be directly involved in the pathogenesis of PD; indeed, extensive accumulation of nitrated aS has been detected in amyloid aggregates in PD post-mortem brain tissue. In vitro, oxidative modifications to aS can inhibit fibrillation and lead to the build-up of stable oligomers, which may cause increased toxicity. Here, we use single molecule fluorescence techniques (fluorescence correlation spectroscopy and single molecule Förster energy transfer) to investigate the influence of oxidative modifications on the molecular mechanisms of aS aggregation and membrane interaction. aS is unstructured in solution but residues 1-90 form an alpha-helix upon binding lipid bilayers. Tyrosine nitration leads to decreased binding of aS to lipid membranes, which may entail a loss of aS native function. Interestingly, we find that nitration of tyrosines located at the C-terminus of the protein, which stays unstructured upon membrane binding, can modulate the affinity of the N-terminus. Another consequence of nitrosative insult to the protein is the formation of di- and oligomeric aS species by di-tyrosine cross-linking. We find that protein cross-linking does not perturb the protein’s ability to form an alpha-helix upon membrane binding, although the binding affinity is altered. Nitrosative stress has been implicated to be involved in PD pathology and the characterization of its effects on aS conformation and membrane interaction will help to refine our understanding of the toxic form(s) of aS.

1349-Pos  Nature of the Low pH Alpha Synuclein Conformational State Revealed with Single Molecule Fluorescence  
Adam Trexler, Elizabeth Rhoades. Yale University, New Haven, CT, USA.  
Alpha-Synuclein (aS) is a natively unstructured protein that is strongly implicated in Parkinson’s disease (PD) pathogenesis. Aggregated aS is the main component of Lewy body plaques, a hallmark of PD, but smaller aS oligomers are thought to be the cytotoxic agent responsible for neuronal death in the disease. Thus, understanding how this monomeric, unstructured protein becomes a toxic oligomeric state is a vital question in understanding the role of aS in PD. Low pH has been shown to induce the formation of a partially folded structure in aS, which is likely the first step in aS aggregation pathways. We use single molecule Förster resonance energy transfer (smFRET) and fluorescence correlation spectroscopy (FCS) to study a low pH aS conformational state, smFRET measurements have shown that C-terminal residue 130 makes close contact with the central, hydrophobic region of aS at low pH. The N-terminal helix-forming region of aS undergoes little change from neutral to low pH. We have also used guanidine denaturation experiments monitored by smFRET to study the stability of the low pH state. Characterizing the nature of the low pH aS state is critical for understanding this transition, as therapeutic targeting of this state could stop the aggregation process before it even begins.

1350-Pos  Monitoring the Lipid-Binding Properties of Beta- and Gamma-Synuclein using Fluorescence Correlation Spectroscopy (FCS)  
Vanessa C. Ducas, Elizabeth Rhoades. Yale University, New Haven, CT, USA.  
The synucleins are a family of natively unstructured proteins consisting of z-, , and -synuclein, which are primarily expressed in neurons. The synucleins have been linked to the pathogenesis of various neurological disorders, such as Parkinson’s disease (z-synuclein) and Dementia with Lewy bodies (z- and -synuclein). Interestingly, -synuclein might also have a protective role in neurodegenerative diseases that are associated with formation of -synuclein aggregates. -synuclein was first identified in breast cancer cells, and was later found to be overexpressed in other types of cancer, such as ovarian cancer and retinoblastoma. Recent studies indicated that overexpression of -synuclein promotes cancer cell survival and metastasis. Still, the biological relevance of the synucleins is yet to be elucidated. All the synucleins share a 6-residue motif, KTEKGV, in their N-terminal region that is commonly found in lipid-binding proteins (apolipoproteins), and it is thought that their native function likely entails binding to biomembranes. In this study, we use fluorescence correlation spectroscopy (FCS) to monitor the lipid-binding properties of -synuclein and -synuclein. Our findings will help determine the underlying factors governing the synuclein-membrane interactions, as well as the strength of these interactions, which would not only reflect the native functions of these proteins, but would also help understand their involvement in disease states.

1351-Pos  Determining the Effects of Disorder on Binding Affinity  
Wai Kit Ma, Rebecca Sacora, Matthew Gage. Northern Arizona University, Flagstaff, AZ, USA.  
It has long been believed that proteins require a defined three-dimensional structure to perform their specific functions. However, a class of proteins called intrinsically disordered proteins has been identified that do not require a stable structure to perform their functions. These proteins play important roles in many diverse biological processes including signal transduction, transcription, and cell division. Therefore, understanding how these proteins recognize and bind to other proteins to perform their functions is an important question. FlgM is an 88-residue intrinsically disordered protein from bacteria that regulates flagella synthesis by binding the RNA transcription factor Sigma 28. When FlgM is bound to Sigma 28, it inhibits transcription of the genes encoding the late flagella proteins. The FlgM protein is an interesting IDP since FlgM genes from different bacteria exhibit different degree of disorder region. Specifically, our lab has shown that the FlgM gene from A. aeolicus is significantly more disordered than the S. typhimurium FlgM. It is predicted that the more ordered the protein, the higher the affinity of the FlgM for Sigma 28. We are using a combination of Isothermal Titration Calorimetry (ITC) and fluorescence to determine the equilibrium binding constant and the binding kinetics for FlgM binding to Sigma 28 using proteins from a series of different bacteria, including A. aeolicus, S. typhimurium, E. coli, P. aeruginosa, and B. subtilis.

1352-Pos  Mechanism of Small-Molecule Binding by Intrinsically Disordered Proteins  
Steven J. Metallo, Arielle Vlacava Folli, Dalia I. Hammoud, Edward V. Prochownik. 1Georgetown University, Washington, DC, USA, 2Children’s Hospital of Pittsburgh, Pittsburgh, PA, USA.  
We have demonstrated multiple examples of small molecules that are capable of specific binding to relatively short segments of intrinsically disordered (ID) proteins. Molecules that bind to the ID monomer of the cMyc bHLHZip protein are capable of disrupting the extensive protein-protein interface normally formed between cMyc and its heterodimerization partner Max. The kinetics of the disruption is dependent on the location of the small-molecule binding site along the bHLHZip structure. One site allows rapid disruption with the small molecule acting as a wedge while two other sites are inaccessible to inhibitors when cMyc is dimerized and function only by trapping cMyc when it is in the dissociated, monomeric state. High-affinity, bivalent inhibitors retain the fast disruption profile of one of the constituent parts.

Ribosomes & Translation

1353-Pos  Simulations of the Ribosome Suggest Reversible Transitions and Parallel Pathways are Involved in the Large-Scale Functional Motions of tRNA During Translation  
Paul C. Whitford, Peter Geggier, Roger Altman, Scott C. Blanchard, Jose’ N. Onuchic, Kevin Y. Sanbonmatsu. 1Los Alamos National Laboratory, Los Alamos, NM, USA, 2Weill Cornell Medical College, New York, NY, USA, 3Center for Theoretical Biological Physics, UCSD, La Jolla, CA, USA.  
Through model building and large-scale computer simulations, we present a structural framework for understanding the molecular mechanisms of transfer RNA (tRNA) movement through the ribosome. In the context of RNA accommodation (the process by which tRNA enters the ribosomal complex), these models predict that highly-specific functional motions are determined by the atomic details of the ribosome. Significant findings include 1) large-scale reversible fluctuations in tRNA position precede complete RNA accommodation, 2) the accommodation process possesses multiple kinetic intermediates that may be related to ribosomal “proofreading” and 3) parallel pathways of accommodation may allow incoming tRNA molecules to be re-routed in response to changes in cellular conditions. In addition to illuminating the role of the ribosome’s structure, this work also predicts that large changes in entropy in the individual tRNA molecules lead to energetically favorable accommodation pathways. The dynamics predicted in these models are validated through comparison with crystallographic data, explicit-solvent simulations and smFRET experiments.

1354-Pos  Fast Biosynthesis of GFP Molecules - A Single Molecule Fluorescence Study  
Georg Büldt1, Alexandros Katranidis1, Ramona Schlesinger1, Knud H. Nierhaus1, Ingo Gregor1, Michael Gerrits3, Jürg Fitter1. 1Research Centre Jülich, D-52425 Juelich, Germany, 2Max-Planck Institut für molekulare Genetik, D-14195 Berlin, Germany, 3University of Göttingen, Institute of Physics, D-37077 Göttingen, Germany, 4RiNA GmbH, D-14195 Berlin, Germany.  
Numerous studies showed that protein folding and maturation can differ substantially between de novo synthesized proteins and in vitro refolded proteins.
In classical folding studies folded proteins are initially denatured into an unfolded state before the (re-)folding process can be studied. It has been demonstrated that protein folding takes place already during the elongation of the nascent chain (co- translational folding).

Here we present an approach employing a two color single molecule sensitive fluorescence wide-field microscope in order to visualize surface tethered fluorescently labeled ribosomes and in vitro synthesized GFP molecules in real time [1]. Suppression of protein release after synthesis keeps the synthesized GFP bound to the ribosome and allows to image GFP fluorescence for extended observation times.

We demonstrate that the characteristic time for the production of the mature GFP mutant Emerald (GFPeM) is five minutes, which is one of the fastest maturation times for a GFP mutant observed so far. Early GFPeM molecules appear even faster, within one minute. Processes preceding to chromophore formation, such as polyepitope synthesis and protein folding, are fast and last less than one minute. Thus cellular processes within a time range of a few minutes can be followed by GFPeM.

Fluctuating tRNA Guided by Induced Fit as a Basis of High Fidelity Translation by the Ribosome

Padmaja P. Mishra, Wenhui Ren, Mohd Tanvir Qureshi, Tae-Hee Lee.
Pennsylvania State University, University park, PA, USA.

Positional fluctuations and structural flexibility of molecules play important roles in various cellular processes. We implemented a single molecule method that can simultaneously measure fluorescence resonance energy transfer (FRET) and the antibody FRET acceptor emission. Based on the method, we monitored the process of aa-tRNA selection by the ribosome and evaluated the positional fluctuations of a cognate and a near-cognate tRNA at the GTPase activated state. The FRET measurements revealed that a cognate tRNA at the GTPase activated state samples the “A” site of the ribosome more frequently than a near-cognate. A cognate tRNA is found fluctuating more slowly within a more restricted space as compared to a near-cognate. These results suggest that induced fit steers a fluctuating cognate tRNA more accurately toward the “A” site of the ribosome. Based on our findings, we propose that fluctuating tRNA guided by induced fit may be the basis of high efficiency tRNA selection by the ribosome.

Simulations of the Bacterial Ribosomal Decoding Switch

Andrea C. Vaiana1, Helmut Grubmuller1, Kevin Y. Sanbonmatsu2.

2Los Alamos National Laboratory, Los Alamos, NM, USA.

Gentamicin is a potent antibiotic often used in therapy for methicillin-resis-
tant Staphylococcus aureus. Gentamicin works by flipping a conformational switch on the ribosome, disrupting the reading head (i.e., 16S ribosomal decoding codes A1492-A1493 used for decoding messenger RNA. We use explicit solvent all-atom molecular simulation to study the thermodynamics of the ribosomal decoding site and its interaction with gentamicin. The replica exchange molecular dynamics simulations allow enhanced sampling of the unbinding free-energy landscape, including a rigorous treatment of enthalpic and entropic effects. The decoding bases flip on a timescale faster than that of gentamicin binding, suggesting a stochastic gating mechanism for antibiotic binding, rather than an induced-fit model where the bases only flip in the presence of a ligand. The study also allows us to explore the nonspecific binding landscape near the binding site and reveals that, rather than a two-state bound/unbound scenario, drug dissociation entails shuttling between many metastable local minima in the free-energy landscape. Additional simulations address the effect of mutation/modification of the A-site on the free energy landscapes. In particular, mutations of base A1408 known to confer high-level resistance in “superbug” bacteria to common antibiotic therapies are investigated. Special care is dedicated to validation of the obtained results, both by direct comparison to experiment and by estimation of simulation convergence.

Single-Molecule Study of Programmed Ribosomal Frameshifting

Jin-Der Wen1, Laura Lancaster2, Harry Noller2, Carlos Bustamante1.
1National Taiwan University, Taipei, Taiwan, 2University of California, Santa Cruz, Santa Cruz, CA, USA, 3University of California, Berkeley, Berkeley, CA, USA.

Programmed ribosomal frameshifting is involved in regulation of gene expres-
sion at the translation level in bacteria, and the frameshifting efficiency has to be well controlled. For example, the dnaX gene of E. coli encodes two sub-units (gamma and tau) of the DNA polymerase III, and the ratio of these two subunits is determined by the frameshifting efficiency. Factors that affect frameshifting have been extensively studied in vitro and in vivo, but the dynamic features of this process are still not well understood. Here we use optical tweezers to follow stepwise translation in real time at the single ribosome level to understand how frameshifting is controlled. Our preliminary data show that the ribosome pauses for various times at, or even one to two codons prior to, the slippery sequence where frameshifting occurs. The pause may be caused, at least in part, by an internal Shine-Dalgarno sequence, which is located upstream to the slippery sequence and is known to induce frameshift-
ing. Correlation between pause duration and occurrence of frameshifting is under investigation.

Ribosomes translate the genetic code in an mRNA into a protein; three nucleo-
tides—one codon-code for one amino acid. Because natural RNAs contain base-paired regions, the ribosome needs to unwind these structures into single-strands before the structured regions can be translated. Furthermore, mRNA secondary and tertiary structures are involved in translation regulation mechanisms, such as frame-shifting. Bulk studies have shown that mRNA structures slow down the translation rate and that the unwinding is inherent to the ribosome. But the unwinding mechanism is not well understood. We used optical tweezers to apply force to the ends of an mRNA hairpin being translated by a single ribosome. At constant force, the mRNA end-to-end distance increases as the ribosome translates the message and converts double-stranded RNA into single strand. This technique allows observation of codon-by-codon translation. The translation rate dependence on force provides information on the ribosome unwinding mechanism. We found that the translation rate increases quickly as force is increased within a narrow force range, but the rate plateaus below and above this force range. We also found that the translation rate on duplex mRNA (low force plateau) is ~50% of the rate on single-stranded mRNA (high force plateau). The observed force dependence is inconsistent with a passive unwinding model, or the active unwinding models that have been applied to T7 and NS3 helicases. Instead, the data call for a different type of active unwinding mecha-

Insights into Translational Termination from Crystal Structures of the 70S Ribosome Bound to Release Factor

Hong Jin, Albert Weixlbaumer, Cajetan Neubauer, Rebecca Voorhees, Sabine Petry, David Loakes, Ann Kelley, Venki Ramakrishnan.
MRC-Laboratory of Molecular Biology, Cambridge, United Kingdom.

Here we report high-resolution crystal structures of release factor 2 (RF2) bound to 70S ribosome. These structures emulate the translational states directly before and after hydrolysis of the ester bond in peptidyl-tRNA on the ribosome during translational termination. Our structures show detailed molecular interactions between the ribosome decoding center and RF2 upon stop-codon recognition. After a stop-codon is recognized, the universally conserved GGG motif extends directly into the peptidyl transferase center forming a tightly packed catalytic core. Nucleotide A2602 in the 23S rRNA forms a favourable stack with the GGG motif in RF2. The ribose of the A76 in the peptidyl-tRNA adopts C2'-endo conformation. Our structures help to rationalize a decade of biochemical and computational data on translational termina-
tion. Based on the structures, a mechanistic model on how the ester bond in the peptidyl tRNA is hydrolyzed is proposed.
