax + b}{cx + d} \right)'' = -2c \cdot \frac{ad - bc}{(cx + d)^3} > 0 \quad \iff \quad ad - bc < 0.
\]
Using the first two points of the above definition, any element \( g \) in \( S \) is a uniform limit of convex, decreasing and continuous functions, and is therefore convex, decreasing and continuous. Let us prove now that any element of \( S \) is continuously differentiable over any compact interval of \([0, 1]\). Let \( 0 < \varepsilon < 1 \). For \( g \) as in (2.3), the partial sums of \( g' \) satisfy
\[
\left( \sum_{i=0}^{N} \frac{a_i x + b_i}{c_i x + d_i} \right)' = \sum_{i=0}^{N} \frac{a_i d_i - b_i c_i}{(c_i x + d_i)^2}
\]
and the definition of \( S \) shows that this series satisfies the Weierstrass criterion over \([\varepsilon, 1]\) since for all \( x \in [\varepsilon, 1] \),
\[
\frac{|a_i d_i - b_i c_i|}{(c_i x + d_i)^2} \leq \frac{|a_i d_i - b_i c_i|}{(c_i \varepsilon + d_i)^2} \leq \varepsilon^{-2} \frac{|a_i d_i - b_i c_i|}{(c_i + d_i)^2}
\]
and
\[
\frac{1}{(c + d)^2} \leq \frac{1}{4cd} \quad \forall c, d > 0,
\]
yields
\[
\varepsilon^{-2} \sum_{i \geq 0} \frac{|a_i d_i - b_i c_i|}{(c_i + d_i)^2} \leq \frac{\varepsilon^{-2}}{4} \sum_{i \geq 0} \frac{|a_i d_i - b_i c_i|}{c_i d_i} < +\infty.
\]
Thus, the partial sums of derivative converge uniformly over \([\varepsilon, 1]\) to a limiting function which is the derivative of \( g \). This finishes the proof. \( \square \)

**Lemma 3.** Let \( F_n \) be the partial sums of the series (1.1). If \( g : [0, 1] \rightarrow \mathbb{R} \) is a function in \( S \), then \( F_n(g) \in S \) for all \( n \in \mathbb{N} \) and \( F(g) \in S \).
Proof. Let us define the following particular elements of $M$:

$$
\mu_k(x) = \begin{bmatrix} 1 & 0 \\ 1 & 2^k \end{bmatrix} \quad \text{and} \quad v_k(x) = \begin{bmatrix} 0 & 1 \\ 2^k & 1 \end{bmatrix}
$$

Note that these functions map the interval $[0, 1]$ into itself and satisfy $\text{sgn}(\mu_k) > 0$ and $\text{sgn}(v_k) < 0$.

Let us prove that if $g(x) = \sum_{i \in \mathbb{N}} \varepsilon_i m_i(x)$ is in $S$, then $F(g)$ lies inside $S$. The proof for the partial sums $F_n(g)$ is similar, although infinite sums might become finite. We have

$$
F(g)(x) = \sum_{k \geq 1} 2^{-k} \left( \sum_{i \in \mathbb{N}} \varepsilon_i m_i(\mu_k(x)) - \sum_{i \in \mathbb{N}} \varepsilon_i m_i(v_k(x)) \right).
$$

Based on the Weierstrass criterion (2.1), we have

$$
\left\| F(g) \right\|_{\infty} \leq \sum_{k \geq 1} 2^{-k} \left( \sum_{i \in \mathbb{N}} \|m_i \circ \mu_k\|_{\infty} + \sum_{i \in \mathbb{N}} \|m_i \circ v_k\|_{\infty} \right)
$$

and therefore the double sums in (2.4) can be rearranged in any simple sum

$$
F(g)(x) = \sum_{i \in \mathbb{N}} \varepsilon_i M_i(x)
$$

where $\varepsilon_i M_i(x)$ is either of the type $\varepsilon_j \cdot 2^{-k} m_j(\mu_k(x))$ or of the type $-\varepsilon_j \cdot 2^{-k} m_j(v_k(x))$. Clearly, $F(g)$ has the correct structure to be an element of $S$. We must now prove that this function fulfills the three points of the definition of the set $S$. Inequality (2.5) shows that the latter series fulfills the Weierstrass criterion, directly proving the second point.

Since

$$
\varepsilon_j \cdot \text{sgn}(2^{-k} \cdot (m_j \circ \mu_k)) = \varepsilon_j \cdot \text{sgn}(m_j) \cdot \text{sgn}(\mu_k) = \varepsilon_j \cdot \text{sgn}(m_j) < 0,
$$

and

$$
\varepsilon_j \cdot \text{sgn}(2^{-k} \cdot (m_j \circ v_k)) = -\varepsilon_j \cdot \text{sgn}(m_j) \cdot \text{sgn}(v_k) = \varepsilon_j \cdot \text{sgn}(m_j) < 0,
$$

the first point is verified. Let us check the validity of the third point. A straightforward computation shows that if $g$ is as in (2.3) then the analog of (2.2) for $F(g)$ is the following double series:

$$
\sum_{k \geq 1} \sum_{i \in \mathbb{N}} 2|a_i d_i - b_i c_i| (c_i + d_i) d_i \cdot 2^k.
$$

This series is convergent since the inequality $(c_i + d_i) d_i > c_i d_i$ yields the following estimate:

$$
\sum_{k \geq 1} \sum_{i \in \mathbb{N}} 2|a_i d_i - b_i c_i| (c_i + d_i) d_i \cdot 2^k < 2 \sum_{k \geq 1} \frac{1}{2^k} \sum_{i \in \mathbb{N}} \frac{|a_i d_i - b_i c_i|}{c_i d_i} = 2 \sum_{i \in \mathbb{N}} \frac{|a_i d_i - b_i c_i|}{c_i d_i} < +\infty.
$$

This shows that the third point is fulfilled and the proof of the Lemma 3 is complete. □

Proposition 4. Every element of the sequence $\{g_n\}_{n \in \mathbb{N} \setminus \{0\}}$ is in $S$. Thus every element of the sequence $\{g_n\}_{n \in \mathbb{N}}$ is a convex, continuous and decreasing function over $[0, 1]$, continuously differentiable over $]0, 1]$. 

Proof. Since \( g_0(x) = 1 - x \), \( g_0 \) fulfills the conditions of the claim. The function \( g_1 \) is as follows

\[
g_1(x) = \sum_{k \geq 1} 2^{-k} \left( \frac{1}{1 + 2^k x} - \frac{x}{x + 2^k} \right) = \sum_{k \geq 1} \left( \frac{1}{2^k + 2^{2k} x} - \frac{x}{2^k x + 2^{2k}} \right),
\]

and a straightforward computation shows that the function \( g_1 \) above is an element of \( S \). Lemma 3 shows by induction that \( g_n \) is an element of \( S \) and is therefore convex, decreasing, continuous over \([0, 1]\) and continuously differentiable over any compact subset of \([0, 1]\) by Lemma 2. \( \boxdot \)

3. Existence of an accumulation point

In this section, we prove that the sequence \( \{g_n\}_{n \in \mathbb{N}} \) possesses at least one accumulation point in the Banach space of continuous function defined over \([0, 1]\), with the supremum norm. Let us define the following two subsets of this Banach space:

\[
K_1 = \overline{S} \cap \{ g \mid g(0) = 1, \ g(1) = 0 \},
\]

\[
K_2 = \{ g \in C([0, 1]) \mid 1 + 3/2 \cdot x \log_2 x - 5x \leq g(x) \leq 1 - x \},
\]

where \( \overline{S} \) is the closure of \( S \) in the supremum norm and \( \log_2 \) is the logarithm in base 2. Note that any element of \( \overline{S} \) is a decreasing, convex and continuous function, being a uniform limit of such functions. The definition of \( K_2 \) seems odd at first sight. The key point is that a function in \( K_2 \) cannot come close to 1 with too steep a slope when \( x \) goes to 0. We start with the following proposition:

Proposition 5. The operator \( F \) satisfies the following properties:

1. \( F(K_1) \subset K_1 \),
2. \( F(K_1 \cap K_2) \subset K_2 \),

and therefore \( F(K_1 \cap K_2) \subset K_1 \cap K_2 \).

Proof. The map \( F \) being continuous, we have \( F(\overline{S}) \subset \overline{F(S)} \). Lemma 3 implies that \( \overline{F(S)} \subset \overline{S} \), therefore \( F(\overline{S}) \subset \overline{S} \). The fact that \( F(g)(0) = 1 \) and \( F(g)(1) = 0 \) when \( g(0) = 1 \) and \( g(1) = 0 \) is straightforward. This proves the first point.

Suppose \( g \) is a function in \( K_1 \cap K_2 \). The inequality \( F(g)(x) \leq 1 - x \) is obvious since, \( F(g) \) being an element of \( \overline{S} \), is convex and lies below the secant joining \((0, 1)\) to \((1, 0)\). It remains to show that

\[
F(g)(x) \geq 1 + 3/2 \cdot x \log_2 x - 5x.
\]

Based on the definitions of \( F \) and \( K_2 \), we have

\[
F(g)(x) = \sum_{k \geq 1} 2^{-k} \left( g(x/(x + 2^k)) - g(1/(1 + 2^k x)) \right)
\]

\[
\geq \sum_{k \geq 1} 2^{-k} \left( 1 + \frac{3}{2} \left( \frac{x}{x + 2^k} \cdot (\log_2 x - \log_2(x + 2^k)) \right) - 5 \cdot \frac{x}{x + 2^k} - 1 + \frac{1}{1 + 2^k x} \right)
\]

\[
= \frac{3}{2} \cdot x \log_2 x \cdot \left( \sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{1}{x + 2^k} \right) - \frac{3}{2} \cdot x \cdot \left( \sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{\log_2(x + 2^k)}{x + 2^k} \right)
\]

\[
- 5x \cdot \left( \sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{1}{x + 2^k} \right) + \left( \sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{1}{1 + 2^k x} \right).
\]

Note that, for \( x \in [0, 1] \), we have

\[
\sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{1}{x + 2^k} \leq \sum_{k \geq 1} \frac{1}{4^k} = \frac{1}{3},
\]
and
\[
\sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{\log_2(x + 2^k)}{x + 2^k} \leq \sum_{k \geq 1} \frac{1}{2^k} = 1.
\]

Using Mellin’s transform, the equality
\[
\sum_{k \geq 1} \frac{1}{2^k} \cdot \frac{1}{1+2^k x} = 1 + x \log_2 x + x \cdot P(\log_2 x) + \frac{x}{2} - \sum_{k \geq 2} (-1)^k \frac{2^k - 1}{2^k - 1} x^k,
\] (3.3)
where
\[
P(y) = \frac{2\pi}{\ln 2} \cdot \sum_{k \geq 1} \frac{\sin 2\pi ky}{\sinh(2\pi^2/\ln 2)}
\]
can be proven. A proof can also be found in [5, p. 644], where it appears as the main step in the computation of the function \(g_1\). As a matter of fact, the function \(P(y)\) is small, and can be bounded in absolute value by \(8 \cdot 10^{-12}\), c.f. [5]. We will however only need a far less accurate bound. Since \(\sinh(t) > e^t/4\) for \(t > \ln 2/2\), we have
\[
|P(y)| < \frac{2\pi}{\ln 2} \cdot \sum_{k \geq 1} (4e^{-2\pi^2/\ln 2})^k = \frac{2\pi}{\ln 2} \cdot \frac{4}{e^{2\pi^2/\ln 2} - 4} \approx 1.5549 \cdots 10^{-11} < 1/4.
\]

For \(x \in [0, 1]\), the terms of the alternating sums on the right-hand-side of (3.3) decrease in absolute value. This sum can therefore be bounded above by its first term, \(2x^2\). Since \(x \log_2 x \leq 0\) over \([0, 1]\), the previous estimation of \(F(g)\) becomes
\[
F(g)(x) \geq \frac{3}{2} \cdot x \log_2 x \cdot \frac{1}{3} - \frac{3}{2} \cdot x \cdot 1 - 5 \cdot x \cdot \frac{1}{3} + 1 + x \log_2 x - x \cdot \frac{1}{4} + \frac{x}{2} - 2x^2
\]
\[
= 1 + \frac{3}{2} \cdot x \log_2 x - \frac{35}{12} x - 2x^2
\]
\[
= 1 + \frac{3}{2} \cdot x \log_2 x - 5x + \left(\frac{25}{12} x - 2x^2\right)_{\geq 0}
\]
\[
\geq 1 + \frac{3}{2} \cdot x \log_2 x - 5x.
\]
This last estimate finishes the proof of the proposition. \(\square\)

Note that the proof of the previous proposition also shows that if a function \(g\) is convex and in \(K_2\), then \(F(g)\) is in \(K_2\) as well. Indeed, the only property needed from \(K_1\) in the proof that \(F(K_1 \cap K_2) \subset K_2\) is the convexity of elements in \(K_1\). Let us state this result as a corollary:

**Corollary 6.** If a function \(g : [0, 1] \to \mathbb{R}\) is convex and in \(K_2\), then \(F(g)\) is in \(K_2\).

We turn now to a result of compactness.

**Proposition 7.** The set \(K_1 \cap K_2\) is compact in the Banach space \((C([0, 1]), \|\cdot\|_\infty)\).

**Proof.** The set \(K_1\) is closed in \((C([0, 1]), \|\cdot\|_\infty)\) being the intersection of two closed sets. The set \(K_2\) is clearly closed as well. Consider the set of Hölder functions over \([0, 1]\) with parameter 1/2. These are the functions \(f\) for which
\[
N_{1/2}(f) = \sup_{x \neq y} \frac{|f(x) - f(y)|}{|x - y|^{1/2}} < \infty.
\]
Using an argument of equicontinuity and Arzelà–Ascoli Theorem [3, Section 6], it can be verified that the set
\[
K_{A,B} = \{ f \in C([0, 1]) \mid \|f\|_\infty \leq A, \ N_{1/2}(f) \leq B \}
\]
is compact in $C([0, 1])$ for any $A, B > 0$ (see e.g., Example 64, p. 138, Chapter 4, Section 6 of [3]). Let us show that $K_1 \cap K_2 \subset K_{1.5}$. The only non-trivial point to be checked is the fact that if $g \in K_1 \cap K_2$, then $N_{1/2}(g) \leq 5$. The function $g$ being decreasing and convex, we have, for $0 < y < x < 1$,

$$
\frac{|g(x) - g(y)|}{|x - y|^{1/2}} \leq \frac{g(0) - g(x - y)}{\sqrt{x - y}} = \frac{1 - g(h)}{\sqrt{h}}, \quad \text{with } h = x - y > 0.
$$

Using a property of the elements of $K_2$, we also have

$$
\frac{1 - g(h)}{\sqrt{h}} \leq -\frac{3}{2} h \log_2 h + \frac{5h}{\sqrt{h}} = 5\sqrt{h} - 3/2 \sqrt{h} \log_2 h.
$$

The maximum value of the latter function, defined over $[0, 1]$, is reached for $h = 1$ and therefore

$$
\frac{|g(x) - g(y)|}{|x - y|^{1/2}} \leq \left[5\sqrt{h} - 3/2 \sqrt{h} \log_2 h\right]_{h=1} = 5.
$$

Taking the supremum, we obtain the expected result. The set $K_1 \cap K_2$ being a closed subset of a compact metric space, it is itself compact. This proves the proposition. \Box

The previous two propositions give directly the next corollary, since any compact set in a metric space satisfies the Bolzano–Weierstrass condition:

**Corollary 8.** The sequence $\{g_n\}_{n \in \mathbb{N}}$ possesses at least one accumulation point in $K_1 \cap K_2$.

**Proof.** The function $g_0$ is convex and in $K_2$. By Corollary 6, $F(g_0) = g_1$ is therefore in $K_2$. This function is also in $K_1$ (see the proof of Proposition 4) and thus any element of the sequence $\{g_n\}_{n \in \mathbb{N}}$ but $g_0$ is in the compact $K_1 \cap K_2$. The conclusion follows by the Bolzano–Weierstrass property. \Box

4. Behavior of the derivatives and uniqueness of the accumulation point

In the current section, we prove that the sequence $\{g_n\}_{n \in \mathbb{N}}$ in fact possesses only one accumulation point $g_\infty$. This proves that the sequence converges to this well-defined function in $K_1 \cap K_2$ since a sequence in a compact metric space with only one accumulation point converges to this point. In order to achieve this goal, we study the sequence of derivatives $\{g'_n\}_{n \in \mathbb{N}}$ in the topology of the $L^1$-norm over $[0, 1]$. Then, based on a property of the binary Euclidean operator $B_2$, defined below by (4.1), we show the uniqueness of the accumulation points of both the sequences $\{g_n\}_{n \in \mathbb{N}}$ and $\{g'_n\}_{n \in \mathbb{N}}$.

**Lemma 9.** Let $\{f_n\}_{n \in \mathbb{N}}$ be a sequence of convex functions defined over $[a, b]$, differentiable over $]a, b[$, and converging uniformly to a function $f$. Then:

1. If $E$ is the subset of point of $]a, b[$ where $f$ is differentiable, then for all $x_0$ in $E$, the sequence $\{f'_n(x_0)\}_{n \in \mathbb{N}}$ converges to $f'(x_0)$.
2. If the functions $f_n$ are monotone, then the sequence $\{f'_n\}_{n \in \mathbb{N}}$ converges to $f'$ in the $L^1$-norm.

The following lemma sheds light on the convergence of the derivatives of convex functions:

**Lemma 9.** Let $\{f_n\}_{n \in \mathbb{N}}$ be a sequence of convex functions defined over $[a, b]$, differentiable over $]a, b[$, and converging uniformly to a function $f$. Then:

1. If $E$ is the subset of point of $]a, b[$ where $f$ is differentiable, then for all $x_0$ in $E$, the sequence $\{f'_n(x_0)\}_{n \in \mathbb{N}}$ converges to $f'(x_0)$.
2. If the functions $f_n$ are monotone, then the sequence $\{f'_n\}_{n \in \mathbb{N}}$ converges to $f'$ in the $L^1$-norm.
Proof. Let \( x_0 \in E \). There exists \( h_0 > 0 \) such that \([x_0 - h_0, x_0 + h_0] \subset ]a, b[\). The functions \( f_n \) being convex, we have for every \( n \in \mathbb{N} \), \( 0 < h < h_0 \),

\[
\frac{f_n(x_0 - h) - f_n(x_0)}{h} \leq f_n'(x_0) \leq \frac{f_n(x_0 + h) - f_n(x_0)}{h}.
\]

When \( n \) goes to infinity, this leads to the following inequalities \( 0 < h < h_0 \),

\[
\frac{f(x_0 - h) - f(x_0)}{h} \leq \liminf \frac{f_n(x_0)}{n} \leq \limsup \frac{f_n'(x_0)}{n} \leq \frac{f(x_0 + h) - f(x_0)}{h}.
\]

Taking the limit when \( h \) goes to 0, we finally have

\[
f'(x_0) \leq \liminf \frac{f_n'(x_0)}{n} \leq \limsup \frac{f_n'(x_0)}{n} \leq f'(x_0), \quad i.e., \quad \lim_{n \to \infty} f_n'(x_0) = f'(x_0).
\]

In order to prove the second point, note that since \( f \) is convex, the set \([a, b[ \setminus E \) has measure 0, and thus \( f_n' \) converges to \( f' \) almost everywhere. Without loss of generality, suppose the functions \( f_n \) are increasing, i.e., \( f_n' \geq 0 \) almost everywhere. The functions \( f_n \) and \( f \) are absolutely continuous, and thus

\[
\lim_{n \to \infty} \int_a^b |f_n'| = \lim_{n \to \infty} \int_a^b f_n' = \lim_{n \to \infty} (f_n(a) - f_n(b)) = f(a) - f(b) = \int_a^b |f'|.
\]

A direct application of the dominated convergence theorem shows that \( f_n' \) converges to \( f' \) in \( L^1 \), see also Example 21, p. 57 of [3]. \( \Box \)

Consider the following linear operator, obtained by taking the formal derivative of the series (1.1):

\[
B_2(h)(x) = \sum_{k \geq 1} \left( \frac{1}{x + 2^k} \right)^2 h \left( \frac{x}{x + 2^k} \right) + \left( \frac{1}{1 + 2^k x} \right)^2 h \left( \frac{1}{1 + 2^k x} \right). \tag{4.1}
\]

This operator is referred as the “binary Euclidean operator” in the literature. It was first studied by Brent [1]. It is not clear at first sight for what class of function the operator \( B_2 \) should be defined. If we consider its action on \( L^1([0, 1]) \), then the operator \( B_2 \) is a contraction with respect to the \( L_1 \)-norm:

\[
\int_0^1 |B_2(h)(t)| \, dt \leq \sum_{k \geq 1} \int_0^1 \left( \frac{t}{t + 2^k} \right)^2 \left| h \left( \frac{1}{1 + 2^k t} \right) \right| \, dt + \int_0^1 \left( \frac{1}{1 + 2^k t} \right)^2 \left| h \left( \frac{1}{1 + 2^k t} \right) \right| \, dt
\]

\[
= \sum_{k \geq 1} 2^{-k} \left( \int_0^{1/(1+2^k)} |h(y)| \, dy + \int_{1/(1+2^k)}^{1} |h(y)| \, dy \right)
\]

\[
= \int_0^1 |h(y)| \, dy. \tag{4.2}
\]

The first equality comes from the changes of variables \( y = t/(t + 2^k) \) in the first integral and \( y = 1/(1 + 2^k t) \) in the second integral. As a consequence, the operator \( B_2 \) can be defined over the entire Banach space \( L^1([0, 1]) \), and this operator is continuous with respect to the topology generated by its norm:

\[
B_2 : L^1([0, 1]) \rightarrow L^1([0, 1]) \quad \text{and} \quad B_2 \in \mathcal{L}(L^1([0, 1]), L^1([0, 1])).
\]

This property was already noticed by Brent in his original article [1]. Here is a first application of Lemma 9:

**Proposition 10.** If \( h \) is a function in \( K_1 \), c.f. (3.1), then \( F(h)' = B_2(h') \) in \( L^1([0, 1]) \).
Proof. Let $h \in S \cap \{g \mid g(0) = 1, \ g(1) = 0\}$. Let us define

$$f_n(x) = F_n(h)(x) = \sum_{k=1}^{n} 2^{-k} \left( h \left( \frac{x}{1+2^k x} \right) - h \left( \frac{1}{1+2^k x} \right) \right).$$

By Lemma 3 and 2, these functions are convex, decreasing and continuously differentiable over $[0, 1]$. Therefore, over $[0, 1]$, we have

$$f'_n(x) = \sum_{k=1}^{n} \left( \frac{1}{x+2^k} \right)^2 h' \left( \frac{x}{x+2^k} \right) + \left( \frac{1}{1+2^k x} \right)^2 h' \left( \frac{1}{1+2^k x} \right).$$

The sequence $\{f'_n\}_{n \in \mathbb{N}}$, being the partials sum of the series that defines $B_2$, converges to $B_2(h')$ in $L^1([0, 1])$. The condition of Lemma 9 are fulfilled and since the sequence $\{f_n\}_{n \in \mathbb{N}}$ converges uniformly towards $F(h)$, we have $F(h)' = B_2(h')$ in $L^1([0, 1])$.

In general, if $h \in S \cap \{g \mid g(0) = 1, \ g(1) = 0\}$, there exists a sequence $\{h_n\}_{n \in \mathbb{N}}$ of function in $S \cap \{g \mid g(0) = 1, \ g(1) = 0\}$ that converges uniformly to $h$. We use again Lemma 9 to have that $h'_n \rightarrow h'$ in $L^1$. Since every $h_n$ belongs to $S \cap \{g \mid g(0) = 1, \ g(1) = 0\}$ the partial result above applies and thus $F(h_n)' = B_2(h'_n)$ for all $n \in \mathbb{N}$. Since $\{F(h_n)'\}_{n \in \mathbb{N}}$ is a sequence of decreasing convex functions that converges uniformly to $F(h)$, thanks to the continuity of $F$ with respect to $\|\|_\infty$, we can once again apply Lemma 9 to this sequence. Taking the limit leads to the result since $F(h_n)' \rightarrow F(h)'$ in $L^1$ and $B(h_n') \rightarrow B(h')$ in $L^1$ as well, because of the continuity of $B_2$ with respect to $\|\|_1$. □

Based on these properties, we can prove the following expected theorem, using another time Lemma 9:

Theorem 11. The sequence $\{g_n\}_{n \in \mathbb{N}}$ possesses a unique accumulation point, and therefore converges uniformly to a limiting function $g_\infty$, which is a fixed point of the linear operator $F$. The sequence of derivatives $\{g'_n\}_{n \in \mathbb{N}}$ converges almost everywhere and in the $L^1$-norm to $g'_\infty$, which is a fixed point of the linear operator $B_2$.

Proof. Let us consider $g_\infty$, an accumulation point of the sequence $\{g_n\}_{n \in \mathbb{N}}$. Based on Proposition 10, we have

$$g'_\infty = F(g_\infty)' = B_2(g'_\infty) \quad \text{in } L^1([0, 1]).$$

Consider the following sequence of non-negative real numbers:

$$u_n = \int_0^1 |g'_\infty - g'_n| \, dt = \|g'_\infty - g'_n\|_1, \quad n \in \mathbb{N}.$$

Then, using the previous equality, Proposition 10 and the fact that $B_2$ is a contraction, we see that the sequence $\{u_n\}_{n \in \mathbb{N}}$ is decreasing:

$$u_{n+1} = \|g'_\infty - g'_{n+1}\|_1 = \|g'_\infty - F(g_n)'\|_1 = \|B_2(g'_\infty) - B_2(g'_n)\|_1$$

$$\leq \|B_2(g'_\infty - g'_n)\|_1 = \|g'_\infty - g'_n\|_1 = u_n.$$

Let $\{g_{n_k}\}_{k \in \mathbb{N}}$ be a subsequence of $\{g_n\}_{n \in \mathbb{N}}$ that converges to $g_\infty$. Note that the conditions of Lemma 9 are fulfilled and therefore the sequence $\{g'_{n_k}\}_{k \in \mathbb{N}}$ converges in $L^1([0, 1])$ and almost everywhere to $g'_\infty$. This implies that the decreasing sequence $\{u_n\}_{n \in \mathbb{N}}$ possesses a subsequence that converges to 0 and therefore

$$\lim_{n \to \infty} u_n = 0.$$

In other words, the sequence $\{g'_{n_k}\}_{n \in \mathbb{N}}$ converges to $g'_\infty$ in $L^1([0, 1])$. Thus, since

$$\lim_{n \to \infty} g_n(x) = \lim_{n \to \infty} \left( g_n(0) + \int_0^x g'_n(t) \, dt \right) = 1 + \int_0^x g'_\infty(t) \, dt = g_\infty(x),$$

we see that the sequence $\{g_n\}_{n \in \mathbb{N}}$ converges point-wise to $g_\infty$. This makes impossible the existence of another accumulation point. As explained at the beginning of the section, this shows that the sequence $\{g_n\}_{n \in \mathbb{N}}$ converges to $g_\infty$. □
5. Final remarks

Theorem 11 shows that the operator $B_2$ has a unique eigenfunction with eigenvalue 1. Computational experiments [2] show that the next eigenvalues seem to be conjugate complex numbers $\lambda$ and $\bar{\lambda}$ close to $0.1735 \pm 0.00884i$, with $|\lambda_1| = |\lambda_2| = 0.1948$. Therefore, $B_2$ seems to present the spectral gap Vallée’s operator $V_2$ possesses. This would imply the exponential speed of convergence already suspected in [1]. The method described in this article does not seem to extend in such a way that this spectral gap can be proved.

We did not prove that the function $g'_{\infty}$ is continuous over $[0, 1]$, which is strongly suspected. If proven, this continuity would directly imply the uniform convergence of the sequence of continuous and increasing functions $\{g'_n\}_{n \in \mathbb{N}}$ over any compact set of $[0, 1]$ because of a theorem of Dini.

Acknowledgements

I would like to thank Richard Brent, Joachim Rosenthal, Brigitte Vallée and the anonymous referees for their numerous remarks and advice.
