## SUMMARY

**Tissue culture of immortal cell strains from diseased patients is an invaluable resource for medical research but is largely limited to tumor cell lines or transformed derivatives of native tissues. Here we describe the generation of induced pluripotent stem (iPS) cells from patients with a variety of genetic diseases with either Mendelian or complex inheritance; these diseases include adenosine deaminase deficiency-related severe combined immunodeficiency (ADA-SCID), Shwachman-Bodian-Diamond syndrome (SBDS), Gaucher disease (GD) type III, Duchenne (DMD) and Becker muscular dystrophy (BMD), Parkinson disease (PD), Huntington disease (HD), juvenile-onset, type 1 diabetes mellitus (JDM), Down syndrome (DS)/trisomy 21, and the carrier state of Lesch-Nyhan syndrome. Such disease-specific stem cells offer an unprecedented opportunity to recapitulate both normal and pathologic human tissue formation in vitro, thereby enabling disease investigation and drug development.**

## INTRODUCTION

Cell culture has been the backbone of basic biomedical research for many decades, and countless insights into both normal and pathologic cellular processes have been gleaned by studying human cells explanted in vitro. Most of the human cell lines in wide use today carry genetic and epigenetic artifacts of accommodation to tissue culture and are derived either from malignant

tissues or are genetically modified to drive immortal growth (Grimm, 2004). Primary human cells have a limited life span in culture, a constraint that thwarts inquiry into the regulation of tissue formation, regeneration, and repair. Indeed, many human cell types have never faithfully been adapted for growth in vitro, and the lack of accessible models of normal and pathologic tissue formation has rendered many important questions in human development and disease pathogenesis inaccessible.

Human embryonic stem cells isolated from excess embryos from in vitro fertilization clinics represent an immortal propagation of pluripotent cells that theoretically can generate any cell type within the human body (Lerou et al., 2008; Murry and Keller, 2008). Human embryonic stem cells allow investigators to explore early human development through in vitro differentiation, which recapitulates aspects of normal gastrulation and tissue formation. Embryos shown to carry genetic diseases by virtue of preimplantation genetic diagnosis (PGD; genetic analysis of single blastomeres obtained by embryo biopsy) can yield stem cell lines that model single-gene disorders (Verlinsky et al., 2005), but the vast majority of diseases that show more complex genetic patterns of inheritance are not represented in this pool.

A tractable method for establishing immortal cultures of pluripotent stem cells from diseased individuals would not only facilitate disease research but also lay a foundation for producing autologous cell therapies that would avoid immune rejection and enable correction of gene defects prior to tissue reconstitution. One strategy for producing autologous, patient-derived pluripotent stem cells is somatic cell nuclear transfer (NT). In a proof of principle experiment, NT-embryonic stem (ES) cells generated from mice with genetic immunodeficiency were used to combine gene and cell therapy to repair the genetic defect (Rideout et al., 2002). To date, NT has not proven successful in the human and, given the paucity of human oocytes, is

**Table 1. iPS Cells Derived from Somatic Cells of Patients with Genetic Disease**

Name	Disease	Molecular Defect	Donor Cell	Age	Sex
ADA	ADA-SCID	GGG >AGG, exon 7 and Del(GAAGA) exon 10, <i>ADA</i> gene	Fibroblast	3 M	Male
GD	Gaucher disease type III	AAC > AGC, exon 9, G-insertion, nucleotide 84 of cDNA, <i>GBA</i> gene	Fibroblast	20 Y	Male
DMD	Duchenne muscular dystrophy	Deletion of exon 45–52, <i>dystrophin</i> gene	Fibroblast	6 Y	Male
BMD	Becker muscular dystrophy	Unidentified mutation in <i>dystrophin</i>	Fibroblast	38 Y	Male
DS1, DS2	Down syndrome	Trisomy 21	Fibroblast	1 Y, 1 M	Male
PD	Parkinson disease	Multifactorial	Fibroblast	57 Y	Male
JDM	Juvenile diabetes mellitus	Multifactorial	Fibroblast	42 Y	Female
SBDS	Swachman-Bodian-Diamond syndrome	IV2 + 2T > C and IV3 – 1G > A, <i>SBDS</i> gene	Bone marrow mesenchymal cells	4 M	Male
HD	Huntington disease	72 CAG repeats, <i>huntingtin</i> gene	Fibroblast	20 Y	Female
LNSc	Lesch-Nyhan syndrome (carrier)	Heterozygosity of <i>HPRT1</i>	Fibroblast	34 Y	Female

destined to have limited utility. In contrast, introducing a set of transcription factors linked to pluripotency can directly reprogram human somatic cells to produce induced pluripotent stem (iPS) cells, a method that has been achieved by several groups worldwide (Lowry et al., 2008; Park et al., 2008b; Takahashi et al., 2007; Yu et al., 2007). Given the robustness of the approach, direct reprogramming promises to be a facile source of patient-derived cell lines. Such lines would be immediately valuable for medical research, but current methods for reprogramming require infecting the somatic cells with multiple viral vectors, thereby precluding consideration of their use in transplantation medicine at this time.

Human cell culture is an essential complement to research with animal models of disease. Murine models of human congenital and acquired diseases are invaluable but provide a limited representation of human pathophysiology. Murine models do not always faithfully mimic human diseases, especially for human contiguous gene syndromes such as trisomy 21 (Down syndrome or DS). A mouse model for the DS critical region on distal human chromosome 21 fails to recapitulate the human cranial abnormalities commonly associated with trisomy 21 (Olson et al., 2004). Orthologous segments to human chromosome 21 are present on mouse chromosomes 10 and 17, and distal human chromosome 21 corresponds to mouse chromosome 16 where trisomy 16 in the mouse is lethal (Nelson and Gibbs, 2004). Thus, a true murine equivalent of human trisomy 21 does not exist. Murine strains carrying the same genetic deficiencies as the human bone marrow failure disease Fanconi anemia demonstrate DNA repair defects consistent with the human condition (e.g., Chen et al., 1996), yet none develop the spontaneous bone marrow failure that is the hallmark of the human disease.

For cases where murine and human physiology differ, disease-specific pluripotent cells capable of differentiation into the various tissues affected in each condition could undoubtedly provide new insights into disease pathophysiology by permitting analysis in a human system, under controlled conditions *in vitro*, using a large number of genetically modifiable cells, and in a manner specific to the genetic lesions in each whether known or unknown. Here, we report the derivation of human iPS cell lines from patients with a range of human genetic diseases.

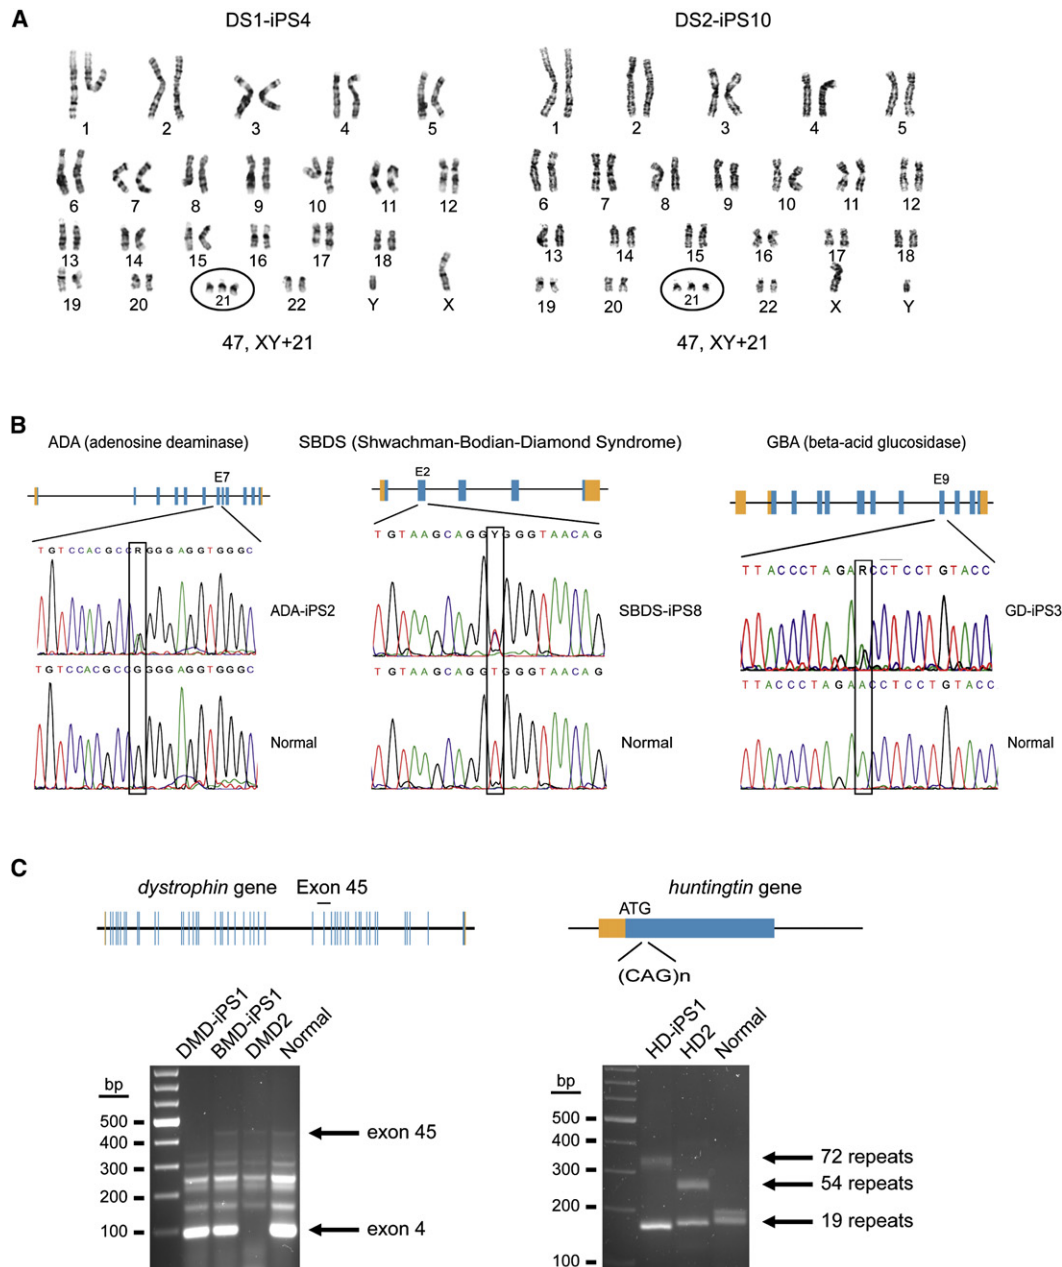

## RESULTS AND DISCUSSION

Dermal fibroblasts or bone marrow-derived mesenchymal cells were obtained from patients with a prior diagnosis of a specific disease and used to establish disease-specific lines of human iPS cells (Table 1). This initial cohort of cell lines was derived from patients with Mendelian or complex genetic disorders, including Down syndrome (DS; trisomy 21); adenosine deaminase deficiency-related severe combined immunodeficiency (ADA-SCID); Shwachman-Bodian-Diamond syndrome (SBDS); Gaucher disease (GD) type III; Duchenne type (DMD) and Becker type (BMD) muscular dystrophy; Huntington chorea (Huntington disease; HD); Parkinson disease (PD); juvenile-onset, type 1 diabetes mellitus (JDM); and Lesch-Nyhan syndrome (LNSc; carrier state).

Patient-derived somatic cells were transduced with either four (*OCT4*, *SOX2*, *KLF4*, and *c-MYC*) or three reprogramming factors (lacking *c-MYC*). Following 2 to 3 weeks of culture in hES cell-supporting conditions, compact refractile ES-like colonies emerged among a background of fibroblasts, as previously described (Park et al., 2008a, 2008b). Although our previous report used additional factors (*hTERT* and SV40 LT) to achieve reprogramming of adult somatic cells, we have found the four-factor cocktail to be sufficient as long as we employ a higher multiplicity of retroviral infection. Additionally, we generated a single line from a carrier of Lesch-Nyhan syndrome using five doxycycline-inducible lentiviral vectors (*OCT4*, *SOX2*, *KLF4*, *c-MYC*, and *NANOG*), a strategy that has been used to isolate murine iPS cells (Brambrink et al., 2008; Stadtfeld et al., 2008) but previously had not been attempted with human somatic cells. Characterization of the iPS cell lines is presented below.

### Mutation Analysis in iPS Cell Lines

The iPS cell lines were evaluated to confirm, where possible, the disease-specific genotype of their parental somatic cells. Analysis of the karyotype of iPS cell lines derived from two individuals with Down syndrome showed the characteristic trisomy 21 anomaly (Figure 1A). Aneuploidies such as that occurring in DS are unambiguously associated with advanced maternal age (reviewed in Antonarakis et al., 2004) and, as such, are occasionally

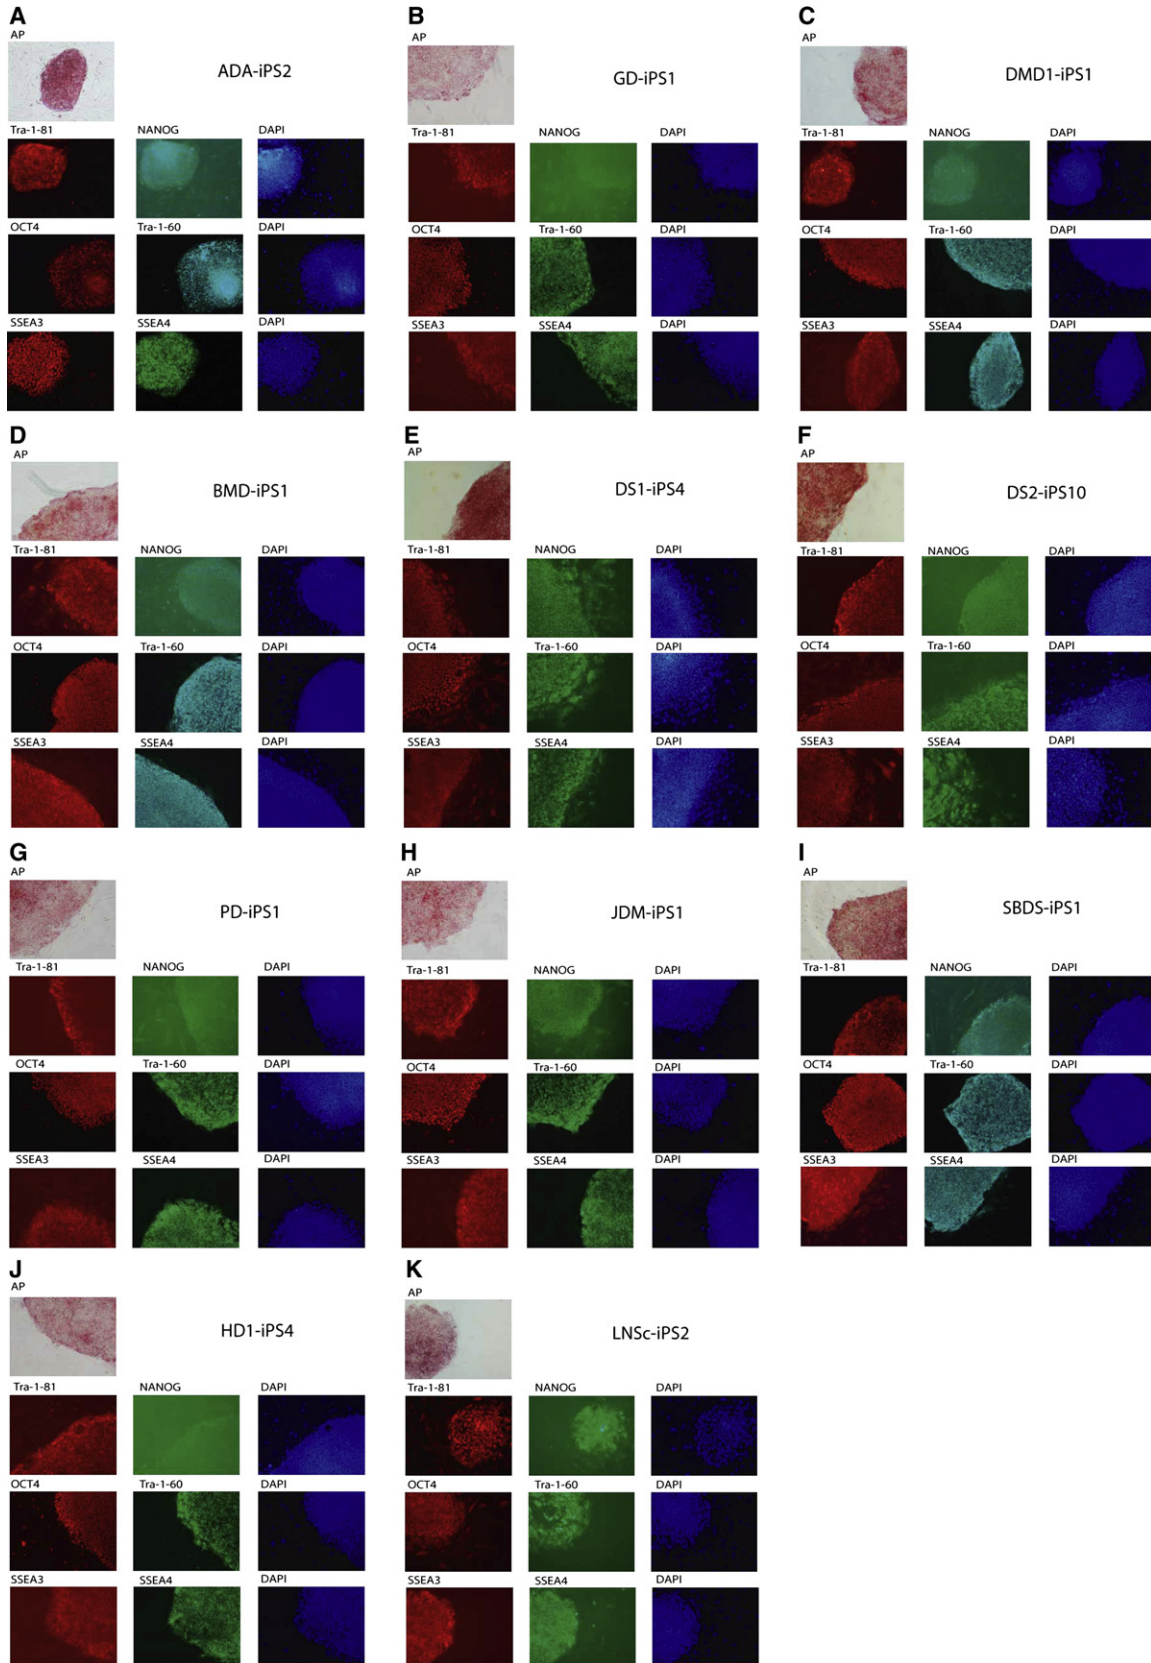

**Figure 1. Genotypic Analysis of Disease-Specific iPS Cell Lines**

(A) Two different, primary fibroblast specimens, DS1 and DS2 from male patients with Down syndrome (trisomy 21), were used to derive DS1-iPS4 and DS2-iPS10. Each has a 47, XY + 21 karyotype over several passages (G-banding analysis).

(B) Fibroblast (ADA and GBA) or bone marrow mesenchymal cells (SBDS) were used to generate iPS cell lines. Mutated alleles identical to the original specimens were verified by DNA sequencing. Adenosine deaminase deficiency line ADA-iPS2 is a compound heterozygote: GGG to GAA double transition in exon 7 of one allele (G216R substitution); the second allele is an exon 10 frameshift deletion (-GAAGA) (Hirschhorn et al., 1993). Shwachman-Bodian-Diamond syndrome line SBDS-iPS8 is also a compound heterozygote: point mutations at the IV2 + 2T > C intron 2 splice donor site and an IVS3 - 1G > A mutation of the SBDS gene (Austin et al., 2005). GD-iPS3 (Gaucher disease type III): a 1226A > G point mutation (N370S substitution) and a guanine insertion at nucleotide 84 of the cDNA (84GG) (Beutler et al., 1991).

(C) Fibroblasts from patients diagnosed with either Duchenne (DMD) or Becker type muscular dystrophy (BMD): DMD-iPS1 has a deletion over exons 45–52 (multiplex PCR for the *dystrophin* gene). We could not determine a deletion in BMD-iPS1 using two different multiplex PCR sets though these assays do not cover the entire coding region. DMD2 is a patient control (exon 4 deletion). The control is genomic DNA from a healthy volunteer. Huntington disease (HD) is caused by a trinucleotide repeat expansion within the huntingtin locus. DNA sequencing shows that HD-iPS1 has one normal (<35 repeats) and one expanded allele (72 repeats). HD2 is a positive control from a second Huntington patient with one normal and one expanded allele (54 repeats). The control is genomic DNA from a healthy volunteer.

detected in the preimplantation embryo when in vitro fertilization (IVF) is coupled with PGD. While it is possible that a discarded IVF embryo found to have trisomy 21 could be donated to attempt hES cell derivation, it is important to point out that many gestating DS embryos do not survive the prenatal period. Some studies place the frequency of spontaneous fetal demise (miscarriage) in DS to be above 40% (Bittles et al., 2007). Thus, the derivation of a human iPS cell line with trisomy 21 from an existing individual may be preferable, as such a line is most likely to harbor the complex genetic and epigenetic modifiers that favor full-term gestation and, by virtue of the often lengthy medical history, will be a more informative resource for correlative clinical research.

Creation of iPS cell lines from patients with single-gene disorders allows experiments on disease phenotypes in vitro, and an opportunity to repair gene defects ex vivo. The resulting cells, by virtue of their immortal growth in culture, can be extensively characterized to ensure that gene repair is precise and specific, thereby reducing the safety concerns of random, viral-mediated gene therapy. Repair of gene defects in pluripotent cells provides a common platform for combined gene repair and cell replacement therapy for a variety of genetic disorders, as long as the pluripotent cells can be differentiated into relevant somatic stem cell or tissue populations.

Three diseases in our cohort of iPS cells are inherited in a classical Mendelian manner as autosomal recessive congenital disorders and are caused by point mutations in genes essential for normal immunologic and hematopoietic function: adenosine deaminase deficiency, which causes severe combined immune deficiency (ADA-SCID) due to the absence of T cells, B cells, and NK cells; Shwachman-Bodian-Diamond syndrome, a congenital disorder characterized by exocrine pancreas insufficiency, skeletal abnormalities, and bone marrow failure; and Gaucher disease type III, an autosomal recessive lysosomal storage disease characterized by pancytopenia and progressive neurological deterioration due to mutations in the acid beta-glucosidase (GBA) gene. Sequence analysis of the *ADA* gene in the disease-associated ADA-iPS2 cell line revealed a compound heterozygote: a GGG to GAA transition mutation at exon 7, causing a G216R amino acid substitution (Figure 1B); the other allele is known to have a frameshift deletion (-GAAGA) in exon 10 (Hirschhorn et al., 1993). The SBDS-iPS8 cell line harbors point mutations at the IV2 + 2T > C intron 2 splice donor site (Figure 1B) and IVS3 - 1G > A mutation (Austin et al., 2005). Molecular analysis of the *GBA* gene in the Gaucher disease line revealed a 1226A > G point mutation, causing a N370S amino acid substitution (Figure 1B); the second allele is known to have a frameshifting insertion of a single guanine at cDNA nucleotide 84 (84GG) (Beutler et al., 1991). The Lesch-Nyhan syndrome carrier line harbors heterozygous deficiency of the *HPRT* gene (Nussbaum et al., 1983).

Two lines were derived from dermal fibroblasts cultured from patients with muscular dystrophy. Multiplex PCR analysis with primer sets amplifying several (but not all) intragenic intervals of the *dystrophin* gene (Beggs et al., 1990; Chamberlain et al., 1988) revealed the deletion of exons 45–52 in the iPS cells derived from a patient with Duchenne muscular dystrophy (DMD; Figure 1C). Despite analysis for gross genomic defects by multiplex PCR, a deletion was not detected in iPS cells derived from a patient with Becker type muscular dystrophy (BMD; Figure 1C). As BMD is a milder form of disease, and the *dystrophin* gene one of the largest in the human genome, definition of the genetic lesion responsible for this condition is sometimes elusive (Prior and Bridgeman, 2005).

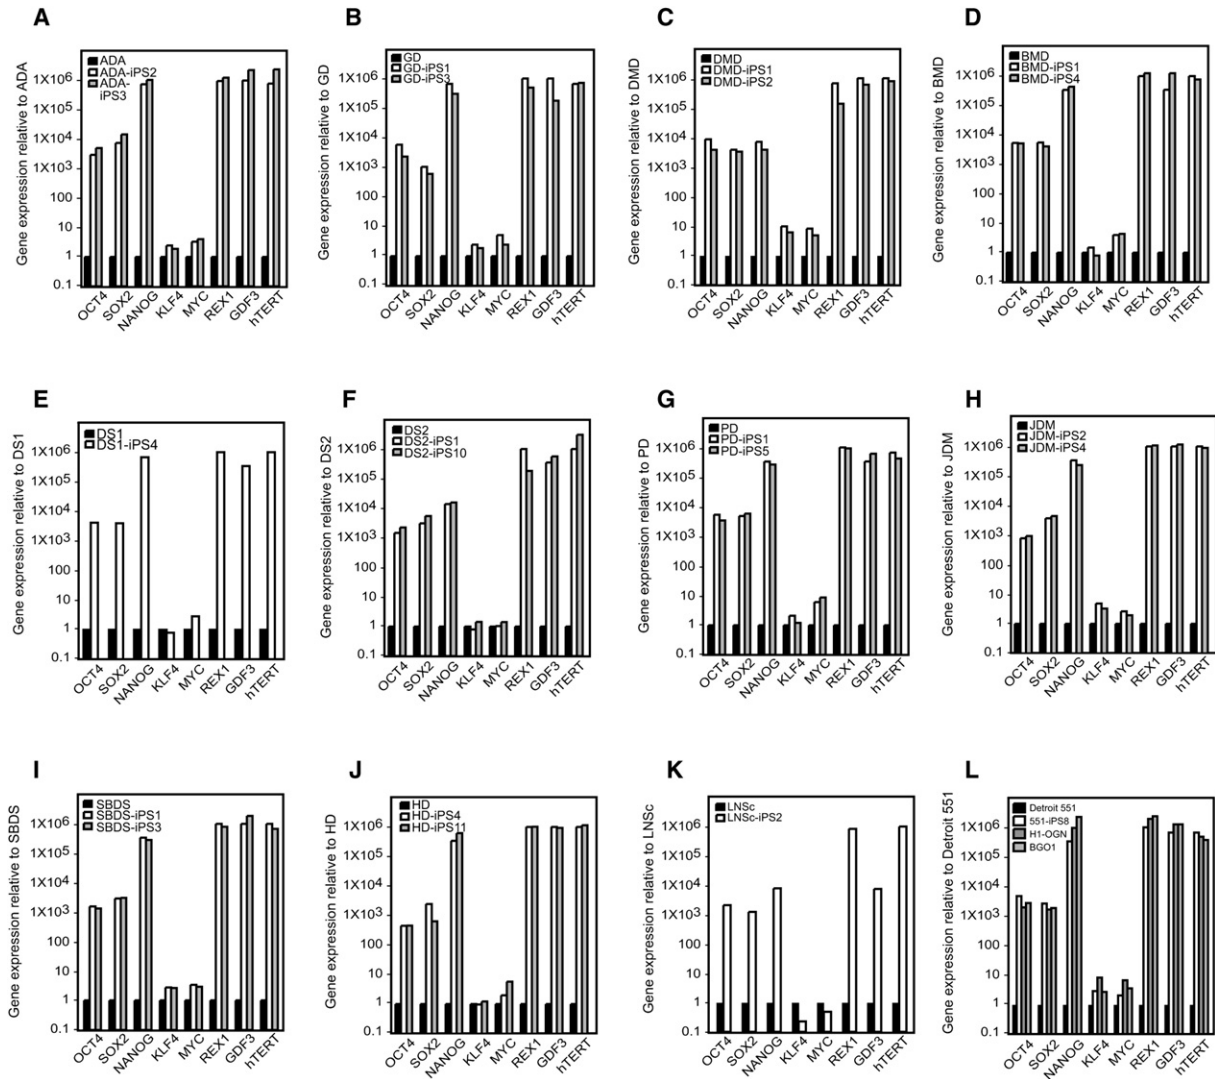

Given that numerous groups have pioneered the directed differentiation of neuronal subtypes, and that genetically defined ES cells from animal models of amyotrophic lateral sclerosis have revealed important insights into the pathophysiology of motor neuron deterioration (Di Giorgio et al., 2007), there is considerable interest in generating iPS cell lines from patients afflicted with neurodegenerative disease. We generated iPS cell lines from a patient with Huntington chorea (Huntington disease; HD) and verified the presence of expanded (CAG)<sub>n</sub> polyglutamine triplet repeat sequences (72) in the proximal portion of the *huntingtin* gene (Figure 1C; Riess et al., 1993) in one allele and 19 repeats in the other (where the normal range is 35 or less; Chong et al., 1997).

Pluripotent cell lines will likewise be valuable for studying neurodegenerative conditions with more complex genetic predisposition, as well as metabolic diseases known to have familial predispositions but for which the genetic contribution remains unexplained. We have generated lines from a patient diagnosed with Parkinson disease (PD) and another from a patient with juvenile-onset (type I) diabetes mellitus (Table 1). Given that these conditions lack a defined genetic basis, genotypic verification is impossible at this time.

The Lesch-Nyhan syndrome is caused by mutations in hypoxanthine-guanine phosphoribosyltransferase (HPRT), an X-linked enzyme in purine metabolism that when deficient leads to abnormal accumulation of uric acid and a neurologic disorder characterized by cognitive deficits and self-mutilating behavior. Cells carrying either intact or deficient HPRT enzyme function can be selectively cultured in media containing hypoxanthine-Aminopterin-Thymidine (HAT) or 6-thioguanine (6-TG), respectively. Strategies for inducing specific mutation or gene repair by homologous recombination were first established for the HPRT locus (Doetschman et al., 1987, 1988; Thomas and Capocchi, 1987). We have generated an iPS cell line from a female carrier (LNSc-iPS2) that will be a valuable resource for studies of homologous recombination in iPS cells and for analysis of X chromosome reactivation during reprogramming and random inactivation with differentiation.

### Figure 2. Disease-Specific iPS Cell Lines Exhibit Markers of Pluripotency

ADA-iPS2, GD-iPS1, DMD-iPS1, BMD-iPS1, DS1-iPS4, DS2-iPS10, PD-iPS1, JDM-iPS1, SBDS-iPS1, HD-iPS4, and LNSc-iPS2 were established from fibroblast or mesenchymal cells (Table 1). Disease-specific iPS cell lines maintain a morphology similar to hES cells when grown in coculture with mouse embryonic feeder fibroblasts (MEFs). Disease-specific iPS cells express alkaline phosphatase (AP). Also, as shown here via immunohistochemistry, disease-specific cells express pluripotency markers including Tra-1-81, NANOG, OCT4, Tra-1-60, SSEA3, and SSEA4. 4,6-Diamidino-2-phenylindole (DAPI) staining is shown at right and indicates the total cell content per image.

**Figure 3. Expression of Pluripotency-Associated Genes Is Elevated in Disease-Specific iPS Cell Lines Relative to Their Somatic Cell Controls**

In each panel, quantitative real-time PCR (RT-PCR) assay for *OCT4*, *SOX2*, *NANOG*, *REX1*, *GDF3*, and *hTERT* indicates increased expression in patient-specific iPS cells relative to parent cell lines while expression of *KLF4* and *cMYC* remains largely unchanged. PCR reactions were normalized against internal controls ( $\beta$ -*ACTIN*) and plotted relative to expression levels in their individual parent fibroblast cell lines.

- (A) the human iPS cell lines ADA-iPS2 and -iPS3 are derived from the adenosine deaminase deficiency-severe combined immunodeficiency fibroblast line ADA.
- (B) GD-iPS1 and -iPS3 are derived from the Gaucher disease type III fibroblast line GD.
- (C) DMD-iPS1 and -iPS2 are derived from the Duchenne muscular dystrophy fibroblast line DMD.
- (D) BMD-iPS1 and -iPS4 are derived from the Becker muscular dystrophy line BMD.
- (E) DS1-iPS4 is derived from the Down syndrome fibroblast line DS1.
- (F) DS2-iPS1 and -iPS10 are derived from the Down syndrome fibroblast line DS2.
- (G) PD-iPS1 and -iPS5 are derived from the Parkinson disease fibroblast line PD.
- (H) JDM-iPS2 and -iPS4 are derived from the juvenile-onset, type 1 diabetes mellitus line JDM.
- (I) SBDS-iPS1 and -iPS3 are derived from the Shwachman-Bodian-Diamond syndrome bone marrow mesenchymal fibroblast line SBDS.
- (J) HD-iPS4 and -iPS11 are derived from the Huntington disease fibroblast line HD.
- (K) LNSc-iPS1 and -iPS2 are derived from the Lesch-Nyhan syndrome carrier fibroblast line LNSc.
- (L) Detroit 551 human fibroblasts are used as the standard here in order to demonstrate the previously described expression pattern in Detroit 551-derived iPS cells (551-iPS8) relative to two bona fide hES cell lines: H1-OGN and BG01.

**Characterization of Disease-Specific iPS Cell Lines**

All iPS cell colonies, which were selected based on their morphologic resemblance to colonies of ES cells, demonstrated compact colony morphology and markers of pluripotent cells,

including alkaline phosphatase (AP), Tra-1-81, Tra-1-60, *OCT4*, *NANOG*, *SSEA3*, and *SSEA4* (Figure 2). Quantitative RT-PCR indicated the expression of pluripotency-related genes including *OCT4*, *SOX2*, *NANOG*, *REX1*, *GDF3*, and *hTERT* regardless of

**Figure 4. Pluripotency-Promoting Genes Are Chiefly Expressed from the Endogenous Loci in Disease-Specific iPS Cell Lines, While the Virally Delivered Transgene Is Predominantly Silenced**

The disease-specific iPS cell lines shown here are preceded by their parental fibroblast controls (from left to right at top): adenosine deaminase deficiency-associated severe combined immunodeficiency (ADA), Becker muscular dystrophy (BMD), Parkinson disease (PD), juvenile type 1 diabetes mellitus (JDM), Huntington disease (HD), Detroit 551 control cells, Duchenne muscular dystrophy (DMD), Shwachman-Bodian-Diamond syndrome (SBDS), Down syndrome (DS), Gaucher disease type III (GD), and Lesch-Nyhan syndrome carrier (LNSc). The semiquantitative expression (RT-PCR) of the four pluripotency-promoting genes used in the reprogramming process, *OCT4*, *SOX2*, *cMYC*, *KLF4*, and *NANOG* is shown for each line using amplification conditions specific to the endogenous (Endo) or virally delivered transgene (Trans) as well as the total expression for each (Total).  $\beta$ -ACTIN is shown at the bottom as a loading control for each lane.

the genetic condition represented within the parental somatic cells (Figure 3; control lines are shown in panel L). Retroviral transgenes were largely silenced in the iPS cell lines, with expression of the relevant reprogramming factors assumed by endogenous loci (Figure 4), as described (Park et al., 2008b). PCR-based DNA fingerprint analysis using a highly variable number of tandem repeats (VNTR) confirmed that the iPS cell lines were genetically matched to their parental somatic lines, ruling out the possibility of crosscontamination from existing cultures of human pluripotent cells (Figure S1 available online). Also, iPS cells showed normal 46 XX or 46 XY karyotypes (Figure S2).

Human disease-associated iPS cell lines were characterized by a standard set of assays to confirm pluripotency and multilineage differentiation. iPS cell lines ( $n = 7$ ) were allowed to differentiate in vitro into embryoid bodies as described (Park et al., 2008b), and their potential to develop along specific lineages was confirmed by PCR for markers of all three embryonic germ layers (ectoderm, mesoderm, and endoderm; Figure 5A). Hematopoietic differentiation of disease-specific iPS cell lines ( $n = 2$ ) produced myeloid and erythroid colony types (Figure 5B). The ultimate standard of pluripotency for human cells is teratoma formation in immunodeficient murine hosts (Lensch et al., 2007). When injected intramuscularly into immunodeficient  $Rag2^{-/-}$   $\gamma C^{-/-}$  mice, disease-specific iPS cell lines ( $n = 7$ ) produced mature, cystic masses representing all three embryonic germ layers (Figure 6).

The technique of factor-based reprogramming of somatic cells generates pluripotent stem cell lines that are effectively immortal in culture and can be differentiated into any of a multitude of human tissues. By comparison of normal and pathologic tissue formation, and by assessment of the reparative effects of drug treatment in vitro, cell lines generated from patients offer an unprecedented opportunity to recapitulate pathologic human tissue formation in vitro, and a new technology platform for drug screening. The Harvard Stem Cell Institute has committed resources to establish a Core Facility for the production of disease-specific iPS cell lines, with the goal of making each of these lines available to the biomedical research community.

## EXPERIMENTAL PROCEDURES

### Somatic Cell Culture, Isolation, and Culture of iPS Cells

Fibroblasts from patients with ADA-SCID (ADA, GM01390), Gaucher disease (GD, GM00852), Duchenne type muscular dystrophy (DMD, GM04981; DMD2, GM05089), Becker type muscular dystrophy (BMD, GM04569), Down syndrome (DS1, AG0539A), Parkinson disease (PD, AG20446), juvenile (type I) diabetes mellitus (JDM, GM02416), Huntington disease (HD, GM04281; HD2, GM01187), and Lesch-Nyhan syndrome carrier (LNSc, GM00013) were obtained from Coriell. Fibroblasts from patients with Down syndrome (DS2, DLL54) and normal fetal skin fibroblasts (Detroit 551) were purchased from ATCC. Bone marrow mesenchymal cells from SBDS patient (SBDS, DF250) have been described (Austin et al., 2005). Cells were grown in alpha-MEM containing 10% inactivated fetal serum (IFS), 50 U/ml penicillin, 50 mg/ml streptomycin, and 1 mM L-glutamine. Retroviruses expressing *OCT4*, *SOX2*, *KLF4*,

**Figure 5. Differentiation of Disease-Specific iPS Cell Lines Reveals Lineage-Specific Gene Expression and Mature Cell Formation**

(A) At top (from left to right) are eight iPS cell lines in their undifferentiated (U) or differentiated (D) state. The lines are adenosine deaminase deficiency-associated severe combined immunodeficiency (ADA), juvenile-onset type 1 diabetes mellitus (JDM), Down syndrome 1 (DS1), Gaucher disease type III (GD), Huntington disease (HD), Duchenne muscular dystrophy (DMD), Down syndrome 2 (DS2), and normal control Detroit 551 (551) cells. Differentiation (D) of these patient-specific iPS cells as embryoid bodies (EB) followed by RT-PCR analysis shows upregulated expression of lineage markers from the three embryonic germ layers relative to their undifferentiated controls (U), including: *GATA4* and *AFP* (endoderm), *RUNX1* and *Brachyury* (mesoderm), and *NESTIN* and *NCAM* (ectoderm).  $\beta$ -*ACTIN* serves as a positive amplification control for each.

(B) Differentiation of ADA-iPS2, a representative patient-specific iPS cell line, as embryoid bodies (EB) is highly reminiscent of that using hES cells where tight clusters of differentiating cells are

well-formed by day 7 and will cavitate, becoming cystic, by day 10. Hematopoietic differentiation of patient-specific iPS cells yields various blood cell types in semisolid methylcellulose colony-forming assays including burst-forming unit-erythroid (BFU-E), which are derivative of red blood cell progenitor cells.

and *MYC* were pseudotyped in VSVg and used to infect  $1 \times 10^5$  cells in one well of a six-well dish. iPS cells were isolated as described previously (Park et al., 2008b). iPS cells from LNSc fibroblasts were isolated using an inducible lentiviral system as previously described (Stadtfeld et al., 2008). cDNAs encoding human *OCT4*, *SOX2*, *cMYC*, *KLF4*, and *NANOG* were cloned into doxycycline-inducible vectors and were coinfecting with a lentivirus harboring a constitutively expressed reverse tetracycline transactivator (rtTA). Infected fibroblasts were split to feeders under hES culture conditions. Doxycycline was added to the culture for 30 days and then withdrawn. Colonies that appeared were picked and expanded into lines in the absence of doxycycline. iPS cell colonies were maintained in hES medium (80% DMEM/F12, 20% KO Serum Replacement, 10 ng/ml bFGF, 1 mM L-glutamine, 100  $\mu$ M nonessential amino acids, 100  $\mu$ M 2-mercaptoethanol, 50 U/ml penicillin, and 50 mg/ml streptomycin).

#### Characterization of Genetic Defects in iPS Cells

Genomic DNA was isolated from cells using DNeasy kit (QIAGEN). PCR reactions were performed using 50 ng of genomic DNA with primers corresponding to the mutated regions of genes responsible for each condition (ADA-SCID, GD, SBDS [Calado et al., 2007], and HD). Primer sequences are provided in Table S1. PCR products were resolved via agarose gels, purified and sequenced, or cloned into the TOPO vector (Invitrogen) for sequencing. The number of CAG repeats in the HD gene was determined by amplifying the 5' end of the *huntingtin* gene by PCR and sequencing. The deletion of exons within the *dystrophin* gene in DMD-iPS cells and BMD-iPS cells was determined by PCR using Chamberlain or Beggs' multiplex primer sets (Beggs et al., 1990; Chamberlain et al., 1988).

#### Karyotype Analysis

Chromosomal studies including karyotype of trisomy 21 in DS1-iPS and DS2-iPS10 cells were performed at the Cytogenetics Core of the Dana-Farber/Harvard Cancer Center or Cell Line Genetics using standard protocols for high-resolution G-banding.

#### Fingerprinting Analysis

Fifty nanograms of genomic DNA was used to amplify across discrete genomic intervals containing highly variable numbers of tandem repeats (VNTR). PCR

products were resolved in 3% agarose gels to examine the differential amplicon mobility for each primer set: D10S1214, repeat (GGAA)<sub>n</sub>, average heterozygosity 0.97; D17S1290, repeat (GATA)<sub>n</sub>, average heterozygosity 0.84; D7S796, repeat (GATA)<sub>n</sub>, average heterozygosity 0.95; and D21S2055, repeat (GATA)<sub>n</sub>, average heterozygosity 0.88 (Invitrogen).

#### Immunohistochemistry and AP Staining of iPS Cells

iPS cells grown on feeder cells were fixed in 4% paraformaldehyde for 20 min, permeabilized with 0.2% Triton X-100 for 30 min, and blocked in 3% BSA in PBS for 2 hr. Cells were incubated with primary antibody overnight at 4°C, washed, and incubated with Alexa Fluor (Invitrogen) secondary antibody for 3 hr. SSEA-3, SSEA-4, TRA 1-60, and TRA 1-81 antibodies were obtained from Millipore. OCT3/4 and NANOG antibodies were obtained from Abcam. Alkaline phosphatase staining was done per the manufacturer's recommendations (Millipore).

#### Analysis of Gene Expression

Total RNA was isolated from iPS cells using an RNeasy kit (QIAGEN) according to the manufacturer's protocol. 0.5  $\mu$ g of RNA was subjected to the RT reaction using Superscript II (Invitrogen). Quantitative PCR was performed with Brilliant SYBR Green Master Mix in Stratagene MX3000P machine using previously described primers (Park et al., 2008b). Semiquantitative PCR was performed to look at the expression of total, endogenous, and recombinant pluripotency genes, as well as genes representing the three embryonic germ layers, using primers described previously and in Table S1.

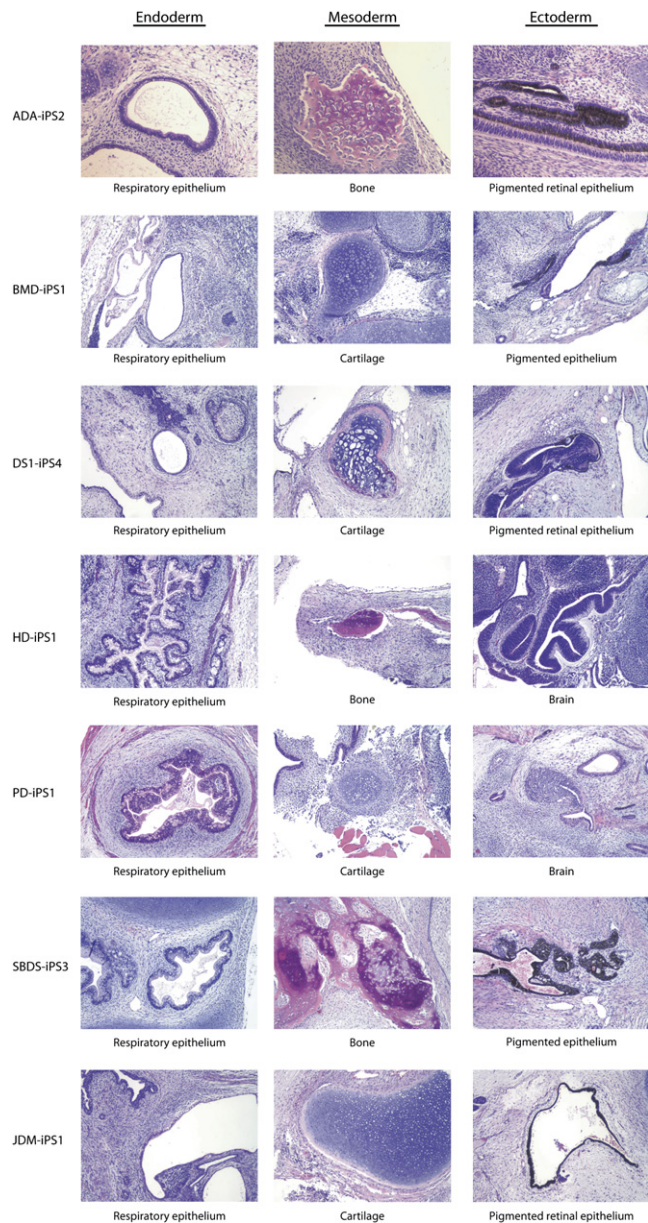

#### Differentiation of iPS Cells

iPS cells were washed with DMEM/F12, treated with collagenase for 10 min, and collected by scraping. Colonies were washed once with DMEM/F12 and gently resuspended in EB differentiation medium. EBs were differentiated with low-speed shaking and the medium was changed every 3 days. After 2 weeks of differentiation, EBs were dissociated and plated in MethoCult (Stem Cell Technologies).

#### Teratoma Formation from iPS Cells

iPS cells were washed with DMEM/F12, treated with collagenase for 10 min at room temperature, scraped using glass pipette, and collected by

**Figure 6. Disease-Specific iPS Cell Lines Form Teratomas in Immunodeficient Mice**

Shown here are the representative series of hematoxylin-eosin (H&E) stained sections from a formalin-fixed teratoma produced from ADA-iPS2, BMD-iPS1, DS1-iPS4, HD-iPS1, PD-iPS1, SBDS-iPS3, and JDM-iPS1 cell lines. They formed mature, cystic teratomas with tissues representing all three embryonic germ layers including respiratory epithelium (endoderm), bone and cartilage (mesoderm), and pigmented retinal epithelium and immature neural tissue (ectoderm).

centrifugation. Cells were washed once with DMEM/F12 and mixed with Matrigel (BD Biosciences) and collagen (Sigma).  $2 \times 10^6$  cells were intramuscularly injected into immune-deficient  $Rag2^{-/-}\gamma C^{-/-}$  mice. After 6 weeks of injection, teratomas were dissected, rinsed once with PBS, and fixed in 10% formalin. Embedding in paraffin, sectioning of tissue, and hematoxylin/eosin staining were performed by the Rodent Histopathology service of the Dana-Farber Cancer Institute.

## SUPPLEMENTAL DATA

Supplemental Data include two figures and one table and can be found with this article online at <http://www.cell.com/cgi/content/full/134/5/877/DC1>.

## ACKNOWLEDGMENTS

G.Q.D. was supported by grants from the National Institutes of Health, the NIH Director's Pioneer Award of the NIH Roadmap for Medical Research, and private funds contributed to the Harvard Stem Cell Institute and the Children's Hospital Stem Cell Program. The work was made possible by the support and vision of Douglas and Diana Berthiaume, Jonathan and Patti Kraft, and the John W. Henry Family Foundation. G.Q.D. is a recipient of Clinical Scientist Awards in Translational Research from the Burroughs Wellcome Fund and the Leukemia and Lymphoma Society and is an Investigator of the Howard Hughes Medical Institute. K.H. was supported by the NIH Director's Innovator Award and the Harvard Stem Cell Institute. N.M. was supported by the Natural Sciences and Engineering Council of Canada and a Sir James Loughheed Award.
