The treatment of recurrent aortic prosthetic detachment with modified Bentall procedure: Results of two cases

Chong Zhang, MD, Yiming Ni, MD, Liping Shi, MD, and Tao Jin, MD, Hangzhou, China

Recurrent prosthetic valve detachment after aortic valve replacement (AVR) for aortic regurgitation is a most serious complication. Endocarditis, aortitis, or other factors are the common causes. AVR or repair of the detachment are usually difficult to manage and still have a high detachment rate. We report 2 cases of successful surgical management with the translocated Bentall procedure for recurrent aortic valve detachment resulting from indefinite causes.

PATIENTS AND METHODS

Two male patients, 33 and 55 years of age, with severe aortic regurgitation were treated in our institute in 2006. The clinical and radiologic findings excluded endocarditis and common aortitis. We performed AVR with the CarboMedics mechanical bileaflet prosthesis (Sulzer CarboMedics, Inc, Austin, Tex) and used 15 double-needled interrupted 2-0 synthetic braided pledget-supported sutures, which were left on the ventricular side. The operative and pathologic findings supported the diagnosis of aortic myxomatous degeneration and also further excluded endocarditis and common aortitis. Unfortunately, the valve became detached from the junction between the annulus and aortic wall, but without any evidence of infection. The 2 patients underwent reoperation, one undergoing detachment repair and the other undergoing aortic root replacement (Table 1). Recurrent prosthetic valve detachment still occurred postoperatively at the same location in these 2 patients without a common cause. Because of the location and frequency of the detachments, the translocated Bentall procedure was performed. In the modified Bentall procedure, the aortic valve prosthesis was sutured into the graft 1 cm from the end of the graft with a continuous 3-0 polyester suture, forming a composite graft. The composite graft then was implanted into the annulus with evertting 2-0 polyester mattress sutures followed by coronary reimplantation and distal anastomosis (Figure 1, A, B, and C).

RESULTS

Patient 1 was discharged 14 days later. He remained well with no evidence of valved conduit detachment and had no reports of symptoms at 1 year’s follow-up. Patient 2 had ventricular fibrillation 5 days after the operation, and cardiopulmonary resuscitation was successfully performed. He was discharged on the twentieth day postoperatively and remained well with no evidence of detachment and had no reports of symptoms at 7 months’ follow-up (Table 2).

DISCUSSION

Prosthetic detachment after AVR is one of the most frequent complications necessitating reoperation. Many common factors, such as endocarditis, aortitis, anatomic characteristics, and surgical management, are thought to predispose to complications. However, endocarditis and common specific aortitis were ruled out in our cases. The intrinsic anatomic factors were also considered. The embryologic origin of partial aortic annular portion could be a reason for its intrinsic weakness. After AVR, some factors could put rigid stress on the weak sector and lead to prosthetic detachment. The aortic leaflets in our patients both exhibited myxomatous degeneration, which manifested as endogenous histologic weakness in the annuloaortic junction. We believe that in AVR, the pressure of valve function directly affects the rigid sewing ring, thereby causing a higher detachment rate.

In accordance with other reports treating Behçet aortitis, we adopted the modified Bentall procedure owing to recurrent detachment without a definite cause. In composite graft reconstruction, the original Bentall operation for this disease was not indicated because of a high risk of suture insufficiency. The translocated Bentall procedure has often been used in prosthetic detachment caused by aortitis to prevent valve detachment. Reconstruction with a valved conduit was helpful because the prosthetic valve did not apply direct pressure to the aortic annulus and the flexible tubular prosthesis cushioned the stress. This new modification of the Bentall technique provides better flexibility and elasticity of the aortic annulus than does the standard Bentall procedure. We present our successful treatment experience and possible clinical values for the consideration of clinicians.

AVR, Aortic valve replacement; RCC, right coronary cups; NCC, noncoronary cups; LVOT, left ventricular outflow tract.
Nevertheless, further investigation is required because of the small cohort of patients and the short follow-up time.

Successful emergency surgery for coexistent acute aortic syndrome and acute carotid artery obstruction

Masahiko Ando, MD, Kazuhito Imanaka, MD, Hideaki Yamabi, MD, and Hiroshige Sato, MD, Saitama, Japan

Few surgeons advocate surgical intervention for patients with acute aortic syndrome and coma, especially on an emergency basis, because of very poor outcome.1 We herein describe an emergency operation for a comatose and hemiplegic octogenarian in a state of profound shock caused by rupture of a penetrating aortic ulcer (PAU) in the ascending aorta. Duplex scanning disclosed a slightly mobile thrombus nearly impacting into the right internal carotid artery. This patient successfully underwent replacement of the ascending aorta and right carotid endarterectomy concomitantly. Removal of this thrombus appeared to be highly beneficial. Preoperative evaluation of the carotid arteries has priority in patients with acute aortic syndrome and some neurologic deficits.
