Methods: 41 consecutive patients (38 men and 3 women; age 52 ± 9 years) with anterior STEMI were enrolled. All patients were randomized into two groups and underwent primary PCI for anterior STEMI stenting after manual thrombectomy (aspiration group, n=22) and stenting without manual thrombectomy (conventional group, n=19). The thrombolysis-derived coronary flow reserve (CFR) and index of microcirculatory resistance (IMR) were measured by using the pressure-temperature sensor-tipped coronary wire at the left anterior descending artery (LAD) after primary PCI. Baseline echocardiography was performed before discharge and follow-up echocardiography was performed 6 months later.

Results: There was no significant difference in reperfusion time (onset to balloon time) and CPR (2.01 ± 1.1 vs. 2.05 ± 1.1, p = 0.83), baseline ejection fraction (EF, 44.5 ± 7.5% vs. 48.0 ± 8.0%, p = 0.15), baseline wall motion score index (WMSI, 1.52 ± 0.32 vs. 1.46 ± 0.31, p = 0.59) between two groups. But, there was a significant difference in IMR (22.3 ± 8.7 vs. 29.5 ± 11.9, p = 0.037), DEFR (follow up EF – baseline EF, 5.86 ± 7.2 vs. 1.29 ± 2.5, p = 0.011), JVM (baseline JVM follow up JVM, 0.199 ± 0.243 vs. 0.003 ± 0.007, p = 0.003) between two groups.

Conclusions: Compared with conventional PCI, manual thrombectomy before stenting for patients with anterior STEMI seems to preserve microvascular integrity. Manual thrombectomy as an adjunctive method of primary PCI for acute anterior STEMI might have beneficial efficacy on myocardial microcirculation.

Background: Drug-eluting stents (DES) are used in ST-segment elevation myocardial infarction (STEMI) patients with good safety and efficacy, even in complex patient subsets. This study aimed to compare the in-hospital and 1-year outcomes of STEMI patients with complex clinical and angiographic characteristics treated with 1st- versus 2nd-generation DES.

Methods: The study included 524 consecutive STEMI patients with ≥1 of the following characteristics: Ejection fraction (EF) <30%, chronic renal insufficiency (CRI), cardiacogenic shock, bifurcation, unprotected left main, totally occluded, ACC/AHA Type C, bypass graft, in-stent restenosis, presence of thrombus, >1 lesion treated, and stent implantation length ≥28 mm. Clinical outcomes of patients treated with 1st-generation DES (Cypher/Taxus) (n=452) were compared to those treated with 2nd-generation DES (Promus/Xience) (n=102).

Results: Baseline demographics were similar in patients treated with 1st- vs. 2nd-generation DES. Mean age was 62.2 ± 12.5 years; 65% males; mean EF was 42 ± 13%; and 13.1% had CRI. IABP use (14.2% overall), procedure time (50 ± 51 min overall), lesion locations, graft and in-stent restenosis lesions were also similar. 2nd-generation DES were used more frequently in Type C lesions (56.8 vs. 27.4%, p=0.003) and in-stent restenosis lesions were also similar. 2nd-generation DES were used more frequently in Type C lesions (56.8 vs. 27.4%, p=0.003) and in-stent restenosis lesions were also similar.

Conclusions: Despite the presence of higher lesion complexity, the use of 2nd-generation DES in a STEMI population with complex clinical and angiographic characteristics results in similarly low rates of in-hospital and 1-year outcomes when compared to 1st-generation DES.

Prognosis of Patients Presenting with Non-ST-Segment Elevation Myocardial Infarction and Non-Obstructive Coronary Artery Disease: Propensity Score Matched Cohort from the ACUTY Trial
David Planer1, E. Magnus Ohman2, Harvey White3, Jeffrey Moses4, Martin Fahy5, Rosana Mehran6, Gregg Stone4
1Hadassah - Hebrew University Medical Center, Jerusalem, Israel, 2Duke University Medical Center, Durham, North Carolina, 3Auckland City Hospital, Auckland, New Zealand, 4Columbia University Medical Center and the Cardiovascular Research Foundation, New York, NY, 5Cardiovascular Research Foundation, New York, NY, 6Mount Sinai Hospital, New York, USA

Background: Troponin elevation is a risk factor for mortality in pts with non ST-segment elevation acute coronary syndromes (NSTEACS). However, prognostic impact of non-obstructive coronary artery disease (CAD) in NSTEACS pts with troponin elevation is unknown.

Methods: In the ACUTY trial, 3- vessel quantitative coronary angiography was performed in a formal substudy of 6,921 pts with moderate and high-risk NSTEACS. Patients with elevated admission troponin levels (>local upper limit of normal) were stratified by the presence or absence of obstructive CAD (any lesion with diameter stenosis (DS) ≥50%). Propensity-score matching was performed to adjust for baseline characteristics.

Results: Of 2,442 patients with elevated troponins, 197 (8.8%) had non-obstructive CAD. Maximum DS was 83.5% ± 17.5 vs. 24.1% ± 12.2 (p<0.0001) in pts with vs. without obstructive CAD. Propensity score matching yielded 117 patients with non-obstructive CAD and 351 patients with obstructive CAD with no significant baseline differences including renal function and diabetes. Overall 1-year mortality was significantly higher in pts with non-obstructive CAD (5.2% vs 1.2%; HR [95%CI] = 4.57 [1.29,16.21], p=0.01), driven mainly by higher non-cardiac mortality (Table). Conversely, recurrent MI and unplanned revascularization rates were higher in patients with obstructive CAD.

Conclusions: Patients presenting with NSTEACS symptoms and elevated troponin levels in whom obstructive CAD is absent, are at significantly higher risk of 1-year all-cause and non-cardiac mortality than those with obstructive CAD, despite lower rates of unplanned revascularization and subsequent MI. Troponin elevation in pts with non-obstructive CAD may be an important risk factor for mortality, prompting a comprehensive search for an alternative diagnosis.

Admission At Nights OrWeekends Has No Adverse Effect On Mortality For ST Elevation Myocardial Infarction Patients Treated By Primary Percutaneous Coronary Intervention: Single Center Study From A Large Tertiary Cardiovascular Unit In United Kingdom
Refal Showkathali1, John Davies1, Paul Kelly1, Jeremy Sayer2, Rajesh Aggarwal3, Gerald Clesham1
1The Essex Cardiothoracic Centre, Basildon, United Kingdom

Background: Mortality amongst emergency medical admissions has been reported to be higher when patients are admitted to hospital at nights and weekends. We studied the
mortality for STEMI patients presenting at different times to a large cardiothoracic center in the UK with a 24/7 primary PCI (PPCI) service delivered by senior medical staff.

**Methods:** We included all patients who underwent PPCI from September 2009 to November 2011. We divided them into three groups according to the time of admission to our unit as group 1: in-hours (8 am to 6 pm weekdays), group 2: out-of-hours (6 pm to 8 am week nights) and group 3: weekend (Saturday 8 am to Monday 8 am) and bank holidays.

**Results:** Of the 1471 patients admitted and underwent PPCI in our unit during the study period, 605 (41.1%), 397 (27%) and 469 (31.9%) were included in group 1, 2 and 3 respectively. Pre-procedure cardiac shock was significantly higher in group 1 compared to group 2 (8.9% vs 5.5%, p = 0.05), but no other significant difference was noted in the baseline and procedural characteristics between the groups (Table 1). When compared to group 1, door to balloon (DTB) time (median, IQR: 29, 24-39 mins) was significantly prolonged in group 2 (33, 24-36 mins, p =0.004) and group 3 (36, 28-47 mins, p<0.0001). There was no difference in DTB time between groups 2 and 3 (p=0.15). However, there was no significant difference in in-hospital mortality (grp 1 vs grp 2 vs grp3: 4.6% vs 4.3% vs 5.3%, p NS), 30-day mortality (6.4% vs 6.3% vs 7%, p NS) or stent thrombosis (0.8% vs 0.8% vs 0.2%, p NS) between the groups.

**Conclusions:** In this consecutive series of patients admitted to a high volume primary PCI center, there was no difference in mortality when patients were admitted at night, at the weekend or during regular office hours. The involvement of senior medical staff early at the hospital increased the time to intervention. The involvement of senior medical staff early at the hospital decreased the in-hospital mortality and major bleeding rates.

**Background:** Apoptosis (AP) has been involved in the pathophysiology of acute myocardial infarction (AMI). The P53 gene plays an essential role in the activation of AP. Recent studies have shown that the Arg72 variant induces apoptosis markedly better than does the Pro72 variant. The objective is to analysis the relationship between P53 codon 72 polymorphism (PLs) with the infarct size and the LVEF in patients with ST-segment elevation acute coronary syndrome (ST-ACS) undergoing primary angioplasty.

**Methods:** DNA of 91 patients with STE-ACS. The PLs were identified by polymerase chain reaction and restriction enzyme analysis. Patients were divided into three groups (homozygous arginine AA, heterozygous arginine/proline –AP– and homozygous proline –PP–). The infarct size was estimated of infarct with the peak serum concentrations of CK and CK-MB. LVEF was determined by 2D echocardiography.

**Results:** 63 men (69%) and 28 women (31%), with an average age of 72 ± 13 years. The prevalence of AA, AP and PP PLs was 51, 41% and 8%, respectively. No significant differences were found regarding the demographic, clinical and pharmacology treatment characteristics in the three groups. The artery responsible for the AMI was the right coronary (46%), left anterior descending (38%), left circumflex (14%) and left main coronary artery (2%). A bare metal stent was implanted in a 40% and drug eluting stent in 59% and the final TIMI-flow achieved was ≥2 in 89% of the patients. Peak levels of CK (AA 1586 ± 1586 vs AP 1737 ± 1197 vs PP 332 ± 1177 U/L; p = 0.02) and CK-MB (AA 128 ± 114 vs AP 97 ± 93 vs PP 22 ± 13 U/L; p =0.04) were significantly higher in heterogeneous AA patients. The LVEF (AA 49.8 ± 5.7, AP 54.7 ± 6.9, p = 0.001) were significantly lower in homozygous AA patients. We carried out a multivariate logistic regression analysis and the AA PL remained as an independent predictor for size of infarct (p = 0.025) and the LVEF (p = 0.001).

**Conclusions:** Patients with STE-ACS homozygous AA for the codon 72 of gene P53 has a larger infarct size and lower LVEF compared to the non-homozygous AA.

**Background:** We have previously shown that a diameter stenosis (DS) of ≥50% is optimal to define incomplete coronary revascularization (ICR) in pts with ACS undergoing PCI. However, the optimal reference vessel diameter (RVD) is unknown. We therefore explored the prevalence and impact of ICR in ACUTY according to different RVDs.

**Methods:** Quantitative coronary angiography (QCA) of the entire coronary tree was performed in 2954 PCI pts with UA/NSTEMI in ACUTY. ICR was defined present if any lesion with a final DS ≥50% is affected. However, we did not consider a reduction of recurrent myocardial infarction or mortality rates. Furthermore, there are concerns of the occurrence of stent thrombosis. As a novel treatment modality, a drug-eluting balloon (DEB) may be a therapeutic challenge, as it can provide the potential advantage of delivering an anti-proliferative drug without leaving a treatment modality, a drug-eluting balloon (DEB) may be a therapeutic challenge, as it can provide the potential advantage of delivering an anti-proliferative drug without leaving a
