We argue that the choice of an appropriate, massive, renormalization scheme can greatly improve the apparent convergence of perturbation theory at finite temperature. This is illustrated by the calculation of the pressure of a scalar field theory with quartic interactions, at 2-loop order. The result, almost identical to that obtained with more sophisticated resummation techniques, shows a remarkable stability as the coupling constant grows, in sharp contrast with standard perturbation theory.

1. Introduction

Over the last two decades considerable efforts have been made to understand the behavior of perturbation theory in quantum field theory at finite temperature (for reviews, see [1–3]). These efforts are in part motivated by the physics of the quark–gluon plasma, and the hope that QCD asymptotic freedom would allow for reliable calculations at sufficiently high temperature. It is well known, however, that in QCD infrared divergences inevitably occur and eventually cause a breakdown of perturbation theory at a finite order in the expansion in powers of the coupling constant [4]. But even in theories where such a breakdown does not occur, such as in scalar theories, perturbation theory at finite temperature appears as poorly convergent as in QCD.

Two routes have been followed to try to overcome these difficulties. The first one is to include more and more terms into the perturbative series, hoping in doing so to compensate for the poor apparent convergence. Thus, the pressure of the massless scalar theory with a quartic interaction is now known up to order $g^8 \log(1/g)$ (see Ref. [5] and references therein). While definite improvements are observed at small coupling when high orders are taken into account, the bad behavior of the perturbative series resurfaces as soon as the coupling gets moderately large.

The other route involves various reorganizations of the perturbative expansion, such as screened perturbation theory [6], infinite resummations, the use of functional variational techniques such as the so-called 2PI (two particle irreducible) formalism [7], or the non-perturbative renormalization group (NPRG) [8]. Remarkably, all these approaches produce results that remain stable as one increases the coupling constant, in sharp contrast with strict perturbation theory. At the same time, some of these calculations suggest that the physics at moderate coupling is minimally non-perturbative. In particular, calculations using the functional renormalization group within the most sophisticated approximation scheme available [8,9] yield results that do not deviate much from simple self-consistent quasiparticle approximations (such as the lowest order 2PI approximation, or the local potential approximation of the NPRG [10]).

These latter results suggest to look for an underlying simplicity, and it is indeed the purpose of this paper to report on progress in this direction. We shall argue that the difficulties encountered in finite temperature calculations can be attributed to a large extent to inappropriate choices of renormalization schemes. The success of the NPRG invites us to look for a scheme where the thermal mass plays a central role, and also where a decoupling of modes occurs when the typical scales exceed the temperature, both features that are automatically included in the NPRG. We shall exhibit such a massive renormalization scheme and show that it yields indeed a well behaved perturbative expansion. This will be illustrated in this letter with the calculation of the pressure of a scalar field theory. More elaborate calculations will be presented in forthcoming publications.
2. Massive thermal scheme

Let us start by recalling the origin of the difficulties with standard perturbation theory at finite temperature, focusing on a scalar theory of massive modes with quartic interactions \( \sim g^2 \phi^4 \) (see Eq. (4) below). The expansion parameter, which is not simply \( g^2 \), depends on the magnitude of the average fluctuations of the field, given by (we ignore here the vacuum fluctuations)

\[
\langle \phi^2 \rangle_k \approx \frac{d^3 p}{(2\pi)^3} n_p \approx T \kappa, \quad n_p = \frac{1}{e^{E_p/T} - 1},
\]

where \( E_p = \sqrt{m^2 + p^2} \), with \( m \) the mass, \( \kappa \) is an ultraviolet momentum cutoff and the approximation for \( \langle \phi^2 \rangle_k \) is valid for \( \kappa \lesssim T \).

Using this, we can define a dimensionless expansion parameter, \( \gamma_\kappa \), as the ratio between the interaction energy \( \sim g^2 \langle \phi^2 \rangle_k^2 \), and the kinetic energy \( \sim \kappa^2 \langle \phi^2 \rangle_k \) of modes with typical momentum \( \kappa \).

\[
\gamma_\kappa \sim \frac{g^2 \langle \phi^2 \rangle_k^2}{\kappa^2} \sim \frac{g^2 T}{\kappa}.
\]

(2)

Thus, for \( \kappa \sim T \), the expansion parameter is essentially the coupling constant \( \gamma_\kappa \sim g^2 \). However, \( \gamma_\kappa \) grows as \( \kappa \) decreases. Eventually \( \gamma_\kappa \) becomes of order unity when \( \kappa \sim g^2 T \), at which point standard perturbation theory breaks down.

However, at least in the case of scalar theories, this scenario is too pessimistic, and this for two reasons.

(a) First, observe that when \( m < \kappa \lesssim T \) the theory behaves as a massless three-dimensional theory (dimensionful) coupling \( g^2 T \). The associated dimensionless coupling can be identified to \( \gamma_\kappa \), and it obeys the one-loop renormalization group equation (see Eq. (23) below)

\[
\frac{d \gamma_\kappa}{d \log \mu} = - \gamma_\kappa + \frac{3}{16} \gamma_\kappa^2.
\]

(3)

The first term in this equation results from the analysis that we just presented, the second term is the one loop correction. This correction tames the growth of the coupling suggested by the first term, and indeed the infrared fixed-point at \( \gamma_\kappa = 16/3 \) prevents the blow-up of \( \gamma_\kappa \). The success of the expansion in \( \epsilon = 4 - d \) indicates that perturbation theory in the vicinity of this fixed point is reasonably accurate [11]. The second reason which prevents the breakdown of perturbation theory is of course the generation of a thermal mass \( \mu \) of order \( g T \) which freezes the running of the coupling at the scale \( \kappa \sim m \).

These considerations concerning the mechanisms that prevent the growth of the coupling, make paradoxical the fact that standard perturbation theory behaves so badly at finite temperature. In fact, as we have already alluded to, the reason may not be perturbation theory itself, but rather the particular scheme used. Most studies are done in non-decoupling schemes, such as the \( \overline{\text{MS}} \) scheme, which is popular because of its technical simplicity. But the discussion above suggests the use of a scheme where the matching between the four-dimensional and the three-dimensional regimes when \( \kappa \lesssim T \), as well as the suppression of fluctuations when \( \kappa \lesssim m \), are manifest order by order in perturbation theory. We shall now present such a scheme.

We consider the theory of a scalar field \( \phi \) with the action

\[
S[\phi] = \int_0^\beta \int d^4 x \left\{ \frac{1}{2} \partial_\mu \phi \partial^\mu \phi - \frac{m_b^2}{2} \phi^2 - \frac{g_b^2}{4!} \phi^4 \right\},
\]

(4)

where \( m_b \) and \( g_b \) denote the bare mass and coupling constant, respectively. The upper bound of the integration over the imaginary time \( \tau \) is \( \beta = 1/T \), where \( T \) is the temperature. In line with the previous discussion, we introduce a specific renormalization scheme with the following, temperature dependent, renormalization conditions:

\[
m^2 = \Gamma^{(2)}(p = 0, \omega = 0, T),
\]

\[
1 = \frac{d \Gamma^{(2)}}{dp^2}(p^2 = \mu^2, \omega = 0, T),
\]

\[
g^2 = \Gamma^{(4)}(p_{sym}^2 = \mu^2, \omega_1 = 0, T),
\]

(5)

where \( \Gamma^{(2)} \) and \( \Gamma^{(4)} \) are renormalized n-point functions, and \( p_{sym} \) refers to a symmetric combination of 3-momenta. There is of course a large flexibility in the choice of renormalization conditions. The scheme presented above satisfies the important requirement that the renormalized coupling constant \( g^2 \) becomes independent of the temperature when \( \mu \gg T \), so that we can isolate unambiguously thermal effects when comparing theories with different values of the coupling constant. The determination of the mass is more subtle. We want to use the thermal mass \( m \) that enters the first renormalization condition (5) within the free propagators of the perturbative expansion. However, the renormalization condition does not determine \( m \), it just fixes the finite parts of counterterms so that \( m \) has a prescribed value. In order to relate this value to a mass that is known, we shall calculate \( m_0 \) the mass at \( T = 0 \), at the order of perturbation theory at which we work. This will then provide a self-consistent equation (occasionally referred to as a gap equation) for the determination of \( m \) as a function of \( m_0 \). One may be worried about the fact that the present scheme involves counterterms whose finite parts depend on the temperature. However, no temperature dependent infinities will remain if subdivergences are carefully eliminated.

3. The 2-point function and the self-consistent thermal mass

The one-loop contribution to the 2-point function is easily calculated:

\[
\Gamma^{(2)}(p, \omega, T) = m^2 + \delta m^2 + \mu^2 + \frac{g^2 T}{2} \sum_n \int \frac{dq}{(2\pi)^d} \frac{1}{\omega_n^2 + q^2 + m^2}.
\]

(6)

where \( \omega_n = 2\pi n T \) is a Matsubara frequency, and we used the fact that the self-energy is independent of \( p^0 \) in order to ignore the field renormalization factor. We have set \( m_b^2 = m^2 + \delta m^2 \), where \( m \) is the renormalized mass. Note that the renormalization of the coupling constant at one-loop order has an impact on the 2-point function only when this is calculated at 2-loop order (see next section). Accordingly, in Eq. (6), \( g \) is taken to be the renormalized coupling constant. It is convenient to set

\[
I(m) = \sum_n \int \frac{1}{\omega_n^2 + q^2 + m^2} = \int \frac{1 + 2nq}{2E_q} = I_0(m) + I_1(m),
\]

(7)

where we have introduced the shorthand notation for momentum space integrals, to be used throughout this paper: \( I_q = \int \frac{dq}{(2\pi)^d} \).

---

1 In QCD, the long wavelength “magnetic” fluctuations have a mass of order \( g^2 T \), which is not large enough to prevent the breakdown of perturbation theory.

2 The explicit calculations of the thermal mass and of the pressure that are presented in this paper, illustrate how the divergences are eliminated. The calculation of the zero temperature pressure in particular shows that, once the mass subdivergences are eliminated, the remaining divergence is a global divergence which is independent of the temperature, as it should (see Eq. (32)).
In most of this paper, unless specified otherwise, we shall work in $d = 3$ dimensions. In the formula above, $n_q$ is the Bose statistical factor (see Eq. (1)), and $E_q = \sqrt{q^2 + m^2}$.

Specifying $p = 0$ in Eq. (6), one gets:

$$I^{(2)}(p = 0, \omega = 0, T) = m^2 + \delta m^2 + \frac{g^2}{2} I_0(m).$$

(8)

By imposing the first of the renormalization conditions (5), namely $m^2 = I^{(2)}(p = 0, \omega = 0, T)$, one deduces the value of the counterterm

$$\delta m^2 = -\frac{g^2}{2} I_0(m).$$

(9)

At this point, the mass $m$ that enters the renormalization condition is in general unknown. However, it can be related to the renormalized mass at zero temperature, which we assume to be a known quantity. To that aim, we repeat, at $T = 0$, the leading order perturbation theory calculation that yields Eq. (8). We get

$$I^{(2)}(p = 0, \omega = 0, T = 0) = m^2 + \delta m^2 + \frac{g^2}{2} I_0(m) = m^2 - \frac{g^2}{2} I_T(m),$$

(10)

where, in the last step, we have used the expression (9) of the mass counterterm. By identifying the left-hand-side of Eq. (10) to $m_T^2$, with $m_0$ the $T = 0$ renormalized mass, one gets the looked for relation between $m_0$ and $m$

$$m^2 = m_0^2 + \frac{g^2}{2} I_T(m).$$

(11)

Eq. (10), which expresses a zero temperature quantity in terms of finite temperature ones, is not usual. But in fact, Eq. (11) tells us that the thermal mass $m$ is adjusted so that $m^2 - \frac{g^2}{2} I_T(m)$ is independent of the temperature.

Eq. (11) is a self-consistent equation for $m^2$. This self-consistent determination of the thermal mass has already been recognized in other approaches as an important factor that stabilizes the weak coupling expansion, and it constitutes an essential aspect of the present renormalization scheme. At this point it is instructive to contrast the result obtained from solving the self-consistent Eq. (11) with that given by standard perturbation theory. Recall that standard perturbative approaches use the zero temperature quantities as their starting point, and consider finite temperature effects as corrections. In the present context, this is equivalent to solve Eq. (11) by expanding with respect to the $T = 0$ parameters, i.e., treating $m - m_0$ as a perturbation. To perform this expansion, we assume a small coupling constant $g$, and a vanishing zero temperature mass, $m_0 = 0$. The leading order contribution is then obtained by neglecting the mass in the calculation of $I_T$. Using $I_T(m = 0) = T^2/12$ in Eq. (11), one gets $m^2 = g^2 T^2/24 = \tilde{m}^2$, where $\tilde{m}$ is the standard Hard Thermal Loop (HTL) result (see e.g. Ref. [1]). We can go beyond this leading order by treating the mass as a small correction in the calculation of $I_T$, that is we define

$$m^2 = \tilde{m}^2 + \Delta m^2, \quad \Delta m^2 = \frac{g^2}{2} (I_T(\tilde{m}) - I_T(0)).$$

(12)

The calculation of $\Delta m^2$ is complicated by the fact that a naive expansion in powers of $\tilde{m}$ generates infrared divergences. This is because the integral that yields $\Delta m^2$ is no longer dominated by momenta of order $T$, but rather by momenta of order $\tilde{m} \sim g T \ll T$. To obtain the limit $\tilde{m} \ll T$ we first perform the change of variables $q = \tilde{m} y$, and only then expand in powers of $\tilde{m}$. One then gets:

$$\Delta m^2 = \frac{g^2}{4 \pi^2} \int_0^\infty dy y^2 \left( \frac{1}{\sqrt{y^2 + 1}} \ln \left( \frac{1}{\sqrt{y^2 + 1}} \right) - \frac{1}{y (e^{\tilde{m} y} - 1)} \right)$$

$$\approx \frac{g^2 T \tilde{m}}{4 \pi^2} \int_0^\infty dy y^2 \left( \frac{1}{y^2 + 1} \right) = - \frac{g^2 T^2}{16 \pi \sqrt{6}}.$$

(13)

which is the known result, usually derived from HTL resummations. We note that the $g^2$ correction is negative, implying that $m^2$ eventually becomes negative as the coupling grows, signaling a breakdown of perturbation theory for $g^2/24 \sim 1$ (see Fig. 2 below). By contrast, the solution of the gap equation remains perfectly regular as the coupling increases.

4. The 4-point function and the $\beta$ function

We turn now to the calculation of the 4-point function at order one-loop. Since the running of the coupling does not play an essential role in the leading order calculation of either the mass (previous section) or the pressure (next section), our goal here is merely to illustrate generic features of the $\beta$-function in the present massive scheme, in particular the role of the mass in cutting off the flow, as well as the decoupling property mentioned in Section 2, i.e., the transition form 4-dimensional to 3-dimensional running when the scale passes below $2 \pi T$.

In order to implement the renormalization condition (the last condition (5)) we need the 4-point function for vanishing external frequencies and a symmetric configuration of momenta (here $p^2 = (p_1 + p_2)^2 = (p_1 + p_3)^2 = (p_2 + p_3)^2$):

$$\Gamma^{(4)}(p^2, \omega_1 = 0, T) = g_B^2 \frac{3 g^4}{2} T^4 \sum_n \int_{q} \frac{1}{\omega_n^2 + q^2 + m^2} \frac{1}{\omega_n^2 + (q + p)^2 + m^2}.$$  

(14)

(We do not need to worry about the potential logarithmic divergence of the integral since this will drop out in the differentiation with respect to $\mu$.) Recalling that $g_B^2(T, \mu) = \Gamma^{(4)}(p^2 = 0)$, $\omega_1 = 0, T)$, and that $g_B$ does not depend on $\mu$, one gets

$$\beta(g^2, \mu, m, T) = \frac{\partial g^2(T, \mu)}{\partial \mu}$$

$$= 6 g_B^2 T \sum_n \int dx \frac{x (1 - x) \mu^2}{\omega_n^2 + q^2 + m^2 + x (1 - x) \mu^2},$$

(15)

where only the explicit $\mu$ dependence was involved in the differentiation, i.e., we have ignored terms of order $g^2$ or higher. By performing (for $d = 3$) the integrals over the Feynman parameter and the momentum, one can put the $\beta$-function in the form

$$\beta(g^2, \mu, m, T) = \beta_0(g^2) F(\bar{\mu}, \bar{m}^2), \quad \bar{m}^2 \equiv \frac{m^2}{(2 \pi T)^2},$$

$$\bar{\mu} \equiv \frac{\mu}{2 \pi T},$$

where $F(\bar{\mu}, \bar{m}^2)$ is the dimensionless function.
\[ F(\bar{\mu}, \bar{m}^2) = \sum_n \left\{ \frac{-2\sqrt{n^2 + m^2}}{\bar{\mu}^2 + 4(n^2 + \bar{m}^2)} + \frac{1}{\bar{\mu}} \arccot\left(2\sqrt{\frac{n^2 + \bar{m}^2}{\bar{\mu}^2}}\right) \right\}, \] (17)

and

\[ \beta_0(g^2) = \frac{3g^4}{16\pi^2} \] (18)
is the standard one-loop \(\beta\)-function for a scalar field theory in 3 + 1 dimensions, in a mass independent scheme.

The sum over the Matsubara frequencies in the expression (17) is dominated by values of \(n\) such that \(\sqrt{n^2 + m^2} \lesssim \bar{\mu}\). When \(\mu \gg 2\pi T (\bar{\mu} \gg 1)\), one expects to recover the known result for the zero temperature theory in 4 dimensions. This is indeed the case: in this regime, one can ignore the discrete nature of the sum over Matsubara frequencies, and replace the sum by an integral. The function \(F(\bar{\mu}, \bar{m}^2)\) becomes then a function of \(x = m^2/\mu^2\) only,

\[ F_0(x) = 1 + \frac{2x}{\sqrt{1 + 4x}} \log\left(\frac{\sqrt{1 + 4x} - 1}{\sqrt{1 + 4x} + 1}\right). \] (19)

When \(\mu^2 \gg m^2\), \(F_0(x) \rightarrow 1\), and \(\beta(g^2, \mu, m^2, T) \rightarrow \beta_0(g^2)\). In the opposite regime where \(\mu^2 \ll m^2\), the \(\beta\) function is suppressed,

\[ \beta(g^2, \bar{\mu}, \bar{m}^2) \simeq \beta_0(g^2) \frac{\mu^2}{6m^2}. \] (20)

In this regime, the flow eventually stops, the fluctuations at a scale smaller than the mass playing essentially no role.

In the regime of high temperature, \(\mu \ll 2\pi T\), one may restrict the sum over the Matsubara frequencies to the lowest one, i.e., to \(n = 0\). The function in Eq. (17) becomes then

\[ F_T(\bar{\mu}, \bar{m}^2) = \frac{1}{\bar{\mu}} \left(\frac{-2\sqrt{\bar{\mu}}}{1 + 4\bar{\mu}} + \arccot(2\sqrt{\bar{\mu}})\right), \] (21)

When \(\mu \gg m\), the \(\beta\)-function reduces to

\[ \beta(g^2, \bar{\mu}, \bar{m}^2) \simeq \beta_0(g^2) \frac{\pi^2 T}{\mu}, \] (22)

and the beta function is enhanced as soon as \(\mu \lesssim 2\pi T\). In fact, in this high temperature regime, the theory becomes essentially 3-dimensional, with a dimensional coupling constant \(g^2 T\). One can introduce (for \(\mu \gg m\)) an effective dimensionless coupling \(\gamma = g^2 T/\mu\), whose flow is easily obtained:

\[ \mu \partial_\mu \gamma = -\gamma + \frac{3\gamma^2}{16\pi^2} f_T(x), \quad x = \frac{m^2}{\mu^2}. \] (23)

with \(f_T(x) = 2\bar{\mu} F_1(\bar{\mu}, \bar{m}^2)\). The function \(f_T(x)\) is a steeply decreasing function of \(x\), starting at \(f_T(0) = \pi\), so that in the regime \(\mu \gg m\), one recovers the \(\beta\)-function (3) mentioned in Section 2. When \(\mu \lesssim m\), the flow of the coupling is suppressed. We have indeed, for \(\mu \ll m\),

\[ \beta(g^2, \mu, m) \simeq \beta_0(g^2) \frac{\bar{\mu}^2}{12m^2}. \] (24)

All the features that we have discussed in this section are illustrated in Fig. 1, for small \((g^2 = 1)\) and moderate \((g^2 = 12)\) coupling. The acceleration of the flow as \(\mu\) gets lower than \(2\pi T\) is clearly seen, as well as the saturation of the flow when \(\mu \ll m\). These features, generic of the present massive scheme, are reminiscent of those observed in the non-perturbative renormalization group approach (see e.g. [8,10]), and indeed, as we have already emphasized, the main properties of the present renormalization scheme are automatically included in such an approach. Note that the calculations presented in Fig. 1 are done with a fixed value of the mass. In an actual calculation, the self-consistent thermal mass should be used, but that would not alter the general behavior illustrated in Fig. 1.

5. Calculation of the pressure

We turn now to the calculation of the pressure, and we limit ourselves to the calculation of the leading order, 2-loop, perturbative correction. We have

\[ P(T) = -\frac{T}{2} \sum_{n} \ln(\omega_n^2 + \mathbf{q}^2 + m^2) - \frac{g^2}{8} l(m^2)^2 \]

\[ -\frac{1}{2} \beta(n^2 + \mathbf{q}^2 + m^2).
\] (25)

where \(\beta P\) is a counterterm that absorbs the overall divergence that remains when mass subdvergences (the next to last term) have been eliminated, and whose finite part is adjusted so that \(P(T = 0) = 0\). In the foregoing calculation, the following expression is useful:

\[ \frac{T}{2} \sum_n \ln(\omega_n^2 + \mathbf{q}^2) = \frac{1}{2} \omega_q + T \ln(1 - e^{-\omega_q/T}). \] (26)

The summation over the Matsubara frequencies requires a regularization that eliminates an infinite constant that does not depend on \(T\) or \(m\). Such a regularization is implied in writing Eq. (26).

---

\(\bar{\mu}\) indicates a running scale, which is related to the cutoff \(\Lambda\) by \(\bar{\mu}^2 = (\Lambda^2 - n^2) \bar{\mu}^2\).
Using this relation we rewrite Eq. (25) as

$$P(T) = -\frac{1}{2} \int \omega_q^T - T \int \ln(1 - e^{-\omega_q^T/T}) - \frac{g^2}{8} [I(m)]^2 - \frac{1}{2} \delta m^2 I_0(m) - \delta P,$$

where $\omega_q^T = \sqrt{q^2 + m^2}$. By using the expression (9) of the mass counterterm, one easily gets

$$P(T) = -\frac{1}{2} \int \omega_q^T - T \int \ln(1 - e^{-\omega_q^T/T}) + \frac{g^2}{8} [I(m)]^2 - \frac{1}{2} \delta m^2 I_0(m) - \delta P.$$

This expression is still divergent, but the divergence is a global divergence present in the $T = 0$ contribution. Let us then calculate the zero temperature pressure, in leading order perturbation theory. We obtain

$$P(T = 0) = -\frac{1}{2} \int \omega_q^T - \frac{g^2}{8} [I_0(m)]^2 - \frac{1}{2} \delta m^2 I_0(m) - \delta P,$$

$$= -\frac{1}{2} \int \omega_q^T + \frac{g^2}{8} [I_0(m)]^2 + \frac{g^2}{4} I_T(m) I_0(m) - \delta P.$$

(29)

Subtracting this from $P(T)$ leaves us with the manifestly finite expression

$$P(T) - P(T = 0) = -T \int \ln(1 - e^{-\omega_q^T/T}) + \frac{g^2}{8} [I_T(m)]^2.$$

(30)

As was the case of Eq. (10), the expression (29) has the unusual feature of giving the zero temperature pressure in terms of temperature dependent quantities. However, it is easy to show that $P(T = 0)$ is independent of the temperature, as it should. Indeed, note that

$$\omega_q^T = \sqrt{q^2 + m^2} \simeq \omega_q^{T = 0} + \frac{m^2 - m_0^2}{2 \omega_q^{T = 0}}, \quad \omega_q^{T = 0} = \sqrt{q^2 + m_0^2}.$$

(31)

Then by using Eq. (11) for $m^2 - m_0^2$, one gets, in leading order in $g^2$,

$$P(T = 0) = -\frac{1}{2} \int \omega_q^{T = 0} + \frac{g^2}{8} [I_0(m_0)]^2 - \delta P,$$

which is independent of the temperature. Note that in arriving at this result, the self-consistent relation (11) for $m$ has played an essential role. Eq. (32) can be used to fix the counterterm $\delta P$ by requiring that $P(T = 0) = 0$.

As we have done for the mass, it is a simple exercise to show that the expression (30) for the pressure reproduces the first terms, i.e. the $g^2$ and $g^3$ contributions of the standard weak coupling expansion [7]

$$P(T) - P(T = 0) \approx \frac{\pi^2 T^4}{90} - \frac{\hat{m}^2}{48} T^2 - \frac{\hat{m}^4 T}{12\pi}.$$

(33)

The large differences between successive orders that was observed for the mass is also visible for the pressure. However, as illustrated in Fig. 2, the full result is much more stable as the coupling increases. Note that the curves in Fig. 2 correspond to calculations at fixed values of the coupling constant.

The curves in Fig. 2 contain a comparison with the results of the 2PI approximation, which, at 2-loop order yields for the pressure [7]

$$P = -T \int \ln(1 - e^{-\omega_q^T/T}) + \frac{m^2}{4} I_T + \frac{m^4}{128\pi^2},$$

with $m$ solution of the gap equation

$$m^2 = \frac{g^2}{2} I_T + \frac{g^2 m_0^2}{32\pi^2} \left( \ln \frac{m^2}{\mu^2} - 1 \right).$$

(35)

The latter expression is obtained by using dimensional regularization and minimal subtraction [7], and $g = g(\mu)$ is the running coupling. The natural choice of scale in this scheme is $\mu = 2\pi T$, and this is the value of the fixed coupling that is used in drawing the curves in Fig. 2.4 The results of the 2PI approximation are quite similar to those of the present scheme. We note again the stabilizing effect of the mass resummation, that is accounted for here by an equation quite similar to that of the massive scheme (cp. Eqs. (11) and (35)).

Note that at this level of approximation, the $\beta$-function is $\mu \frac{d\beta}{d\mu} = g^2/(16\pi^2)$, i.e., one third of the perturbative beta function (18). This is because only one channel out of three is taken into account at this level of the 2PI approximations. With this particular value of the beta-function, the solution of the gap equation (35) is independent of $\mu$. 
The relations between $m^2$, or $P$, and the coupling constant depend on course of the renormalization scheme. To make a fair comparison between the two approximations, and eliminate most of this scheme dependence, we have plotted in Fig. 3 the pressure as a function of the thermal mass. Both quantities are determined as a function of the coupling as indicated earlier. However, the 2PI result is actually independent of the choice of the renormalization scale $\mu$. As for the massive scheme, the running of the coupling determined in Section 4 is in perfect agreement with the standard perturbative expansion in the regime where both can be compared (that is, when $\mu \gg m$). The corresponding running has a two-loop effect on both the mass and the pressure, but this effect needs not be analyzed further here because performing the calculation with a running coupling would not affect the relation between $P$ and $m$: indeed, since the scale $\mu$ does not explicitly appear in the calculation, all the dependence on $\mu$ is in the coupling constant. Since, in the massive scheme, the mapping between $m$ and $g$ is one-to-one, it can be used to express, in Eq. (30), $g^2$ in terms of $m^2$. It follows then that the relation between $P$ and $m^2$ is stable, independent of the choice of $\mu$. Fig. 3 shows that the 2PI result is almost identical to that of the massive scheme, and both are quite distinct from that of standard perturbation theory.

6. Conclusions

We have shown that, by adopting a massive, temperature dependent, renormalization scheme, one can greatly improve the apparent convergence of perturbation theory at finite temperature. The thermal mass scheme presented in this letter yields a well behaved perturbative expansion in powers of $g^2$. The familiar nonanalytic contributions (such as the contribution of order $g^3$) are hidden in the dependence of the mass on the coupling constant (and would resurface if we were to expand in powers of $m$, which we do not need to do of course). Calculations in a massive scheme are more difficult than, say, standard calculations for massless theories using the $\overline{MS}$ scheme. But this is a small price to pay if accurate results are obtained with the first few orders of perturbation theory. An additional complication of the massive scheme is that a self-consistent equation for the mass needs to be solved. Although it looks very similar to that of the 2PI scheme, this equation is in fact much simpler: it is an equation for the mass, instead of an equation for the fully self-consistent propagator.

For illustration purposes, we have presented a comparison with the 2PI approximation. But we should mention here that various methods to reorganize perturbation theory have been proposed over the years. Some bear strong similarity with what we propose here, as they emphasize the need to expand around a massive theory. Among those, we have already mentioned screened perturbation theory [6,12,13], where one expands with respect to an auxiliary mass whose value is eventually determined by various prescriptions. We should also mention numerous versions of optimized perturbation theory, where the variation of the auxiliary mass is parametrically correlated to that of the coupling constant (see for instance [14], and references therein). We believe that the present scheme is conceptually simpler since the determination of the mass is part of the renormalization scheme, rather than being fixed by some external prescription. It may be also technically simpler if only a few orders of the perturbative expansion are needed in order to achieve the desired accuracy. This can be checked explicitly by performing higher order calculations. Results of such calculations will be presented in forthcoming publications.
