Abstract

We show that the class of Petri nets is less expressive with respect to bisimulation equivalence than the class of PA processes extended with a finite state control unit.

Keywords: Petri nets; Process algebras; Strong bisimulation; Expressiveness

1. Introduction

Process rewrite systems (PRS) [7] are widely accepted as a formalism for finite specifications of infinite state systems. One reason for its popularity is that a variety of infinite state systems including basic process algebras (BPA), basic parallel processes (BPP), pushdown processes (PDA), process algebras (PA) and Petri nets (PN) as well as the class of finite state systems (FS) can be uniformly defined as subclasses of PRS given by syntactic restrictions on the form of rewrite rules. Weaker syntactic restrictions give rise to another two classes, namely PAD (a common generalization of PDA and PA) and PAN (a common generalization of PDA and PN), while the class of general (unrestricted) PRS is a common generalization of PDA and PN. The relevance of PRS (and their subclasses) for modelling and analysing programs is shown, for example, in [2].

According to their expressive power, the PRS classes can be arranged into a PRS-hierarchy [7] depicted in Fig. 1. A line between two classes means that the upper class is strictly more expressive than the lower class, in the sense that for every labelled transitions system (LTS) generated by the lower class there is a bisimilar system generated by the upper class, but not vice versa. Two classes of the hierarchy are expressively incomparable if no such relation can be derived from the picture. We recall that LTSSs generated by (S, S)-PRS, i.e. sequential/prefix rewrite systems, are exactly those generated by PDA up to the relabelling of states, see [1].

1. Introduction

Process rewrite systems (PRS) [7] are widely accepted as a formalism for finite specifications of infinite state systems. One reason for its popularity is that a variety of infinite state systems including basic process algebras (BPA), basic parallel processes (BPP), pushdown processes (PDA), process algebras (PA) and Petri nets (PN) as well as the class of finite state systems (FS) can be uniformly defined as subclasses of PRS given by syntactic restrictions on the form of rewrite rules. Weaker syntactic restrictions give rise to another two classes, namely PAD (a common generalization of PDA and PA) and PAN (a common generalization of PDA and PN), while the class of general (unrestricted) PRS is a common generalization of PDA and PN. The relevance of PRS (and their subclasses) for modelling and analysing programs is shown, for example, in [2].

According to their expressive power, the PRS classes can be arranged into a PRS-hierarchy [7] depicted in Fig. 1. A line between two classes means that the upper class is strictly more expressive than the lower class, in the sense that for every labelled transitions system (LTS) generated by the lower class there is a bisimilar system generated by the upper class, but not vice versa. Two classes of the hierarchy are expressively incomparable if no such relation can be derived from the picture. We recall that LTSSs generated by (S, S)-PRS, i.e. sequential/prefix rewrite systems, are exactly those generated by PDA up to the relabelling of states, see [1].
A similar expressiveness hierarchy of classes of infinite state systems is presented in [9,4]. In contrast to the PRS framework, the hierarchy of [9] does not cover the classes combining both sequential and parallel compositions like PA and its superclasses. On the other hand, it contains the class of *multiset automata* (MSA) [4], also known as *parallel pushdowns* (PPDA) [9], which is not covered by the PRS-hierarchy. The MSA class can be defined as BPP systems extended with a finite state control unit. A systematic *state extension* of all PRS classes, denoted by the prefix se-, is considered in [5]. Clearly, the classes of FS, PDA and PN coincide with their respective state-extended counterparts, and seBPA coincides with the PDA class. The state-extended versions of the other classes do not coincide with any of the PRS classes.

![PRS-hierarchy](image1)

**Fig. 1.** The PRS-hierarchy.

![State-extended PRS-hierarchy](image2)

**Fig. 2.** The state-extended PRS-hierarchy.

The expressiveness hierarchy of all PRS classes and their state-extended versions is depicted in Fig. 2. The dotted lines represent the relation where the strictness is just conjectured (see [11, Section 3.2.2] for further details). The shape of the hierarchy follows from the definition of state extension, the shape of the PRS hierarchy, Lemma 4.13 of [7] which says that a particular MSA is not bisimilar to any PAD, Theorem 20 of [4] showing a PN which is not bisimilar to any MSA, and finally the result presented in this paper: every Petri net can be translated into a bisimilar sePA system. Further, the strictness of the relations between PN and sePA follows immediately from incomparability of the classes PDA and PN.\(^1\) (Note that Lemma 4.13 of [7] says that a particular PN is not bisimilar to any PAD, but it is easy to see that the PN is actually an MSA system.)

The rest of the paper is divided into two sections: the next one recalls all the necessary definitions, and the other presents the main result.

---

\(^1\) Loosely speaking in terms of Fig. 2, our result means that an evident line connecting seBPP to sePA is replaced by that going from PN to sePA.
2. Preliminaries

Let \( \text{Act} = \{a, b, \ldots\} \) be a set of actions. A labelled transition system (LTS) is a triple \((S, \longrightarrow, s_0)\), where \( S \) is a set of states, \( \longrightarrow \subseteq S \times \text{Act} \times S \) is a transition relation, and \( s_0 \) is the initial state. We write \( s_1 \xrightarrow{a} s_2 \) instead of \((s_1, a, s_2) \in \longrightarrow\). A binary relation \( R \) on \( S \) (of an LTS) is a (strong) bisimulation [8] iff whenever \((r_1, r_2) \in R\) then, for any \( a \in \text{Act}\),

- if \( r_1 \xrightarrow{a} r_1' \) then, for some \( r_2', r_2 \xrightarrow{a} r_2' \) and \((r_1', r_2') \in R\), and
- if \( r_2 \xrightarrow{a} r_2' \) then, for some \( r_1', r_1 \xrightarrow{a} r_1' \) and \((r_1', r_2') \in R\).

States \( r_1 \) and \( r_2 \) are bisimilar, written \( r_1 \sim r_2 \), iff \((r_1, r_2) \in R\) for some bisimulation \( R \). Two LTSs are bisimilar if their initial states are bisimilar. Let \( \text{Const} = \{X, \ldots\} \) be a set of process constants. The set of process terms (ranged over by \( t, \ldots\)) is defined by the abstract syntax

\[
 t ::= \varepsilon \mid X \mid t.t \mid t.t
\]

where \( \varepsilon \) is the empty term, \( X \in \text{Const} \) is a process constant, and the operators ‘.’ and ‘\( \| \)’ stand for sequential and parallel composition respectively. We always work with equivalence classes of terms modulo commutativity and associativity of ‘\( \| \)’, associativity of ‘.’, and neutrality of \( \varepsilon \), i.e. \( \varepsilon.t = t.\varepsilon = t\|\varepsilon = \varepsilon \).

We distinguish four classes of process terms as:

- \( S \) — terms consisting of a single process constant only, in particular \( \varepsilon \notin S \),
- \( P \) — parallel terms — terms without sequential composition, e.g. \( X.Y.Z \),
- \( G \) — general terms — terms with arbitrarily nested sequential and parallel compositions, e.g. \( (X.(Y.Z)).W) \).

**Definition 1.** Let \( \alpha, \beta \) be classes of process terms \( \alpha, \beta \in \{1, S, P, G\} \) such that \( \alpha \subseteq \beta \). An \((\alpha, \beta)\)-prs (process rewrite system) \( \Delta \) is a pair \((R, t_0)\), where

- \( R \) is a finite set of rewrite rules of the form \( t_1 \xleftarrow{a} t_2 \), where \( t_1 \in \alpha \setminus \{\varepsilon\} \), \( t_2 \in \beta \) are process terms and \( a \in \text{Act} \) is an action,
- \( t_0 \in \beta \) is the initial term.

Given a prs \( \Delta \), let \( \text{Const}(\Delta) \) and \( \text{Act}(\Delta) \) be the respective (finite) sets of all constants and all actions which occur in the rewrite rules of \( \Delta \). We often write \( t_1 \xrightarrow{a} t_2 \in \Delta \) instead of \( t_1 \xleftarrow{a} t_2 \in R \) where \( \Delta = (R, t_0) \).

An \((\alpha, \beta)\)-prs \( \Delta = (R, t_0) \) determines an LTS whose states are process terms \( t \in \beta \) over \( \text{Const}(\Delta) \) and \( t_0 \) is the initial state. The transition relation \( \longrightarrow \) is the least relation satisfying the following inference rules (recall that ‘\( \| \)’ is commutative):

\[
\begin{align*}
(t_1 \xrightarrow{a} t_2) \in \Delta & \quad \Rightarrow \quad t_1 \xrightarrow{a} t_2 \\
(t_1 \xrightarrow{a} t_2) & \quad \Rightarrow \quad t_1.\varepsilon \xrightarrow{a} t_2.\varepsilon \\
(t_1 \xrightarrow{a} t_2) & \quad \Rightarrow \quad t_1.t \xrightarrow{a} t_2.t
\end{align*}
\]

The formalism of process rewrite systems can be extended to include a finite-state control unit in the following way.

**Definition 2.** Let \( M = \{m, n, \ldots\} \) be a set of control states. Let \( \alpha, \beta \) be classes of process terms \( \alpha, \beta \in \{1, S, P, G\} \) such that \( \alpha \subseteq \beta \). An \((\alpha, \beta)\)-seprs (state-extended process rewrite system) \( \Delta \) is a triple \((R, m_0, t_0)\), where

- \( R \) is a finite set of rewrite rules of the form \( (m, t_1) \xleftarrow{a} (n, t_2) \), where \( t_1 \in \alpha \setminus \{\varepsilon\} \), \( t_2 \in \beta \), \( m, n \in M \), and \( a \in \text{Act} \),
- \( m_0 \in M \) is the initial control state,
- \( t_0 \in \beta \) is the initial term.

\( M(\Delta) \) denotes the finite set of control states which occur in \( \Delta \).
An \((\alpha, \beta)\)-sePRS \(\Delta = (R, m_0, t_0)\) determines an LTS whose states are the pairs of the form \((m, t)\) such that \(m \in \mathcal{M}(\Delta)\) and \(t \in \beta\) is a process term over \(\text{Const}(\Delta)\). The initial state of the transition system is the pair \((m_0, t_0)\). The transition relation \(\rightarrow\) is the least relation satisfying the following inference rules:

\[
\begin{align*}
((m, t_1)) & \xrightarrow{a} ((n, t_2)) \in \Delta \\
(m, t_1) & \xrightarrow{a} (n, t_2) \\
(m, t_1 \parallel t) & \xrightarrow{a} (n, t_2 \parallel t) \\
(m, t_1 . t) & \xrightarrow{a} (n, t_2 . t)
\end{align*}
\]

To shorten our notation we write \(mt\) in lieu of \((m, t)\).

Fig. 2 shows the correspondence between some of the \((\alpha, \beta)\)-PRS classes and the classes of infinite state systems mentioned in the Introduction. Instead of \((\alpha, \beta)\)-sePRS we use the prefix ‘se-’ together with the acronym for the corresponding \((\alpha, \beta)\)-PRS class. For example, we use sePA rather than \((1, G)\)-sePRS.

To see that the LTSS generated by labelled (place/transition) Petri nets (see e.g. [10]) are exactly those generated by \((P, P)\)-PRS, we use arguments of [7,2]. Let \(X^n\) denote a parallel composition of \(n\) copies of \(X\) (in particular, \(X^0\) denotes \(\varepsilon\)) for the moment. Let \(\Delta\) be a \((P, P)\)-PRS and \(\{X_1, \ldots, X_k\} = \text{Const}(\Delta)\) be the set of its process constants. Each \(X_i\) corresponds to a place \(P_i\) in the net and the number of occurrences of \(X_i\) in a process term corresponds to the number of tokens in this place \(P_i\). Hence, a process term \(X_1^{p_1} \cdots X_k^{p_k}\) corresponds to the marking \((p_1, \ldots, p_k)\), where \(p_i\) is the number of tokens in the place \(P_i\). Finally, each rewrite rule in \(\Delta\)

\[
X_1^{l_1} \cdots X_k^{l_k} \xrightarrow{a} X_1^{r_1} \cdots X_k^{r_k},
\]

where \(l_i, r_i \geq 0, i = 1, \ldots, k\), corresponds to an \(a\)-labelled transition having places \(l_i, l_i > 0\), in its preset and places \(r_i, r_i > 0\), in its postset. We shall write this PN transition as \((l_1, \ldots, l_k) \xleftarrow{a} (r_1, \ldots, r_k)\).

As we employ the place/transition description of PN, \(X^n\) stands only for a sequential composition of \(n\) copies of \(X\) in the rest of this paper.

3. Main result

The basic idea of our proof is similar to the idea of Hirshfeld’s proof of the fact that PN and MSA are language equivalent. This proof was presented in his talk [3], but was never published.

The heart of our argument is the construction of an sePA \(\Delta’\) that is bisimilar to a given PN \(\Delta\). The main difficulty in this construction is to mimic the number of tokens at the places of a PN. To this end, we may use two types of sePA memory:

- a finite control unit, which cannot represent an unbounded counter,
- a term of an unbounded length, where just one constant can be rewritten in one step.

**Intuition**

Our construction of an sePA \(\Delta’\) can be reformulated on an intuitive level as follows. Let a marking \((p_1, \ldots, p_k)\) mean that we have \(p_i\) units of the \(i\)-th currency, \(i = 1, \ldots, k\). An application of a PN transition

\[(l_1, \ldots, l_k) \xrightarrow{a} (r_1, \ldots, r_k)\]

has an effect of a currency exchange from \(p_i\) to \(p_i - l_i + r_i\) for all \(i\).

An sePA reseller \(\Delta’\) will have \(k\) finite pockets (in its control states) and \(k\) bank accounts (a parallel composition of \(k\) sequential terms \(t_i\)). The reseller \(\Delta’\) maintains an invariant \(p_i = \text{pocket}_i + \text{account}_i\) for all \(i\). He must obey sePA rules to mimic a PN transition, i.e. he may use all his pockets, but just one of his accounts in one exchange–transition.

A solution is to do \(\text{pocket}_i \leftrightarrow \text{account}_i\) transfers cyclically, \(i = 1, \ldots, k\). Hence, rebalancing \(\text{pocket}_i\) the reseller \(\Delta’\) must be able to perform the next \(k - 1\) exchanges without accessing \(\text{account}_i\) as he is visiting the other accounts. Therefore, \(\Delta’\) needs sufficiently large (but finite) pockets and sufficiently high (and still fixed) limits for \(\text{pocket}_i \leftrightarrow \text{account}_i\) transfers. In what follows, we show that these bounds exist.
Bounds

In one step, the amount of the $i$-th currency can be changed at most by

$$L_i = \max\{l_i, r_i \mid (l_1, \ldots, l_k) \xrightarrow{a} (r_1, \ldots, r_k)\}$$

thus the upper bound for the total effect of $k$ consecutive steps can be set up to $M_i = k \cdot L_i$. Any rebalancing of the $i$-th pocket sets its value to

$$\{M_i, \ldots, 2M_i - 1\}$$

(or to $\{0, \ldots, 2M_i - 1\}$ if $account_i$ is empty). Hence, after $k$ transitions the value of $pocket_i$ is in

$$\{0, \ldots, 3M_i - 1\}.$$

Then the next rebalancing takes place and $account_i$ is increased or decreased (if it is not empty) by $M_i$ to achieve the (rebalanced) value of $pocket_i$ in $\{M_i, \ldots, 2M_i - 1\}$.

Construction

Each state of sePA $\Delta'$ consists of a control state and a term (parallel composition of $k$ stacks, in fact just counters, representing accounts). Each control state is a member of the following product.

$$\{1, \ldots, k\} \times \{0, \ldots, 3M_1 - 1\} \times \cdots \times \{0, \ldots, 3M_k - 1\}$$

update controller pocket$_1$ pocket$_k$

The update controller goes in round-robin fashion on its range and refers to the account being updated (rebalanced) in the next step. The value of each $pocket_i$ (subsequently denoted by $m_i$) is equal to the number of tokens at $P_i$ counted modulo $M_i$.

We define $2k$ process constants $B_i, X_i \in Const(\Delta')$, where $i = 1, \ldots, k$. The $i$-th stack $t_i$ is of the form $X_i^n \cdot B_i$ where $n \geq 0$. $B_i$ represents the bottom of the $i$-th stack, and each $X_i$ represents $M_i$ tokens at place $P_i$.

Given an initial marking $\alpha_0 = (p_1, \ldots, p_k)$ of $\Delta$, we construct the initial state

$$\beta_0 = (1, m_1, \ldots, m_k) t_1 \parallel \cdots \parallel t_k$$

of the sePA $\Delta'$, where denoting $n_i = \max(0, (p_i \text{ div } M_i) - 1)$ we put $m_i = p_i - n_i M_i$ and $t_i = X_i^{n_i} \cdot B_i$. In other words, we have $p_i = m_i + n_i M_i$ and moreover $m_i \in \{M_i, \ldots, 2M_i - 1\}$ if $p_i \geq M_i$ (i.e. $p_i$ is big enough).

To each transition $(l_1, \ldots, l_k) \xrightarrow{a} (r_1, \ldots, r_k)$ of PN $\Delta$ we construct the set of sePA rules

$$(s, m_1, \ldots, m_k) t \xrightarrow{a} (s', m'_1, \ldots, m'_k) t'$$

such that they obey the following conditions:

- Update controller conditions:
  - $s, s' \in \{1, \ldots, k\}$ and
  - $s' = (s \text{ mod } k) + 1$.
- General conditions for pockets ($1 \leq i \leq k$):
  - $m_i, m'_i \in \{0, \ldots, 3M_i - 1\}$,
  - $m_i \geq l_i$ (i.e. the transition “is enabled”), and
  - if $i \neq s$ then $m'_i = m_i - l_i + r_i$.
- The case $i = s$ means to specify $m'_s$ and the terms $t, t'$ that effect the $pocket_s \leftrightarrow account_s$ rebalancing transfer.

These are given by the rules of the following table. The first two Bottom rules are the rules for working with the empty stack. The next three Top rules describe the rewriting of process constant $X_s$. Depending on the value of $\overline{m}_s = m_s - l_s + r_s$, there are dec, inc, and basic variants manipulating the $s$-th stack.

<table>

</table>
Now we are ready to formulate and prove our main result.

**Theorem 3.** Every PN can be translated into a strongly bisimilar sePA.

**Proof.** Let $\Delta$ be an arbitrary PN with an initial marking $a_0$. According to the construction given above, we build the sePA $\Delta'$ with the initial state $\beta_0$. In the rest of the proof, we show that the binary relation

$$ R = \{ (\alpha, \beta) \mid \alpha = (p_1, \ldots, p_k) \text{ is a marking of } \Delta, $$

$$ \beta = (s, m_1, \ldots, m_k) X_1^{n_1}.B_1 \| \cdots \| X_k^{n_k}.B_k \text{ is a state of } \Delta', $$

$$ s \in \{ 1, \ldots, k \}, \text{ and,} $$

for all $i = 1, \ldots, k$, it holds that

- $p_i = m_i + n_i M_i \land$
- $m_i < 2 M_i + (s - i \mod k) L_i \land$
- if $n_i > 0$ then $M_i - (s - i \mod k) L_i \leq m_i$

is a strong bisimulation.

It follows directly from the construction that the pair $(\alpha_0, \beta_0)$ of the initial states of $\Delta$ and $\Delta'$ is in $R$.

We follow the definition of bisimulation to prove that the relation $R$ is a bisimulation. Let $\alpha = (p_1, \ldots, p_k)$ be a marking of PN $\Delta$ and

$$ \beta = (s, m_1, \ldots, m_k) X_1^{n_1}.B_1 \| \cdots \| X_k^{n_k}.B_k $$

be a state of sePA $\Delta'$ such that $(\alpha, \beta) \in R$.

Let us assume that a transition $(l_1, \ldots, l_k) \xrightarrow{a} (r_1, \ldots, r_k)$ is fired in $\alpha$ and leads to $\alpha' = (p'_1, \ldots, p'_k)$, i.e. $p_i \geq l_i$ and $p'_i = p_i - l_i + r_i$, for all $i = 1, \ldots, k$. According to the definition of bisimulation, we will show that there is also a state $\beta'$ of $\Delta'$ and a transition with a label $a$ leading from $\beta$ to $\beta'$ such that $(\alpha', \beta') \in R$. Looking into the construction, it is easy to see that such a transition exists if $m_i \geq l_i$ for all $i = 1, \ldots, k$. These inequalities can be easily proved as follows. For each $i = 1, \ldots, k$, we discuss two cases:

- If $n_i = 0$ then $(\alpha, \beta) \in R$ implies $p_i = m_i + n_i M_i = m_i$. This, together with $p_i \geq l_i$, leads directly to the desired $m_i \geq l_i$.
- If $n_i > 0$ then $(\alpha, \beta) \in R$ implies $M_i - (s - i \mod k) L_i \leq m_i$. As $M_i$ is defined to be equal to $k \cdot L_i$, we get that $m_i \geq L_i$. Now, the definition of $L_i$ implies $L_i \geq l_i$ that directly results in $m_i \geq l_i$.

It remains to show that $(\alpha', \beta') \in R$. This can be obtained by a straightforward inspection of the definitions of all the rule types.

The symmetric case, starting with a transition from $\beta$, proceeds in a similar way. Hence, $\Delta$ and $\Delta'$ are bisimilar. \[\square\]

**4. Conclusion**

We have presented an algorithm transforming any given Petri net to a bisimilar sePA process, i.e. a PA process extended with a finite state control unit. We note that the sePA system constructed does not need to be isomorphic to the original PN system; it can be exemplified by the states which differ by the values of the update controller only. To the best of our knowledge, it is not known whether the result can be refined to isomorphism rather than bisimilarity.
