Point: Minimally invasive bipolar radiofrequency ablation of lone atrial fibrillation: Early multicenter results

Erik Beyer, MD, a Richard Lee, MD, b and Buu-Khanh Lam, MD c

Objective: The treatment of lone atrial fibrillation can be a minimally invasive procedure using bipolar radiofrequency ablation technologies. Our objectives were to report on the safety and early efficacy of this novel therapeutic modality.

Methods: At 3 North American institutions between February 2005 and August 2007, 100 patients underwent minimally invasive bilateral pulmonary vein isolation, autonomic denervation, and left atrial appendage resection. The mean age was 65 ± 11 years, and 70% were male. The median duration of atrial fibrillation was 5.0 years; atrial fibrillation was paroxysmal in 39 patients (39%), persistent in 29 patients (29%), and permanent in 32 patients (32%). Indications for surgery included failure of medical therapy or percutaneous ablation and severe symptoms. Mean follow-up was 13.6 ± 8.2 months.

Results: The mean operative time was 253 ± 65 minutes, and the median hospital length of stay was 5 days. There were no intraoperative conversions and no mortality to report. Postoperative complications included pacemaker requirement in 5 patients (5%), phrenic nerve palsy in 3 patients (3%), hemotherax in 3 patients (3%), transient ischemic attack in 1 patient (1%), and pulmonary embolism in 1 patient (1%). At follow-up, 87% of patients were in normal sinus rhythm (paroxysmal 93%, persistent 96%, permanent 71%; P < .05); antiarrhythmic therapy was discontinued in 62% of patients, and anticoagulation therapy was discontinued in 65% of patients.

Conclusion: Minimally invasive bipolar radiofrequency ablation of lone atrial fibrillation is a safe and efficacious therapeutic option in selected patients. Further development is needed to reduce the rate of complications. Long-term prospective results are required to further validate this modality as a therapeutic option to treat lone atrial fibrillation.

As many as 6 million Americans already have atrial fibrillation (AF). By 2020, AF could affect as many as 9 million people in the United States alone. Despite advances in medical therapy, medications have only been effective in restoring sinus rhythm (SR) in approximately one half of all the patients with AF. This lack of successful SR restoration has limited the advantage of rhythm control in several large studies. However, AF remains a major cause of stroke and has limited the advantage of rhythm control in several large studies.2,3 However, AF represents a major cause of stroke and an independent risk factor for mortality.2,5,6 There is speculation that improved success in SR restoration may offer measurable survival advantages to the population with AF.2

Maze surgery was established as a curative procedure for patients with AF more than 2 decades ago and has been suggested to reduce stroke in patients with AF.7,8 Although more intensive monitoring suggests that results may be slightly less curative than historical reports state,9 the results of the complete Maze procedure are clearly more successful than catheter-based interventions.10 Unfortunately, the Maze procedure has not been embraced as a stand-alone procedure, with only 600 cases performed for lone AF in the Society of Thoracic Surgeons database in 2006.11

New technologies have allowed the creation of transmural lesions on a beating heart through alternative, less-invasive incisions. Although many of these have demonstrated early success, the results are often not as good in larger series. One of these new technologies has been the application of bipolar radiofrequency ablation to create pulmonary vein isolation via a bilateral thoracotomy approach.15,16 However, the series are generally small and limited to a single institution.

The objective of this study was to examine the results of this approach in a multi-institutional setting. In addition to the pulmonary vein isolation, autonomic ganglionic plexi (AGP) stimulation and ablation and left atrial (LA) appendage ligation and resection were performed at all institutions.

PATIENTS AND METHODS

Patient Population

At 3 North American institutions between February 2005 and August 2007, 100 patients underwent thoracoscopic-assisted bilateral pulmonary vein isolation, autonomic denervation, and LA appendage resection via bilateral mini-thoracotomies. Main indications for surgery were failure of medical therapy or percutaneous ablation and severe symptoms.
mean age was 65 ± 11 years. Baseline patient characteristics are described in Table 1.

Mild aortic valvular disease was present in 17 patients (17%), whereas mild to moderate mitral valve insufficiency was present in 58 patients (58%) with no significant differences associated with the type of AF (P = .53). The presence of mild coronary artery disease was noted on preoperative angiogram in 23 patients (23%), with no significant difference observed (P = .30).

All patients with AF who were referred for minimally invasive bipolar radiofrequency ablation had previously failed medical therapy or catheter ablation. Some referred patients were not considered suitable candidates if they had previous thoracic surgery leading to severe adhesions, had an enlarged left atrium (>6.0 cm), had evidence of thrombus in the left atrium, were not able to tolerate single lung ventilation, or were considered too high risk because of age or comorbidities.

**Definitions of Atrial Fibrillation Type**

Paroxysmal AF was defined in this study as AF less than 7 days in duration and self-terminated. Persistent AF was defined as AF greater than 7 days in duration or terminated by direct-current cardioversion or pharmacologically within 7 days. Permanent AF (recently changed to long-standing persistent) was defined as continuous AF lasting more than 1 year in duration.

**Surgical Technique**

General endotracheal anesthesia is delivered via a double-lumen endotracheal tube. A central line is placed, and a transeosophageal echocardiogram is performed to determine the presence or absence of clot in the LA appendage. If thrombus is identified, the procedure is aborted.

A video-assisted bilateral mini-thoracotomy technique is used to electrically isolate the pulmonary veins. The patient is positioned in the left lateral decubitus position, and a small incision is made at the intersection of the anterior axillary line and the line at the level of the xyphoid process. A 5-mm trochar is inserted, and a 30-degree degree angled 5-mm videoscope is directed through this port. An incision is made at the midaxillary line over the fourth intercostal space, and the intercostal muscle and the pleura are divided. A soft tissue retractor (CardioVations, Edwards Lifesciences Corp, Irvine, Calif) is placed.

The pericardium is divided anterior to the phrenic nerve from the superior vena cava to the inferior vena cava. Retraction sutures are placed on the inferior cut edge of the pericardium and brought out through separate small stab incisions on the lateral chest wall. The oblique and transverse sinususes are entered using blunt dissection, and an artificulating lighted tip dissector (Navigator, Medtronic Inc, Minneapolis, Minn) is placed through a separate port. The dissector is introduced through the oblique sinus and directed posterior to the right pulmonary veins. The tip of the dissector is then guided between the right superior pulmonary vein and the right main pulmonary artery. A Silastic guide is then attached to the tip of the dissector via a guide wire and brought back through the dissector port.

Saline-irrigated and nonirrigated bipolar radiofrequency clamps (BP2 or Gemini, Medtronic Inc; Atricure Inc, Cincinnati, OH) are applied to the pulmonary veins to achieve transmural lesions. The generator used to deliver the radiofrequency energy has a digital graph that displays conducance of the tissue between the clamp. Once the tissue becomes electrically inert, according to the predefined limits, a visual and audible signal is produced, as well as to ensure electrical isolation of the pulmonary veins by both sensing and pacing technology.

With the pulmonary veins anatomically isolated, a pacing/sensing and ablation pen/probe (MAPS pen, Medtronic Inc or Atricure Bipolar Pen, Atricure Inc) is used to identify AGP and ablate them. The pen/probe is placed in pacing mode, and high-frequency pacing (800–1000 bpm) is applied to the fat pad overlying the right atrium and along Waterston’s groove. Atrioventricular nodal slowing, as defined by a greater than 50% increase in the R-to-R interval, is marked as a site of autonomic ganglion clusters. These sites (Figure 1) are then ablated with the bipolar radiofrequency pen/probe.

The pen/probe is also used to document preablation electrical conductivity across the pulmonary veins by both pacing and sensing the superior and inferior pulmonary veins. Once the baseline electrical activity is recorded, the bipolar radiofrequency clamp is positioned around the pulmonary veins. The Silastic guide directs the lower jaw of the clamp posterior to the right pulmonary veins. Once the jaws of the clamp are correctly positioned around the antrum of the pulmonary veins and onto the left atrium, bipolar energy is delivered to the tissue. We routinely performed 3 ablations for each lesion. After the ablation, the pulmonary veins are again tested for electrical activity; the pen/probe is used to sense and pace across the pulmonary veins. The inability to pace across the pulmonary veins (exit block) and the absence of atrial electrical activity on the pulmonary veins during sensing (entrance block) determine whether the PV ablation line is complete, and therefore whether further ablations are necessary. The latter was necessary in less than 10% of patients. The evaluation of entrance block is especially important in the setting of patients with permanent AF in whom cardioversion may not always be successful intraoperatively. The clamp is removed, and a 24F Blake drain is placed. The port sites are closed once the right lung is reinflated.

The patient is repositioned into the right lateral decubitus position, and the procedure is reproduced on the left side. Instead of the fourth interspace for the working port, the third interspace is entered. The pericardium is divided posterior to the phrenic nerve from the pulmonary artery superiorly to the inferior pulmonary veins. The ligament of Marshall is divided, and testing for autonomic ganglion occurs along the Marshall tract. Entrance and exit block testing are performed once ablation is complete.

The LA appendage is excised using a 60-mm endoGIA stapler (Auto suture, United States Surgical Corporation, Norwalk, Conn). The stapler is inserted through the same port as the bipolar clamp. If at the end of the procedure the patient is in AF or atrial flutter, synchronized direct-current cardioversion is performed.

**Follow up**

The mean follow-up was 13.6 ± 8.2 months and 100% complete; all patients had at least a 24-hour Holter monitor after a blanking period of 3 months and then on a recommended yearly basis. Procedural success was defined as the absence of AF or atrial flutter on follow-up electrocardiograms and Holter monitor recordings after the blanking period. Informed consent for continuous follow-up monitoring had been given a priori by the patients as part of a standardized protocol for this minimally invasive ablative therapy. All protocols were reviewed and approved by the institutional health research ethics board.

**Statistical Analysis**

Baseline patient characteristics were compared between patients’ groups via chi-square test and Fisher’s exact test when frequency was less than 5. Continuous variables were assessed using the Student t test when normally distributed and the Wilcoxon rank-sum test when data were skewed. One-way analysis of variance tests, with Bonferroni’s t test for the means, were performed on continuous variables that were dependent on a classification.

The Kaplan–Meier method was used to assess time-related outcome (recurrence of AF). Predictors of recurrence of AF were identified using

AF, Atrial fibrillation; DCC, direct-current cardioversion; NYHA, New York Heart Association; COPD, chronic obstructive pulmonary disease; TIA, transient ischemic attack; CVA, cerebrovascular accident; CAD, coronary artery disease; Ca\(^{2+}\), calcium; LA, left atrium; EF, ejection fraction; PAP, pulmonary artery pressure; SD, standard deviation.

RESULTS

Preoperative and Operative Characteristics

Table 1 shows the preoperative characteristics of patients undergoing the minimally invasive ablation; of note is the significantly longer duration of AF in patients with AF qualified as persistent or permanent (P = .03). These latter patients were also found to experience more dyspnea (P = .02), have a greater proportion of smokers (P = .005), and have more significant LA enlargement (P = .0003).

The mean operative time was 253 ± 65 minutes. Intraoperative direct-current cardioversion was performed at the conclusion of the surgical procedure in 14 patients (36%) with paroxysmal AF, 12 patients (41%) with persistent AF, and 21 patients (66%) with permanent AF (P = .03). The number of patients leaving the operating room in normal sinus rhythm (NSR) was as follows: 37 (95%) with paroxysmal AF, 25 (86%) with persistent AF, and 24 (75%) with permanent AF (P = .05).

Outcomes

In this series of patients, no intraoperative conversions to sternotomy or standard thoracotomy were required. There was no 30-day in-hospital mortality. The rate of postoperative procedure-related complications was 14% and included the need for permanent pacemaker in 5 patients (5%), postoperative hemotherax managed conservatively in 3 patients (3%), and phrenic nerve injury in 3 patients (3%). Pulmonary embolus occurred in 1 patient (1%) and transient ischemic attack occurred in 1 patient (1%) on postoperative day 2.

The mean hospital length of stay was 6.5 ± 3.9 days (range 2–35, median 5 days). At the time of discharge, 67 patients (67%) were in NSR, 27 patients (27%) were in AF, 1 patient (1%) was in atrial flutter, and 5 patients (5%) were in NSR via a permanent pacemaker; there was no difference observed in discharge rhythm between patients with paroxysmal, persistent, or permanent AF (P = .26). Medications at the time of discharge included amiodarone in 52 patients (52%), sotalol in 11 patients (11%), flecainamide in 19 patients (19%), beta-blockers in 50 patients (50%), calcium...
channel blockers in 9 patients (9%), digitalis in 14 patients (14%), and warfarin in 86 patients (86%).

At the time of follow-up, the proportion of patients in NSR was 87% overall. NSR was restored in 93% of patients with paroxysmal AF, 96% of patients with persistent AF, and 71% of patients with permanent AF ($P = .03$) (Figure 2). Subjective reports of improvement in symptoms were observed in 87% of patients with paroxysmal AF, 100% of patients with persistent AF, and 72% of patients with permanent AF ($P = .007$). Antiarrhythmic drugs and warfarin use were discontinued in 63% and 64% of patients, respectively, with no significant difference among AF type ($P = .27$).

Table 2 lists predictors of recurrence of AF with the strongest factor observed being the presence of permanent AF (hazard ratio 9.3; confidence interval, 2.2–38.5). The duration of AF was not found to be a significant predictor of recurrence of AF. There was a weak relationship observed between the presence of active autonomic ganglia on the left side superior pulmonary vein/ligament of Marshall areas and the recurrence of AF (hazard ratio 3.7; confidence interval, 1.1–13.2). By logistic regression, permanent AF, older age, and presence of AF at the time of discharge from the operating room were all strongly associated with recurrence of AF. There was no difference noted in the technology (irrigated vs nonirrigated) to create the pulmonary vein lesions ($P = .9$). LA size was not found to be a predictor of failure to restore NSR.

**DISCUSSION**

During the last 20 years, surgeons and electrophysiologists have been making progress toward finding a cure for AF that offers patients an acceptable risk/benefit profile. The full cut-and-sew Maze procedure has delivered excellent results but has not been widely accepted as a stand-alone therapy. Catheter-based techniques do offer a fast recovery when successful, but they have had modest success in restoring SR and still have measurable risk. Minimally invasive surgical techniques represent a compromise between these 2 approaches. Previous reports with alternate approaches have not delivered sustainable success. We believe that this approach offers satisfactory outcomes and brings us one step closer to therapy that offers our patients and referring colleagues an acceptable risk/benefit ratio.

The use of a bilateral thoracotomy approach for AF has been described for more than a decade. The reliability of bipolar radiofrequency ablation as an alternative to
cut-and-sew techniques has led to an explosion of AF surgeries in patients undergoing cardiac surgery. However, its success after use on a beating heart with only the creation of pulmonary vein islands has been limited to single-institution case series. This multi-institutional report represents the largest experience to date and offers results from 3 surgeons. Our early results suggest that the procedure is safe, with a complication rate lower than those reported with the classic Maze procedure. In addition, in early follow-up, the procedure appears effective, particularly for paroxysmal and persistent AF. The majority of patients are removed from medication and anticoagulation, and are symptomatically improved.

The complication rate and recovery time were still higher than we would hope for and do not represent a benign procedure. We believe that the benefit outweighs the risk and offers an improvement over the traditional Maze approach, but more data are needed before making this claim. We hope that with more experience, the complication rate will decrease and the advance of new technology will make this even less morbid.

We understand that the AGP play an integral role in the induction and maintenance of AF. We also understand that their destruction may only be a temporary phenomenon, and thus may not lead to long-term success. The role of this portion of the therapy needs to be more completely understood in this and all other approaches to AF that rely on the destruction of atrial tissue.

We know that the atrial appendage plays a role in stroke in patients with AF. We think that its ligation will offer a stroke benefit and may be a major benefit of the Maze procedure. However, the amount of investigation in this area makes any thoughts on this issue premature. More investigation, including randomized studies that answer this question, are needed.

In this report, the mean LA dimension was close to normal and relatively homogenous; therefore, no correlation could be established between LA dimension and recurrence of AF. This may have been one of the main contributors to our encouraging early results. We do note, however, that patients with persistent AF have significantly larger LA dimensions than their paroxysmal and persistent counterparts.

### Limitations

This is a multi-institution, nonrandomized, observational clinical study in which group differences and known confounders were controlled for in the multivariable analysis. Despite the adequate sample size and statistical adjustments applied, unmeasured and unknown confounders may have influenced the results. As those of other observational cohorts, the results of these analyses may not be generalizable to all patients who have undergone this procedure at other centers.

The follow-up, although complete, remains short. The long-term efficacy can only be known with additional follow-up. Furthermore, the use of at least a 24-hour Holter may be insufficient in the detection of recurrent tachyrhythmias; perhaps the future availability of permanent loop recorders in this setting will allow us to better ascertain the procedure’s long-term success. Until this latter becomes standard of care, we are confident that our follow-up protocols remain superior to the phone call follow-up methodology of the initial experience with the Maze procedure. The bar must be raised if we are to continue to offer patients any intervention for AF, including medical therapy.

### Conclusions

We believe that this approach to AF brings us closer to a procedure that is efficacious and offers a risk/benefit profile that will allow a benefit to patients with AF. If the results from this study are sustained, this approach is already a viable therapeutic option for appropriate patients.
